3. *Easing off the points of the tooth.* As was suggested to the writer a short time ago by Mr. Fellows, of the Fellows Gear Shaper Co., this matter of impact affects gear tooth design in another way. There has always been a sort of superstition that the points of the tooth should be eased off to make the action smoother. This is done, of course, in standard involute gears, though for another reason, that of avoiding interference with the flanks of the pinions. It can now be seen that there is a solid basis for this practice in all cases where gears are to run at such speeds that severe impact is liable to take place. Referring to Fig. 2, teeth *A* and *B* are taking up the load very suddenly, owing to the fact that they are out of step, due to the deflection of the other teeth momentarily carrying the load. Easing away the points of *A* and *B* would mitigate this sudden reception of the load, allowing the inevitable deflection to take place more slowly, with a consequent gain in the strength of the gear at high speeds. It would have a similar effect in minimizing impact due to inaccuracy of outline.

This modification of the outline of the tooth should be very slight, and extend but a short distance, so that, when the load is entirely transferred, the "doctored" portion of the curve will be passed, and the true involute or cycloidal portion begun.

* * *

The question of aerial navigation is coming so much to the front that, while it is as yet only in its first experimental stage, any engineering review would be incomplete without a reference to what has been done in this territory of human achievement. Various European governments have already experimented with steerable airships for military purposes, and our own government has made an appropriation for the same purpose. A German steerable airship, according to a recent statement in the *Berliner Tageblatt*, was constructed in perfect secrecy, and has performed, with satisfactory results, a first four-hour trial run. The airship navigated at a height of about one mile with a speed of from 28 to 31 miles an hour, and showed a remarkable stability. The platform under the supporting balloon, which latter is of the spindle shape, affords accommodation for six persons and can be armed by automatic guns. Remarkable feats have also been accomplished by ordinary balloons. The results obtained from the international contest at St. Louis are well-known, but even more interesting feats have been accomplished on the other side of the ocean. The *Daily Graphic* of London financed a balloon expedition which recently left London with the hope of securing the world's record for long distance balloon traveling, which consists of a travel of 1,193 miles, from Paris to Russia. The *Daily Graphic* balloon did not accomplish this object, but its passage over the sea is of interest as being the longest over-sea balloon voyage undertaken. The balloon crossed the North Sea, then moved across Northern Denmark and over the Cattegat, until the descent was finally made in Sweden after a distance of about 1,000 miles entirely over the sea had been covered. The balloon, it is stated, was the largest that has ever been manufactured, having a capacity of 108,000 cubic feet. The car was so constructed that if it dropped into the sea, it would be capable of keeping afloat.

'Tis a shifting belt that has no crowned pulley.

A belt-shifter that sticks, and the man who does not as he is told shall be "cussed."

DECEMBER MEETING OF THE A. S. M. E.

The New York meeting of the American Society of Mechanical Engineers, held in December of each year, was a notable event this year, inasmuch as it was the first general meeting of the society held in the new Engineering Societies Building. This magnificent structure was dedicated last April 16 and 17 (see the May, 1907, issue), but the spring meeting of the A. S. M. E. always being held outside of New York City had prevented many of the members seeing the new building until the regular December meeting. That its spacious assembly rooms, splendid auditorium, fine library and many other carefully planned features were generally appreciated, there can be no doubt. Many were the expressions of pleasure in regard to the new society house and the manner in which the meetings were carried on.

Following is a list of papers presented and their authors:

The Mechanical Engineers and the Function of the Engineering Society (presidential address)..Prof. F. R. Hutton
The Rational Utilization of Low-Grade Fuels in Gas Producers ....F. E. Junge
Duty Test on Gas Power Plant..................J. R. Bibbins
Control of Internal Combustion in Gas Engines, Prof. C. E. Lucke
Evolution of the Internal Combustion Engine....S. A. Reeve
Industrial Education..........................W. B. Russell
The Foundry Department and the Department of Engineering Design..............................W. A. Bole
Molding Sand..............................A. E. Outerbridge
Power Service in the Foundry...............A. D. Williams
Foundry for Bench Work......W. J. Keep and Emmet Dwyer
A Volumetric Study of Cast Iron................H. M. Lane
Specifications for Iron, Coke, and Method of Testing Output ....Dr. R. Moldenke
Foundry Cupola and Iron Mixtures..............W. J. Keep
Foundry Blower Practice........................W. B. Snow
Patterns for Repetition Work....................E. H. Berry
Some Limitations of Molding Machines........E. H. Mumford
The Specific Heat of Superheated Steam...Prof. C. C. Thomas
Engine Design Adapted for the Use of Superheated Steam.................................Max E. R. Toltz
Power Transmission by Friction Driving..Prof. W. F. M. Goss
Cylinder Port Velocities..................Prof. J. H. Wallace

The fact that both the main auditorium and smaller assembly rooms were available for the meetings of the society permitted the papers to be discussed simultaneously. The papers were read in the main auditorium and the discussions of some, which were very lengthy, continued during the following sessions in the smaller assembly rooms, thus permitting full discussion by all who wished to take part.

On Wednesday afternoon between 300 and 400 of the members and guests crossed the North River on the Lackawanna ferry to the Lackawanna Railroad terminal station, and there met Mr. Chas. M. Jacobs, chief engineer of the Hudson Companies, who escorted the party on a tour of inspection through the tunnel. The route followed the North River shore from the Lackawanna Railroad terminal to 15th St., Jersey City, where the tunnel first built crosses the river. The party emerged from the tunnel at Morton and Hudson Sts., New York. The tunnel trip was a novel and interesting experience to the engineers and their friends, and nearly all thought it well worth the fatigue incident to the rough walking. It is expected that trains will be running in a few weeks.

The symposiums on foundry work and power development included the bulk of the papers presented, the papers by Mr. Russell: Industrial Education, and by Prof. Goss: Power Transmission by Friction Driving, being the exceptions. Mr. Russell's paper provoked considerable discussion, which is an indication of the interest in this present vital subject.

This meeting was the first in recent years in which all functions incident to the meeting, except excursions, were held in the Society house, including the reception and ball. This latter event for several years heretofore has been held at Sherry's.

There was a large registration of members and guests, the total number of members registered being 699; and of guests, 613.

The following officers were elected: President, M. L. Holman; vice-presidents, L. P. Breckenridge, Arthur West, Fred J. Miller; managers, Wm. L. Abbott, Henry G. Stott, Alexander C. Humphreys; treasurer, Wm. H. Wiley.

M. L. HOLMAN, PRESIDENT A. S. M. E.

Minard LaFever Holman, the newly elected president of the American Society of Mechanical Engineers, was born in Maine in 1852. His father was Col. Holman of the United States supervising architect's department. Col. Holman moved his family from Maine to St. Louis in 1860, and the subject of this sketch has lived in that city ever since. He graduated from Washington University of St. Louis in 1874 with the degree of Civil Engineer, and the University has since conferred on him the honorary degree of Master of Arts. For some time after his graduation Mr. Holman was connected with the supervising architect's department. He left that position to connect himself with the St. Louis Water Department under the late Thomas J. Whitman. After serving several years as principal assistant engineer under Mr. Whitman,

M. L. Holman.

he was appointed Water Commissioner of St. Louis in 1887. This office he held for three terms of four years each, making twelve years in all. Under his efficient supervision the St. Louis water works was almost entirely rebuilt, and experiments were inaugurated which resulted in a satisfactory clarification of the Mississippi River water, making it available for general city use.

After leaving the water department, Mr. Holman was for over four years the general superintendent of the Missouri Edison Electric Co., and for the last four years he has devoted his entire time to consulting work, having formed a partnership for this purpose with Mr. John A. Laird, member of the American Society of Mechanical Engineers, under the firm name of Holman & Laird. Mr. Holman has made a specialty of water works and power plants and has served on some important commissions, notably the one for designing new water works for Omaha. He was chairman of that committee, and he is now a member of the committee for appraising the property of the Denver Water Co., representing the city of Denver on the commission. Besides being a member of the A. S. M. E., Mr. Holman is a member of the American Society of Civil Engineers, American Institute of Electrical Engineers, St. Louis Engineers' Club, St. Louis Academy of Science, and is an honorary member of the American Water Works Association.

* * *

A contributor to the *Practical Engineer* states that it is possible to harden copper on its surface. This is accomplished by heating the copper, which is filed up clean before the process, to a bright red heat throughout its mass, and then plunging it into a pot of pure melted tin. The copper should remain in the tin until its heat is the same as that of the melted tin. The tin should be well covered with ground charcoal to prevent oxidation to any great extent. Proceeding in this way, the surface of the copper will be even harder than that of unhardened tool steel, and the hardness will penetrate to some depth. The tin alloys with the surface of the copper to cause hardness.

GEAR-CUTTING MACHINERY.—1.

METHODS OF CUTTING GEAR TEETH.

RALPH E. FLANDERS.*

There is no form of machine tool which has called for more ingenuity in design than the gear-cutting machine. The methods by which gears may be cut are so numerous, the requirements are so varied, the possible application of ingenious geometrical principles through the mechanism used are so nearly limitless, that a wonderful variety in design and construction has been evolved, affording a field of study which is unparalleled in its interest to the machine designer.

The earliest form of gear-cutting machinery to attain anything like its present state of development was the automatic spur gear machine using a milled cutter to shape the tooth. Later, came a period in which various forms of bevel gear cutting machinery were evolved, the demand being stimulated by the necessities of the chainless bicycle business. More recently, the requirements of the automobile have resulted in another period of inventive activity, which has resulted in the development of new machines and processes for gears of all kinds, though the bulk of the attention has been given to the spur and bevel forms.

In the following pages we have attempted to cover the whole field of gear cutting, representing, so far as possible,

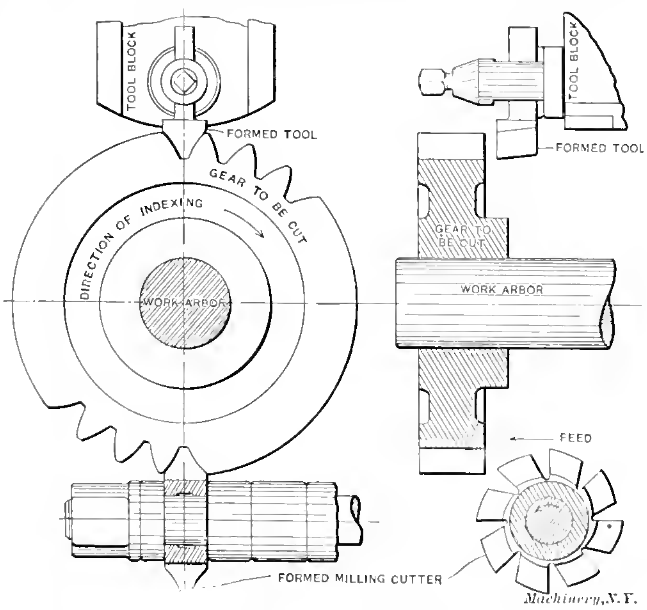

Fig. 1. The Formed Tool Principle of Action as exemplified by the Shaper Tool and the Milling Cutter.

every machine and process which has come into commercial use, including at the same time some which have been built and used successfully, but which have not been, for one reason or another, placed on the market. Some of these machines are old, some of them new, some of them simple, some of them complicated. Some of them are used for the finest kind of work, such as is required in watch and instrument gearing, while one of them will cut teeth in a gear up to 10 feet in diameter. The reader will see, as we proceed, that all these widely varying tools may be brought into a definite classification which links them all into one large family—the old and new, simple and complicated, large and small—by characteristics which are common to the different groups.

The Classification of Gear-cutting Machinery.

Gear-cutting machinery may be classified, first, according to its *product*. There are four main divisions in this classification, separating from each other the machines designed for cutting spur, spiral, bevel and worm gearing, respectively. The cutting of internal gears and racks is analogous to the cutting of spur gears, and is included with it. Twisted or herringbone gears having parallel axes are in general cut in the same way as spiral gears, though, as gears, they belong to a different class. Some machines are so designed as to be capable of cutting more than one form of gear, but it is only done by making certain adjustments or using certain attachments which, for the time being, convert them into machines of other types. The best example of a machine which covers all the divisions of this classification is the universal miller, which may be arranged to cut the teeth in any one of the four forms mentioned.

The second classification of gear-cutting machinery depends on the *principle of action* involved. The five methods we will consider are—the formed tool, templet, odontographic, describing-generating, and molding-generating methods. This classi-

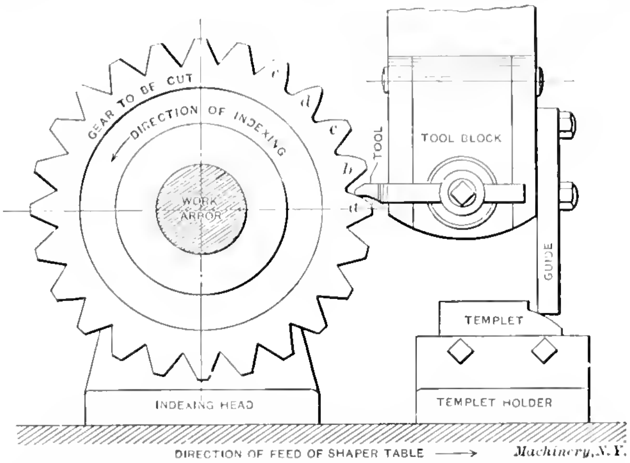

Fig. 2. The Templet Principle, as arranged to be applied to the Shaper.

fication relates particularly to the way in which the tool is held and guided with reference to the work, to produce the desired form for the tooth surfaces.

The third method of classification relates to the *nature of the operation*. The four operations we will consider are—forming the tooth by impression, by planing or shaping, by milling, and by grinding or abrasion.

In studying the various combinations possible in these three different classifications, it will be simplest to first consider the matter of cutting the teeth of spur gearing, investigating the principle of action involved, and the nature of the operation performed, in the different methods. From that we will be able to proceed to the application of these principles and operations to the other forms of gearing, like the spur, bevel and worm.

Five Principles of Action.

The Formed Tool Principle: This, the simplest and most obvious way of forming a gear tooth, is illustrated in Fig. 1. The gear to be cut is held firmly on a work arbor which, in

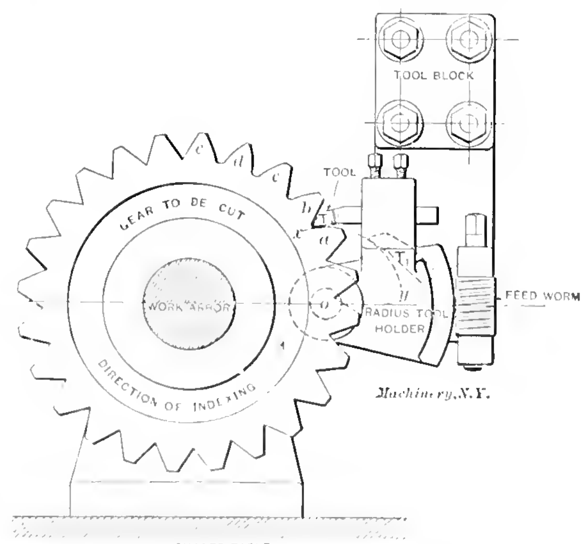

Fig. 3. The Odontographic Principle, which approximately outlines the Tooth Form by Mechanical Means.

turn, is firmly supported in the machine, in such a way that it can be *indexed* (or rotated through an angular distance corresponding to one tooth) from time to time as occasion requires. In the upper part of the cut is shown a planer or shaper toolpost, carrying a formed tool having outlines accurately corresponding to the shape of a space between two of the teeth it is desired to form. It is evident that this formed tool,

* Associate Editor of MACHINERY.

when mounted in the tool-post of the planer or shaper, may bo fed down into the work to the proper depth, in which case, being set centrally, it will reproduce its outline in the work. The work may then be indexed, and the operation repeated to form another tooth space. With the work indexed in the direction shown in the cut, four tooth spaces, or three complete teeth have been formed. A formed milling cutter may be used instead of the planer or shaper tool. This is shown

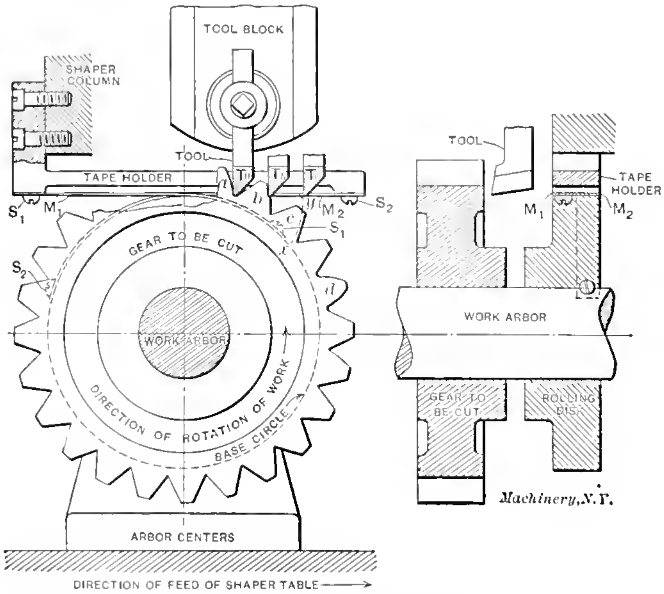

Fig. 4. The Describing-Generating Process, by which the Point of the Tool is constrained to follow the Desired Outline.

at work on the under side of the blank. It reproduces its outline in the work in the same way as does the planer tool, being rotated in the direction indicated, and fed through the work at the same time.

The Templet Principle: This method of cutting gears is shown in Fig. 2. As in the previous case, the work is held on the table of the shaper. A templet holder is also mounted on the shaper table, carrying a templet, having a surface formed to the exact outline desired for the finished tooth. The tool block is disconnected from the feed screw, and weighted

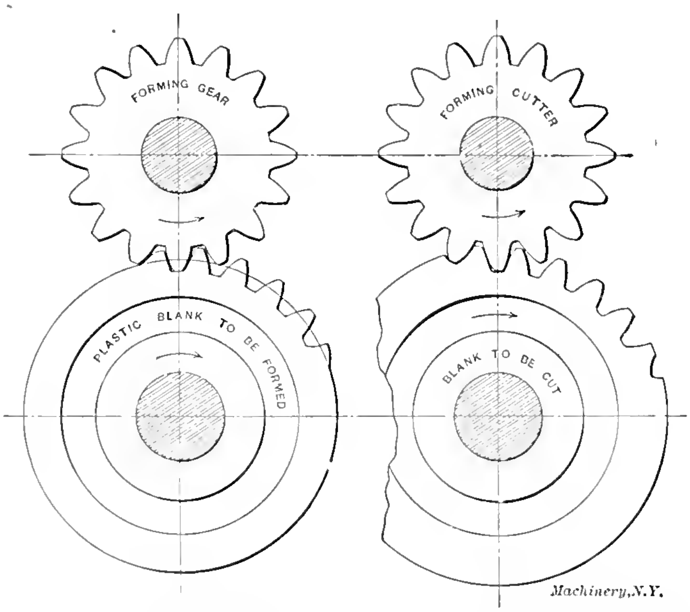

Fig. 5. The Molding-Generating Principle applied to Rolling the Proper Form in a Plastic Blank.

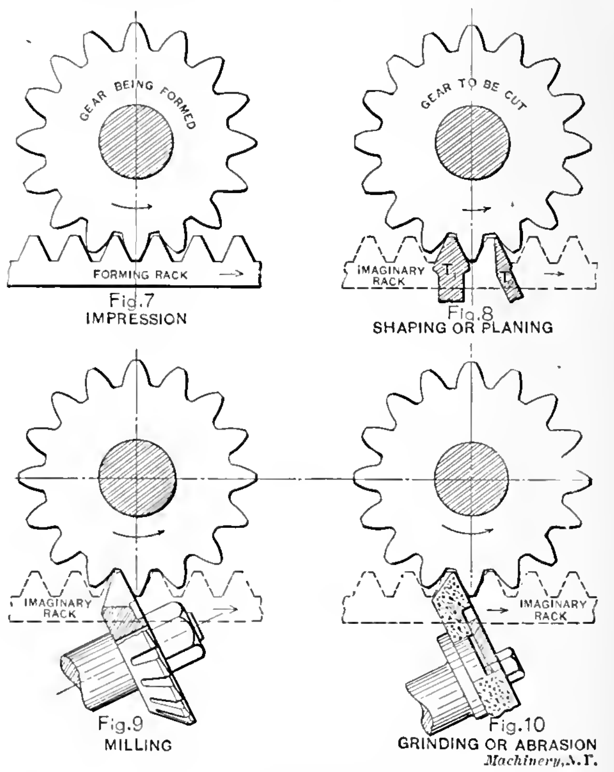
Fig. 6. The Same Principle employing a Cutter having a Shaping Action, cutting Teeth in a Solid Blank.

so that it falls of its own accord. To its side is clamped the guide shown, which bears on the templet. As the table of the shaper is fed to the right, it will be seen that the curved surface of the templet will raise the guide, the tool block and the tool, in such a fashion that the desired outline will be reproduced on the gear tooth. The upper surfaces of teeth *a*, *b*, *c* and *d* have been formed in turn in this way, the work being indexed for this purpose as in the previous case. With the primitive arrangement shown, it will be necessary to reverse the work in the arbor to form the other side of the teeth. Teeth *d* and *e* had their faces finished in this way, tooth *d* being thus completely formed. It will be seen that obtaining accurate teeth by this method requires—first, an accurate templet; second, accurate setting of the templet and tool in proper relation to each other; and third, a bearing surface on the guide of exactly the same shape as the cutting edge of the tool. As shown, the gear to be cut has had the tooth spaces roughed out to shape, so that the finishing operation removes a comparatively small amount of metal.

The Odontographic Principle: In shaping teeth by the odontographic principle, the tool is guided in some way by suitable mechanism, to closely approximate the desired tooth outline by means of circular arcs, or other easily obtained curves. A simple example is shown in Fig. 3. The gear to be cut is held and indexed as in the two previous cases. The blank has had the teeth roughed out as in the previous case. The gear to be cut has involute teeth. With teeth of this form, in most cases a circular arc may he found which will more or less closely approximate the true outline. Such a circular arc is shown at $x\,y$, with its center at o. The radius tool holder shown has its center at o to agree with that of arc $x\,y$. The



Figs. 7, 8, 9 and 10. The Four Methods of Operation, as applied to the Molding-Generating Principle of Action.

cutting point of the tool used is located on arc $x\,y$. It will be seen from this, that when the radius tool is fed from position T_1 to T_2 by the feed worm, its point will follow the desired arc and cut the desired outline for the tooth. By this means, the upper surface of tooth *a* is formed. The same surfaces of teeth *b*, *c* and *d* have previously been cut, as well as the opposite faces of *d* and *e*, tooth *d* being completed. To cut the opposite faces, the work may be reversed on the arbor.

The Describing-Generating Principle: This principle is shown in Fig. 4, applied to the shaping of involute teeth. The cutting of involute teeth only has been hitherto shown in these examples, owing to the fact that in other cases, as in this, it lends itself most readily to the purposes of illustration. The involute, as is well known, is the curve formed by a point in a cord which is being unwrapped from the periphery of a circle. In the cut, the dotted line $x\,y$ shows an involute generated in this fashion from the *base circle* shown. This base circle is formed by the periphery of the rolling disk, which is firmly connected with the gear to be cut through the work arbor on which both are mounted. Unlike the previous cases considered, the work arbor in this case is free to revolve on centers without being restrained by an indexing mechanism; as in previous cases, the blank has had the teeth

roughed out. The tool used is a shaper, as before. To some fixed part of the machine is clamped the tape holder shown. This has fastened to it two thin flexible metallic tapes, M_1 and M_2 the former stretched between screw S_1 on the tape holder and the corresponding screw on the rolling disk, while the latter is similarly stretched between screws S_2 and S_3. By this means, it will be seen that when the shaper table is fed in the direction indicated, the unwinding of M_1 and the winding of M_2 will positively roll the disk and the work with it. If now, a tool be placed in the tool block of the shaper, having a cutting point set at the same height as the middle thickness of the steel tapes, and if the table be fed as shown, the mechanism will constrain the tool point to cut an involute on the side of the tooth of the gear blank. When the tooth is at c, the tool will be at T_c; when the tooth is at b, the tool, at T_b, will have cut down about half the length of the face, as shown; when the tooth is at a, its outline will have been completed on that side by the tool, at T_a. The way in which the involute is generated will be easily understood, when it is seen that the cutting point of the tool always coincides with a given point y in tape M_2, so that the same involute as is generated by this point in the unwinding tape is reproduced by the tool point. The device is incomplete, as shown, in that no provision is made for indexing. In this case the gear to be cut and the rolling disk have to be indexed with relation to each other, so as to present the different teeth properly for the tool to act upon them. At d is shown a completed tooth.

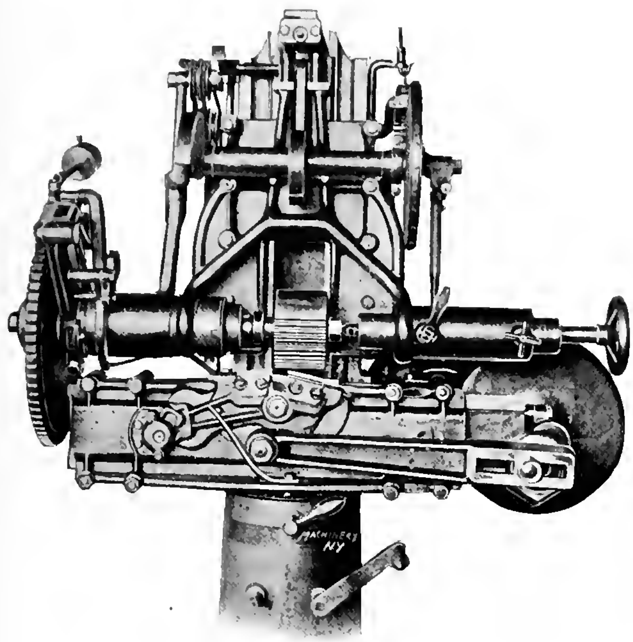


Fig. 11. The Pederson Formed Tool Gear Shaping Machine.

The Molding-Generating Principle: This method of making gears depends on the fact that in a set of interchangeable gearing a gear formed correctly to run with one of the series will run with all of the series. The molding process consists in using a completed gear tooth or gear, of proper shape, to from the others. Two examples of this are shown in Figs. 5 and 6. The first case supposes a forming gear, as shown, of correct shape. The blank to be formed is made of some plastic material like wax or clay. The blank and the forming gear are mounted on arbors at the proper distance apart, and rotated together at the proper speed ratio. The teeth of the forming gear, pressing into the plastic blank, will form spaces and press out teeth of the correct shape to mesh with itself, or with any other gear of the same interchangeable series.

In Fig. 6 the blank is of metal or other non-plastic material, and the forming gear is replaced with a forming cutter, having sharp edges of exactly the same outline. The blank, which in this case is of the full outside diameter of the gear into which it is to be made, is rotated with the cutter, as in Fig. 5. The cutter is reciprocated in the direction of its axis so as to take a series of cuts, to form the tooth spaces as the rotation takes place. The principle is identical with that shown in Fig. 5. Of course, the cutter has to be fed directly in to the proper depth to start with, before the rotating commences.

Four Methods of Operation.

In classifying gear-cutting methods by the operations involved, we will take for the purpose of illustration the molding-generating method as applied to the spur gear. Later on we will see how the same operations are applied to the cutting of other forms of gears, by other methods. In the four cases shown in Figs. 7 to 10, the molding-generating is done by a rack working in a gear, not by one gear working in another, as in Figs. 5 and 6.

By Impression: Fig. 5 is an example of this kind, the teeth in the plastic blank being formed by the impression made by them on the forming gear. In Fig. 7 the same thing is shown, except that the forming member is a rack which has shaped the periphery of the gear with which it meshes into correct teeth, as shown.

By Shaping or Planing: In Fig. 8 but one tooth space of the gear is formed at a time, and instead of using a rack to do the forming, a tool T_1 may be used having an outline the shape of a rack tooth. This is fed along horizontally, and the gear to be cut is rotated in unison with it, the same way as in Fig. 7. If tool T_1 is given a cutting movement in a shaper, the spaces formed will be of exactly the right shape and identical with those formed in the previous case. Each of the spaces will have to be formed in the same way one after another, the work being indexed with reference to the imaginary rack, to bring the tool into the proper position for each of them. Instead of forming both sides of a space at one operation, as with tool T_1, a single side tool T_2 may be used, corresponding with one side only of the rack. In this case one side only of each tooth is finished, so the tool or the work has to be reversed, after which the other sides are completed.

By Milling: Instead of using a planer or shaper tool to match the side of the imaginary rack tooth, a milling cutter may be used, as shown in Fig. 9. In this case the gear is rotated, and the milling cutter advanced to agree with the advance of the imaginary rack. The cutting face of the cutter must of course be formed on a plane surface, as shown. This arrangement presents some difficulties when the gear to be cut has a wide face, since the circular cutter will cut deeper into the tooth space at the center than it will toward the edges. This deepening of the tooth space at the center does not affect the acting tooth surface, and so is harmless (except possibly in the case of the generation of pinions having a small number of teeth, and involute outlines of low pressure angle, in which case the trouble due to interference is aggravated). The larger the diameter of the cutter as compared with the face of the gear, the less is the trouble on this score.

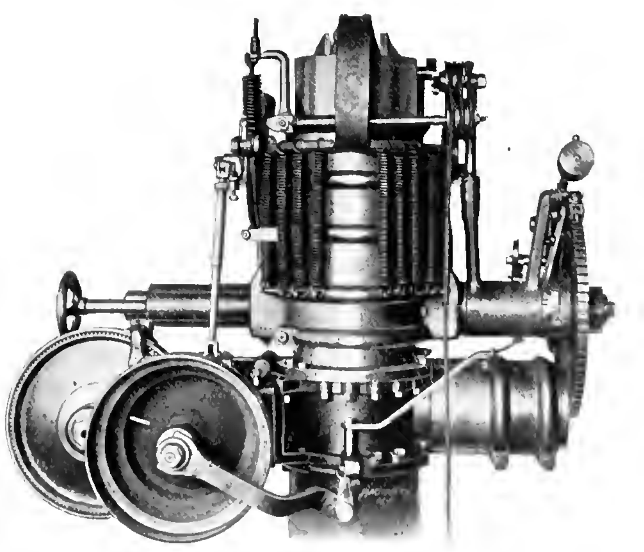

Fig. 12. Rear View of the Pederson Machine.

By Grinding or Abrasion: In Fig. 10, the milling cutter of Fig. 9 has been replaced by an emery wheel of similar shape, having a plane face perpendicular to the axis of the wheel

spindle. The action on the work is identical with that in the previous case, subject only to the limitations of the grinding process, such as the rapid wearing away of the material of the wheel, involving the necessity for constantly truing it up. Besides this, only a small amount of stock can be removed in a given time, as compared with the execution possible with a milling cutter. The process has the advantage that it can be used in hardened work.

As intimated, each of these various operations can be applied to different kinds of gears, acting according to different principles, though many of the possible combinations are impracticable. This preliminary discussion of methods, however, will serve to systematize the study of the various machines illustrated and described in the following pages, and will render an understanding of their construction more easily intelligible.

MACHINES FOR FORMING THE TEETH OF SPUR GEARS.

As described in the previous section, spur gear teeth may be formed in any one of five ways—by the formed tool method, the templet method, the odontographic method, the describing-generating method, or the molding-generating method. The extent to which these various schemes have been applied in practical use varies greatly. The formed tool method is at once the most obvious and the most used of them all. The templet principle has been applied to a limited extent, principally for gears of very large size. So far as the writer is aware, no practical application of the odontographic principle has been made in the cutting of spur gears. The only machine that has come to his notice involving the describing-generating process, was one invented by Mr. Ambrose Swasey, and in use a number of years ago in the shops of the Pratt & Whitney Co. This was not used, however, for making gear teeth, but for making gear tooth cutters—before the days of the formed cutter, which it was not adapted to making. The molding-generating process in various forms has received a wide application, second only to the formed tool method.

The operations available for the formed tool method are—impression, shaping or planing, milling, and grinding or abrasion. Of these, the impression process is obviously unsuited for practical work. The shaping or planing, and the milling (particularly the latter) have a wide range of application.

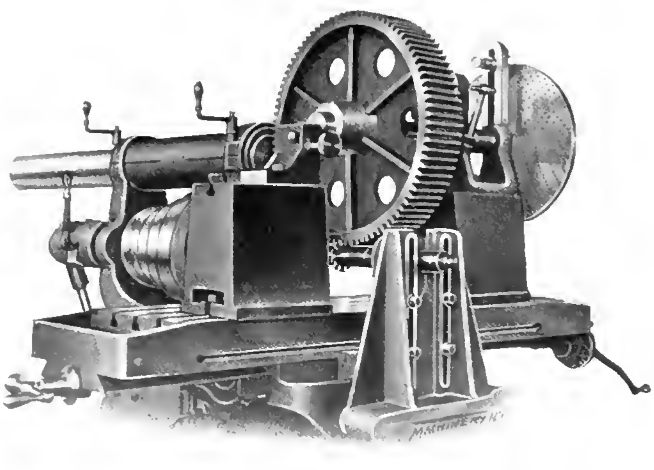

Fig. 13. Attachment for cutting Gears of Large Diameter on Cincinnati Milling Machines.

In the case of the operation of grinding or abrasion, but a single machine has ever been built embodying the formed tool principle, so far as the writer is aware.

Machines using Formed Shaper or Planer Tools.

The primitive application of the formed tool method is that in which a gear blank is mounted on index centers on the planer or shaper table, and has its teeth cut by a tool having an outline corresponding to the desired tooth space. In this operation the tool is fed by hand to the proper depth and withdrawn. The work is then indexed for a second cut, the tool is fed down again, and the operation is repeated until the gear is finished. This is shown diagrammatically in the upper part of Fig. 1. It is the simplest method of cutting a gear which has to be made immediately, and for which formed milling cutters are not available. It also has its application in the case of gears of unusual size. Under these circumstances, however, the machine used is generally a slotter instead of a planer or shaper. A formed tool is fastened in the tool-post of the machine, while the work is clamped to the revolving table. The indexing is done by such means as may be provided, usually a worm and worm gear or a master wheel.* The Gleason and Newton templet machines (described in the next installment) also may be, and doubtless often are, used in the same way.

Figs. 11 and 12 show a machine using the formed tool with the shaper method of action. The machine is an interesting one in its details, and it would require considerable space to

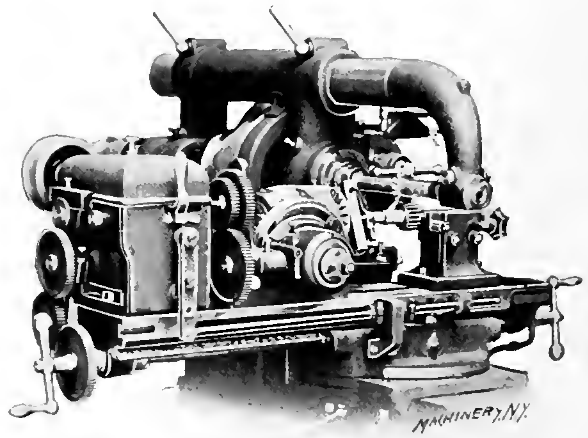

Fig. 14. Attachment made by Ludwig, Loewe & Co. for converting the Milling Machine into an Automatic Gear Cutter.

go into full particulars, so only a general description of it will be given. The mechanism is mounted on a circular column. The work arbor is carried by a slide, vertically adjustable to suit the diameter of the work, the adjustment being obtained by the crank handle shown at the front of the column. The feed and indexing movements for the work are controlled by cams on the shaft shown at the upper side of the work slide, this cam shaft being operated by an adjustable ratchet mechanism from the driving gear. One of these cams, by suitable lever connections, feeds the blank slowly down toward the cutters until the proper depth has been reached, when it allows the springs shown at the rear of the column to quickly return it, whereupon the cam at the left of the shaft operates the mechanism by which the work is indexed. The feeding cam then comes into action again—and so on until the work is completed. The depth of the feed given the work slide by the cam movement is varied by altering the position of the contact block by which the cam lever transmits the feeding movement to the slide. This is changed by the horizontal square-head screw seen at the extreme top of the column. The indexing is effected by a notched dial plate, operated by pawls and locking levers moved by the cam previously mentioned. The number of notches moved at each indexing can be regulated by a guard covering more or less of the teeth included in the stroke of the indexing pawl. Provision is made for stopping the action of the machine automatically when the required number of teeth have been cut.

The cutter slide is driven by a back-geared crank movement, adjustable for length of stroke and for various numbers of strokes per minute. Two tools are used, one cutting on the forward, the other on the return stroke. These tools, as may be seen from Fig. 11, are mounted in a rocking holder, which is tipped to bring first one and then the other into action as the end of each stroke is reached. This tipping is effected by the rocking and locking cam at the left end of the cutter slide in Fig. 11. This rocking and locking cam is connected with a slot cam near the right-hand end of the slide, this latter being operated by a pin near the crank end of the connecting-rod. As the connecting-rod passes the center, going in either direction, it operates the slot cam, which, through its connection with the rocking and locking cam, brings the desired

* See "Generating a Large Index Plate," by A. L. DeLeeuw, August, 1905.

one of the two blades into action. The one of these blades which has the heaviest of the cutting to do is of a simple U-shape, forming the bottoms and fillets of the tooth spaces. The other one, which has a lighter cut, forms the curved faces of the teeth.

Among the advantages claimed for this machine are extreme rigidity of action, exceeding that of the ordinary automatic gear cutter, and very low first cost. The cost of the cutters is also very moderate, being about one-fifth of that for formed milling cutters of the same pitch. These cutter blades are planed to shape, and may be ground on the face without change of contour. By means of special cutters straddling the teeth of the gear, provision is made for cutting pinions of few teeth and considerable under-cut. We are informed that the British rights have been acquired by Vickers Sons and Maxim, who are preparing to manufacture it on a large scale.*

Standard Machine Tools and Attachments Using Formed Milling Cutters.

More gears are cut by formed milling cutters than in any other way. It is distinctly a commercially successful process. The cutting tools are comparatively inexpensive, and retain

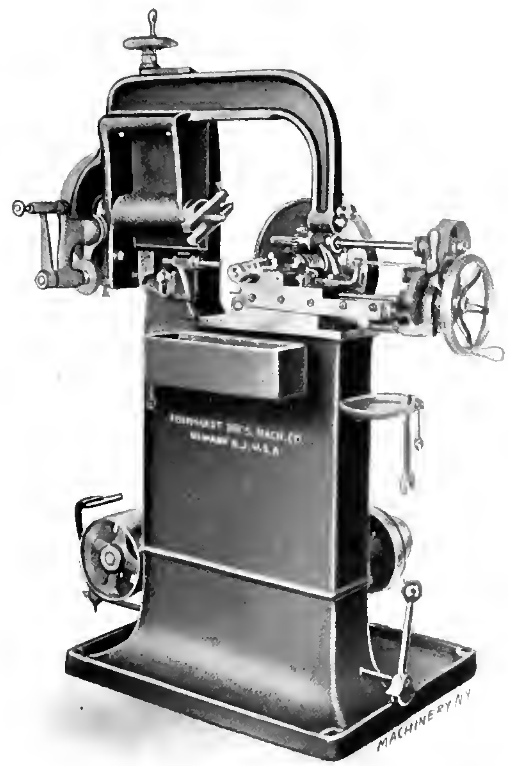

Fig 15. Eberhardt Bros. Semi-automatic Gear Cutter for Small Work.

their shape until they are entirely ground away, which is only after the accomplishment of a surprising amount of work.

The simplest way to use a formed cutter is in the milling machine. In a milling machine provided with an indexing head, no attachments are required for gears of moderate size and small pitch, and many thousands of them are cut with this simple equipment. For gears of larger diameter, though still of a pitch small enough so as to be within the range of the pulling power of the spindle, the worm-wheel of the dividing head becomes too small to satisfactorily and accurately index the wheel. For such work, many of the milling machine makers provide indexing attachments suitable for work of greater diameter than is possible otherwise. In Fig. 13 is shown an outfit of this kind built by the Cincinnati Milling Machine Co., Cincinnati, Ohio. The head- and foot-stock are mounted on elevating blocks which make it possible for them to swing work of a larger diameter. When working on large diameters, the table is raised and the cut taken on the under side of the work. This brings the thrust due to the cut down nearer to the bearing surfaces which have to resist it, and gives a steadier cutting action than would be the case if the work were lowered far enough to have the cutter act on the top of the blank. The indexing is done simply and directly by a plate with rows of holes, of numbers corresponding to the number of teeth it is desired to cut. This plate is of much greater diameter than the index worm of the regular spiral head, and so gives more accurate results.

An attachment of a different kind for cutting gears in the milling machine is shown in Fig. 14. Here we have an ar-

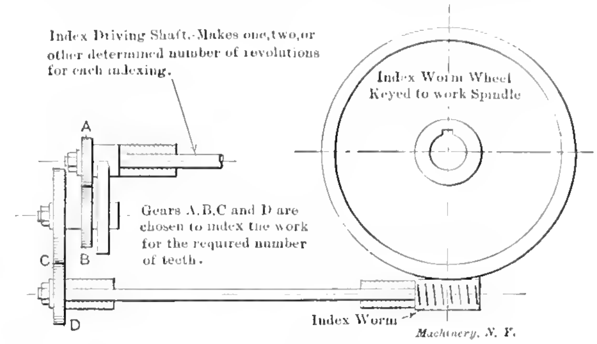

Fig. 16. Diagram showing the arrangement of the Standard Indexing Mechanism.

rangement which is bolted on the milling machine table and connected with the dividing head. This attachment is driven from the counter-shaft by a special belt connection which serves to operate the feed and indexing of the work, the usual feed connections being disconnected. The device renders the milling machine automatic in all its actions. The table with the work on it is fed forward slowly until the cutter has passed through the work and formed the tooth space. The table and work are then rapidly returned, when the work is indexed and again fed forward as before. These processes are repeated until the gear is finished. The milling machine is thus made in effect an automatic gear cutter, capable of cutting bevel gears and clutches, as well as spur gears. This device is made by Ludwig, Loewe & Co., Berlin, Germany.*

Semi-automatic Machines Using Formed Milling Cutters.

Leaving the special use of the standard milling machine in this work, and coming to milling machines specially adapted to cutting gear teeth, we are met by a bewildering variety of designs of varying degrees of ingenuity and interest. We will first consider the simpler forms of these specialized milling machines, or "gear-cutting machines," as we may better call them.

In the simpler forms, the development from the milling machine consists principally in embodying the dividing mechanism as a part of the machine, instead of making it an at-

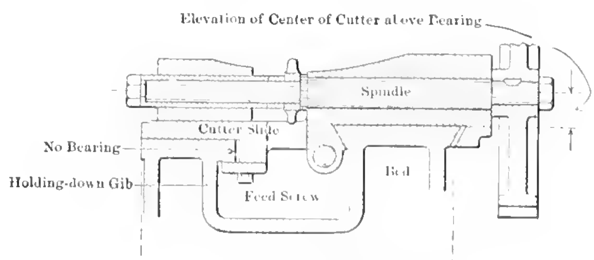

Fig. 17. Cross-section through Cutter Slide of Typical Gear Cutter, Illustrating Certain Principles relating to Accuracy and Cutting Power.

tachment. The feed may be operated by hand, or it may be connected by belt or gearing with the spindle, so as to be driven positively. In the latter case, an automatic stop is provided for throwing the feed out when the cut is completed. In the automatic form of machine the indexing mechanism, as well, is operated by power, as is also the quick return of the feed; and the movements are made dependent on each other

* Information concerning the American rights for this machine, may be obtained from Mr. H. A. Elliott, with Alfred H. Schutte, corner of Cedar and West Streets, New York.

* See article entitled "Automatic Indexing and Feed Attachment for the Milling Machine" in the June, 1907, issue of MACHINERY.

in such a way that the machine of itself feeds the cutter through the work, returns it when the cut has been completed, indexes the work, and repeats the cycle until the job is finished.

An example of the semi-automatic form of the machine, made by Eberhardt Bros. Machine Co., Newark, N. J., is shown in Fig. 15. The mechanism is quite simple and may be readily understood from the cut. The spindle is carried on a slide which may be adjusted at an angle for cutting bevel gears, though it is shown in the cut down in a horizontal position as required for cutting spur gears. An automatic feed is provided for the spindle slide, connected with the cutter spindle by spiral gears and change gears, which may be set to give the desired rate. An automatic stop is provided for throwing out the power feed when the required length of cut has been taken. The slide then has to be run back by hand and the work indexed by hand, when the automatic feed is again thrown out. The work spindle is carried on a slide gibbed to the face of the column of the machine. This slide carries the indexing mechanism also, and an over-hanging arm for supporting the outer end of the work arbor. The indexing mechanism is of the same type as that illustrated in Fig. 16 and described later. Such tools are adapted to manufacturing in small quantities where unskilled labor is employed. The machines are inexpensive, and the operating skill required is of a comparatively low order.

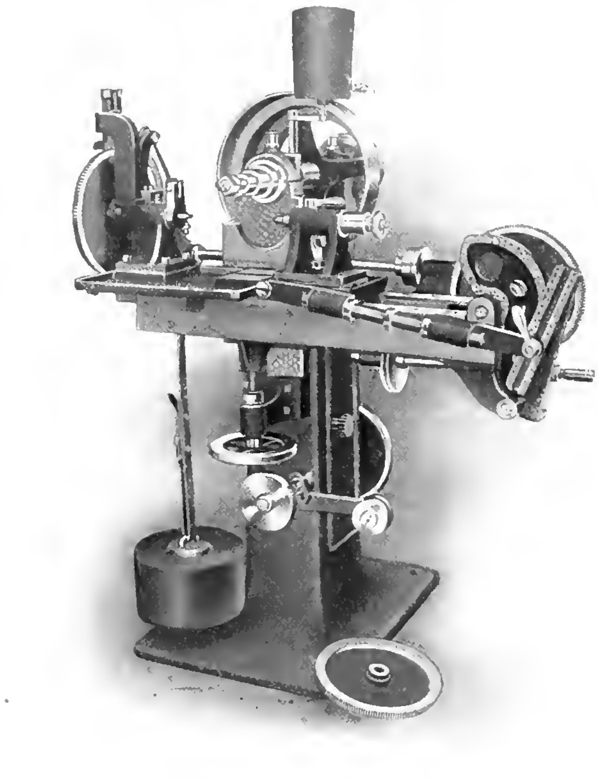

Fig. 18. The Dwight Slate Cam Actuated Automatic Gear Cutter.

Machines of similarly simple action, but for larger work, have been built from time to time by builders of special machinery as required by their customers.* These machines may be handled by comparatively inexpensive labor, are furnished at a low first cost, and are very substantial in construction.

Automatic Machines using Formed Milling Cutters—General Principles of Design.

The fact that we illustrate twenty-five automatic cutting gear machines of this type, built by twenty-two makers, is good evidence of its commercial position. Much thought and experience has gone into the development of the automatic gear cutter. In selecting a machine of this kind, important requirements to be looked out for are—accuracy of indexing, power and durability of the feed and cutter-driving mechanisms, rigidity of construction, convenience of handling, and range of usefulness.

* See, for instance, the description of Newton machine, in article, "American Gear Cutting Machinery," in the June, 1898, issue of MACHINERY.

In the matter of accurate indexing (which is of prime importance, especially for gears which are to run at high speeds), the important considerations are the accuracy of the index worm-wheel and the mechanical construction of the indexing mechanism. With the exception of the machines shown in Figs. 18 and 19 (also 41, 42, 43 and 44, shown in the next installment), which are for comparatively small work with small numbers of teeth, the principle of the indexing mechanism is the same for all of these machines.

The work spindle has mounted on it (see Fig. 16) a worm-wheel driven by an indexing worm. This worm is connected by change gears A, B, C and D with a shaft which is arranged (usually) to make one complete revolution, when the proper time for indexing arrives. The change gears are so set in connection with the invariable movement of the index shaft, as to give the exact movement required to rotate the blank to the point where it is desired to cut the next tooth. In some machines, provision is made for giving two or four complete revolutions to the driving shafts when the number of teeth to be indexed is small. It is important that the mechanism by which this shaft is set in motion and stopped shall be very carefully designed, so that the stopping will always take place at exactly the same point in the rotation, thus permitting no over-running or under-running of the worm.

In the construction of the worm-wheel, there are two plans followed. Some makers, notably the Brown & Sharpe Mfg. Co., prefer to make each worm-wheel an accurate copy of a master wheel which they know to be of unimpeachable accuracy. Other builders prefer to make each index wheel by itself, and generate each one to a high degree of perfection by methods well understood and commonly employed in such work, generally involving making the rim in halves.

In the matter of obtaining power and durability for the drive, a variety of opinions will be found expressed in the various designs. Some of them have the spindles driven by spur gearing (or bevel gearing in some cases) while other makers prefer spiral or worm gear drives. There is much conflict of opinion as to the advantages of these various forms. In some cases the builder is restricted in his choice by structural features which limit him to one form only. In any event, the drive should be smooth and powerful.

The capacity of gear-cutting machines for taking heavy chips may be easily allowed to fall below the limit of the driving power available at the spindle, if the frame of the machine and the design of gibbing of the various slides are such as to make the machine lacking in rigidity. The various requirements for doing work rapidly and accurately may be understood from the rough sketch of a section through the spindle and cutter slide of a gear cutting machine shown in Fig. 17. This sketch does not represent any particular machine, but shows some features which are common to a number of makes; unnecessary details have been omitted. One of the requirements is that the strain of the cutting action shall be brought as close to the bearing surface as possible. This applies in the case of both the work spindle and the cutter spindle. It will be noted in Fig. 17 that the elevation of the center of the cutter above the bearing is very small,

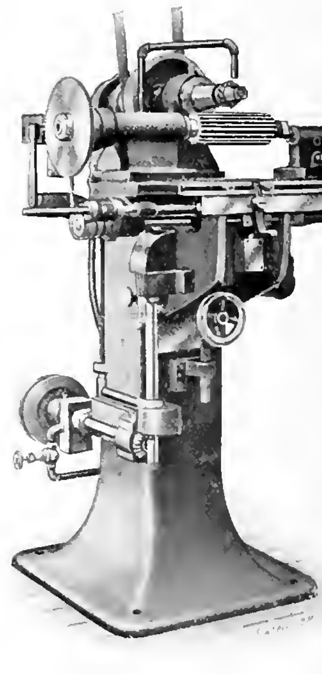

Fig. 19. The Sloan & Chace Automatic Gear Cutter for Small and Medium Work.

so that the irregular thrust of the cutting action when working at full capacity has little effect in disturbing the rigidity of the machine. Bearing surfaces of great area are also advisable to give firmness to the structure. It will be noted that the bearing surface extends the full width of the bed of the machine in the sketch. With this wide bearing surface, however, provision should be made for guiding the slide for alignment, with much narrower surfaces, to prevent a cramping or "bureau-drawer" action, as it has been called. The guiding in this case is done entirely by the comparatively narrow dove-tail slide at the left. There is no side bearing at the

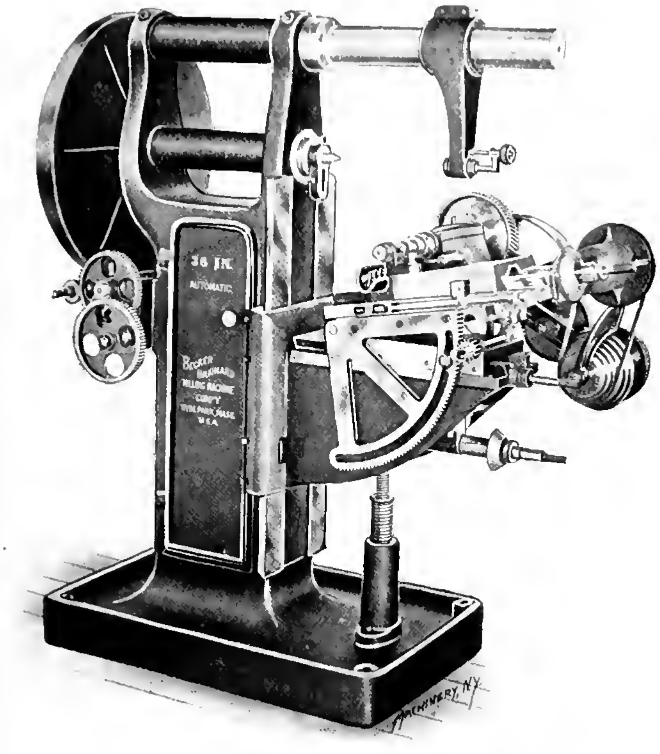

Fig. 20. The Becker-Brainard Automatic Gear Cutting Machine.

right, a clearance space being left at the right hand edge of that slide as indicated. A strap is provided here, however, for holding the slide down onto its bearing, thus preventing any lifting tendency which may develop at this point. It will be noted that the feed screw is placed quite close to the cutting point. This provision also tends toward smoothness and ease of action, since the power is then directly applied instead of being applied in a way to cramp the slide on its bearings. The rigidity and smoothness which these provisions insure are of great importance in permitting the use of very heavy cuts and lengthening the life of the cutter.

In regard to these matters, and the matter of convenience of operation as well, much can be surmised by the mechanic from a careful inspection of the engravings we show herewith. Instead of making invidious comparisons in these particulars, it has been thought best to let the reader draw such conclusions as he can from the information given. The descriptions of the various automatic gear-cutters will be found to contain explanations of their construction, and to refer to such particular points as may be peculiar to each case. To make comparisons easy, machines of similar type have been placed together in regular order. Of course such of the good qualities in a machine tool as depend on accurate workmanship and the design of details not visible from the exterior, will have to be judged by other means than a mere inspection of half-tones. In the matter of accurate workmanship, particularly, the reputation of the builder will go a long way with the intending purchaser.

Miscellaneous Forms of the Automatic Spur Gear Cutter.

As has been stated, the automatic gear cutter is a specialized form of the milling machine. There are no machines in our list that show this more plainly than the two shown in Figs. 18 and 19. The first of these is built by the Dwight Slate Machine Co., of Hartford, Conn. The machine at once shows itself to be a modified milling machine, with the usual screw feed replaced by a cam mechanism which gives a slow forward movement and a quick return. This is altered to give the proper length of feed, by means of the slotted link shown. The orthodox dividing head with worm and worm-wheel, has been replaced by a dividing plate on the head-stock spindle, with notches to correspond with the number of teeth it is desired to cut. An automatic trip is provided which throws out the feed at the completion of the last tooth. The various adjustments for different diameters of gears and lengths of cut will be readily understood from an inspection of the figure. This machine is one of a series of three of varying sizes, one of which is adapted to the cutting of bevel gears as well as spur gears.

In the machine shown in Fig. 19, built by Sloan & Chace Manufacturing Co., Ltd., Newark, N. J., the feed is effected by a screw, as in the ordinary milling machine, instead of by cams as in the previous case. The motion for the indexing and quick return is taken from the counter-shaft by the pulley shown near the base of the machine at the left. This gives a constant speed at the highest practicable rate whatever the spindle speed may be. The cutting feed is obtained from a connection with the spindle through a feed box, giving three changes. The indexing is ingeniously effected by the first half-turn of the feed screw, and is done positively without requiring the use of springs. A dial plate is used as in the previous case. The spindle head is adjustable in and out on the top of the column for centering the cutter. This machine shows the influence of the watch machinery makers' ideas, applied to a machine of rather larger capacity than usual with such construction. It is intended to show the watch makers' ideas of accuracy as well.

Another machine that shows the hereditary influence of the miller is shown in Fig. 20. In this case, however, the relative positions of the work spindle and the cutter spindle have been reversed from that occupied in the milling machine, or in the tools shown in the two preceding cuts. The work spindle passes through the uprights of the column, and carries a worm dividing gear at the rear end, while the cutter slide is located on the knee. In the position shown, with the intermediate quadrant elevated, the cut is being taken on an angle as would be required in cutting bevel gears, for which this machine is also adapted. For cutting spur gears, the slide is horizontal. Change gears for dividing are seen at the rear of the column beneath the casing for the indexing wheel. The indexing is done by a friction mechanism which is released at the proper time, coming up against a positive stop when one revolution has been made. The spindle driving

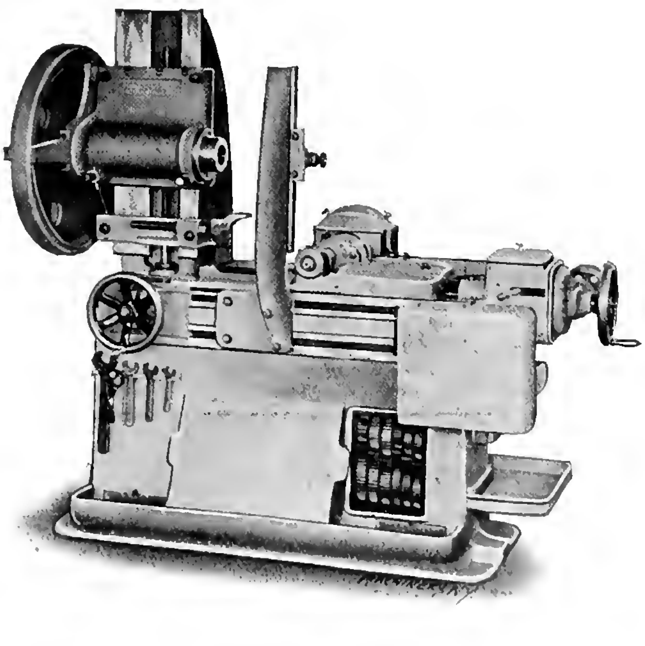

Fig. 21. An Example from the Brown & Sharpe Line of Automatic Gear Cutters.

* Described in "New Machinery and Tools" section of MACHINERY, January, 1907.

and feed mechanisms are carried entirely by the knee. It will be noted that the gear driving the cutter spindle has helical teeth. Where a cutter spindle is to be driven by spur gears, this is a construction often followed, particularly in Europe, to give a smoother and more even motion than would be obtained by teeth cut straight across in the ordinary fashion. An incidental convenience of this machine is a trough just beneath the cutter spindle, enclosing a slowly-moving spiral conveyer. The chips fall from the cutter into the trough, and are pushed by the conveyer out over the edge of the knee into the pan base, away from the mechanism of the machine. This machine is built by the Becker-Brainard Milling Machine Co., Hyde Park, Mass.

The Orthodox Automatic Spur Gear Cutter.

The automatic gear cutters of the conventional type, for small and medium-sized work, have the work and cutter spindles both horizontal, and arranged in the same relation to each other as in the Becker-Brainard machine. Instead, however, of adjusting the machine for the diameter of work by the raising or lowering of the knee carrying the cutter spindle, the work arbor is raised or lowered, being carried for that purpose in a head vertically adjustable on a column at the end of the bed of the machine. The cutter slide on these machines, when arranged for cutting spur gears only, is gibbed directly to the top surface of the bed.

One of the best known examples of this orthodox type of automatic gear-cutting machine is that built by the Brown & Sharpe Mfg. Co., Providence, R. I. A front view of one of their smaller sizes, the No. 3, is shown in Fig. 21. The spindle of this machine is driven by worm gearing, though with the parts reversed from the order they would naturally take, since the worm-wheel is the driver, and the worm, which is much larger in diameter than the wheel, is the driven member.* This arrangement gives the smoothness of drive of worm gearing, an enlarged bearing area, and the advantage of being able to shift the whole spindle with its driving gear endwise in adjusting the cutter centrally with the work, instead of requiring that the driving gear remain fixed in position, driving the spindle by sliding keys, as in the ordinary

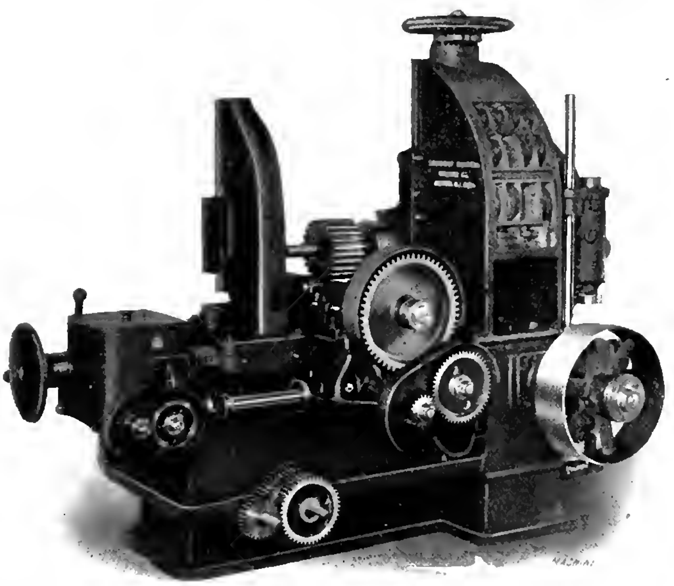

Fig 22. A Machine made by Eberhardt Bros., with Special Shortened Column; of Rugged Design for cutting Coarse Pitch Pinions.

construction. The plan generally followed by this company with all its machinery, of building the various parts of the mechanism on the unit system and assembling them as units in the machines, gives an air of neatness in design to the tool, which will be readily appreciated from the cut. A feature common with most automatic gear cutters, the outboard support for the work arbor, will be noticed clamped to guiding surfaces on the front of the bed. The index wheel is solid, and is made an accurate copy of a precision master wheel, as previously explained.

* Described in article entitled "The Figuring of Gear Drawings," by L. D. Burlingame, in engineering edition of MACHINERY, August, 1906.

The spur gear cutter shown in Fig. 22 is built by Eberhardt Bros. Machine Co., of Newark, N. J. The machine shown was designed primarily for cutting pinions of large pitch. For this reason the machine is ruggedly built and has a comparatively short column, limiting the diameter range for which it is adapted. The whole mechanism is driven from a pulley running at constant speed, the various changes of spindle speed and feed being obtained by change gears. It is like most other machines of its class, also, in the fact that the interior of the base of the machine serves as a collecting chamber for chips and a reservoir for the oil which is drawn from them.

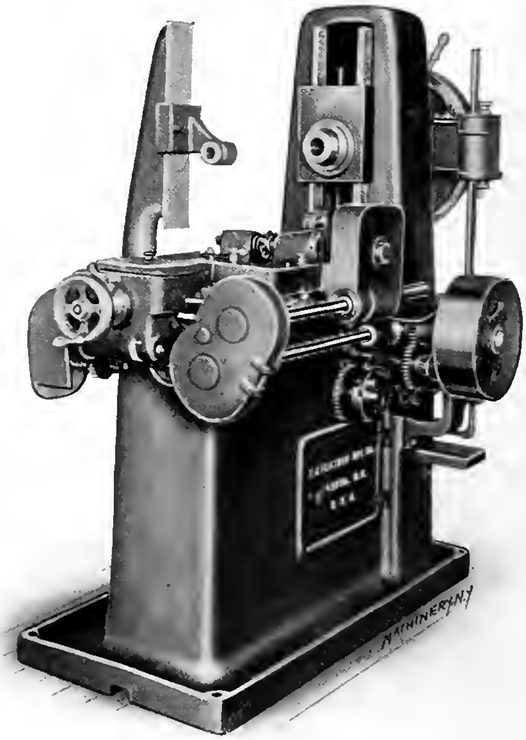

Fig. 23. The Flather Automatic Gear Cutter.

From here it is returned to the cutter by an oil pump. It will be seen that the cutter spindle driving gear in this case is a spur gear. The change gearing for altering the speed is placed next to it in the order of transmission, so that the splined shaft which leads the motion to the cutter shaft runs constantly at high velocity, whatever the speed of the cutter may be. Smaller machines of somewhat similar type are also built by this firm, some of them adjustable for cutting bevel gears as well as spur gears. The machine shown in Fig. 22 is, of course, ordinarily supplied with a higher column, than is here shown, which provides for work of greater diameter.*

An automatic gear cutter built by the E. J. Flather Mfg. Co. is shown in Fig. 23.† One of the most noticeable features of this machine as compared with those previously considered is the construction of the column which supports the work carrying head. This is made double, and the work carrying head passes through it instead of being clamped to ways on its face. The handle shown projecting at an angle in front of the index wheel casing at the back of the column, is used for clamping the work head solidly to its seat on both the front and back sides of the column, when the adjustment for depth of cut has been made. The spindle of this machine is worm-driven. The indexing mechanism is of the positively operated type, with a friction device to prevent rebound. As in previous cases, all changes of feed and speed are made by change gears, the machine being driven by a constant speed pulley.

* * *

A French formula for fireproofing wood and cloth calls for a mixture of $4\frac{1}{2}$ ounces of sulphate of ammonia, one-half ounce of borate of soda, one-sixth ounce of boric acid, all diluted in $2\frac{1}{4}$ pounds of water.

GIGANTIC METAL-WORKING PLANER.

The accompanying illustrations show the largest and heaviest metal-working planer ever built in America, and as far as we know, it exceeds also in size any tool of this class of European production. This planer was recently shipped from the Bement-Miles Works, Philadelphia, of the Niles-Bement-Pond Co., to the Mackintosh Hemphill Co., of Pittsburg. The best idea of the size of this planer is gained from the photograph reproduced on this page, which shows the planer erected in the shop, just prior to shipment, with 89 men distributed over it. If it is preferred to arrive at an idea of the size of this planer from figures, it may be mentioned that the total weight of this gigantic machine is 845,000 pounds (422½ tons), and that five motors, with a total power aggregating 207½ horse-power, are required for its operation. An idea of the difficulties attending the shipment of a machine of this size, as well as of the dimensions of the machine itself, may also be gained from the single fact that a special flat car with a central opening in the deck was required for the uprights alone, these being so large that their dimensions exceeded the clearance limits of tunnels and bridges, if loaded directly on the car deck in the usual position. The total weight of the two uprights is about 110,000 pounds.

General Dimensions.

The machine normally is a 14-foot planer of the ordinary type, as far as general principles of design is concerned, but in addition to the common features of planers, it is provided with some other features, which will be described later, and which are not found on general standard machines. The distance between the uprights is 14 feet 1 inches; the maximum distance from the table to the bottom of the cross-rail, 12 feet 2 inches; maximum stroke of table, 30 feet; total width of bed, 13 feet; length of bed, 60 feet. The table ways are each 15 inches wide. The tool slides are 7 feet 8 inches long, having a 4-foot vertical traverse. The cross-rail is long enough to admit full traverse of either head between the uprights. The face of each upright is 2 feet 6 inches in width, and the vertical height of the cross slide, including the top rib bracing, is 5 feet. Figs. 2 to 9 inclusive, which show the details of the planer, convey also some idea of the great size of the component parts.

Power Equipment.

As mentioned, the machine is provided with five motors. The main driving motor is of 100 horse-power, the lifting motor for the cross-rail is of 20 horse-power, and the traverse motor for the heads on the cross-rail, for fast traverse, is of 7½ horse-power. One motor of 50 horse-power normal capacity is provided for the independent slotter bars placed in each head, which are driven by rack and pinion. This motor also operates the heads for cross planing, the machine being adapted not only to ordinary planing, but to slotting and cross planing work as well, thus enabling the planer to be of service on the top, ends and sides of the work at one setting. The driving clutches are operated pneumatically, and an air compressor is provided, with a 30 horse-power motor, the planer being fitted with its own air compressor and independent motor. The planer is thus independent of the air supply of the shop, although the shop supply may be used, if it is desirable. Another feature of notable interest is a complete switchboard, which is furnished for controlling all the motors.

Provisions for Cross-planing and Slotting Work.

As has been mentioned, each head is fitted with a slotter bar independently driven by a rack, giving practically constant cutting speeds and a quick return. The maximum stroke

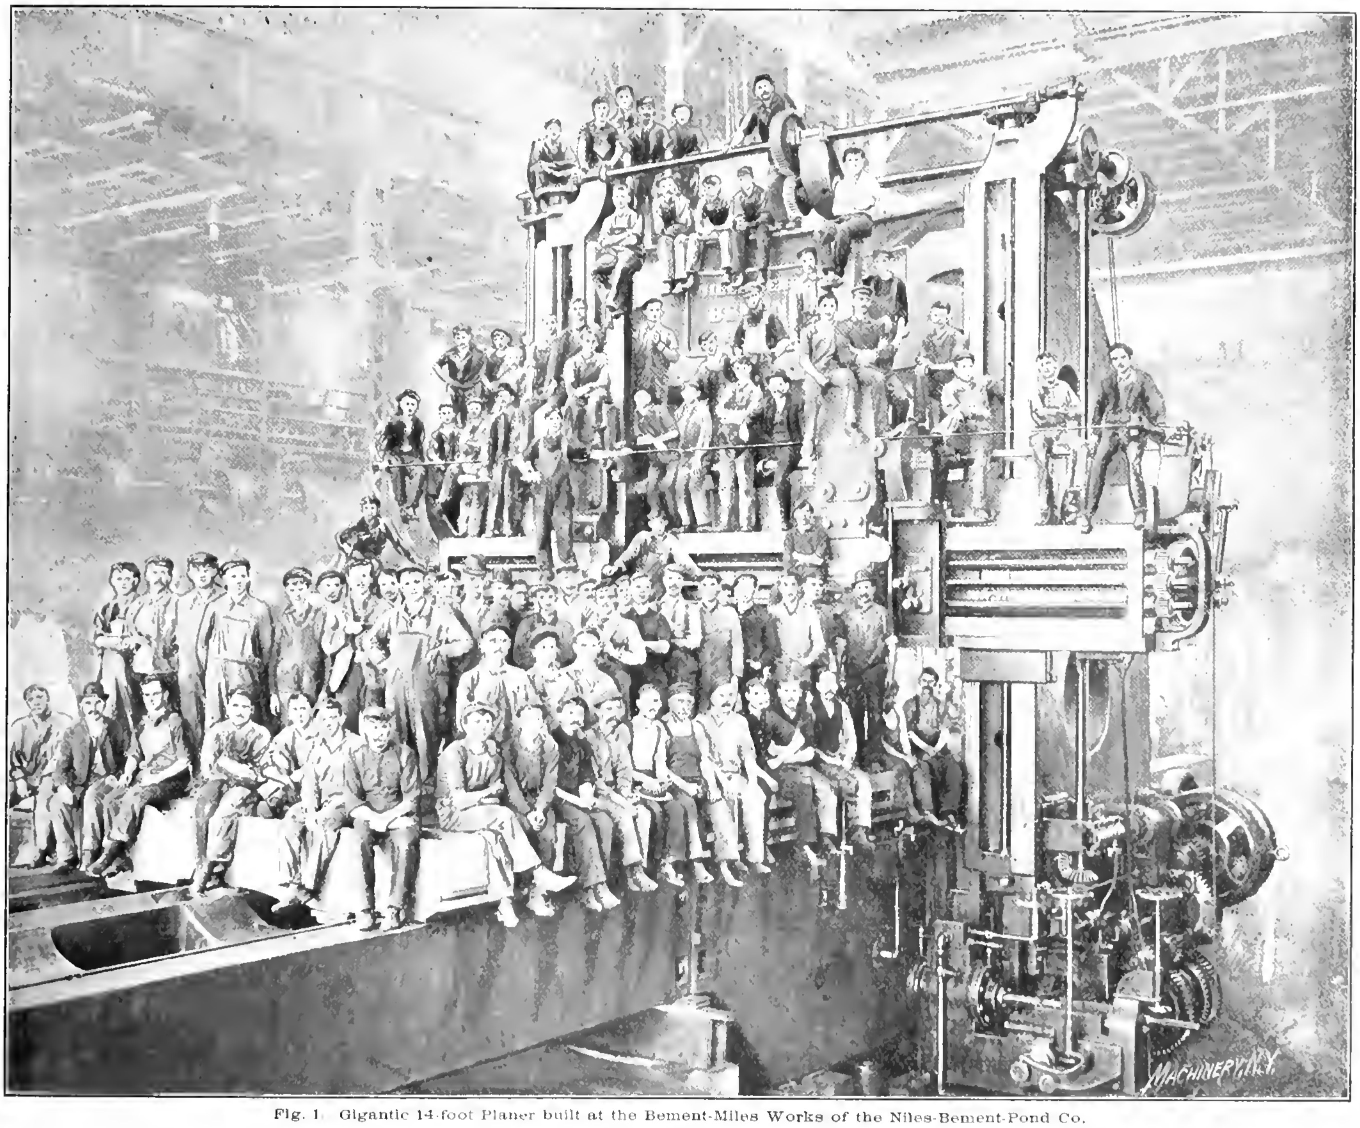

Fig. 1. Gigantic 14-foot Planer built at the Bement-Miles Works of the Niles-Bement-Pond Co.

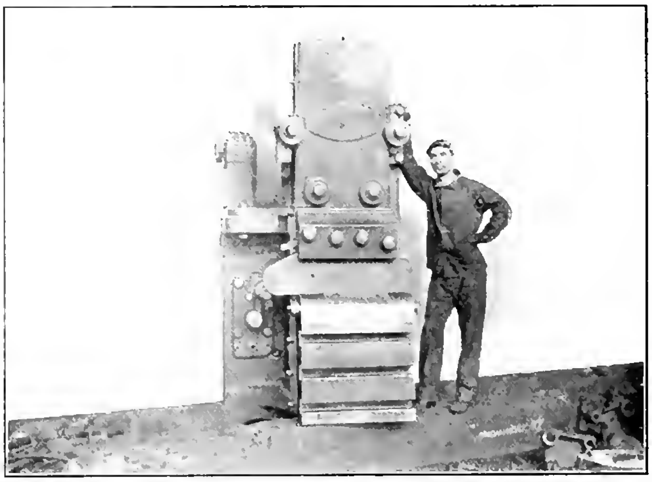

Fig. 5. View showing the Size of the Planer Head.

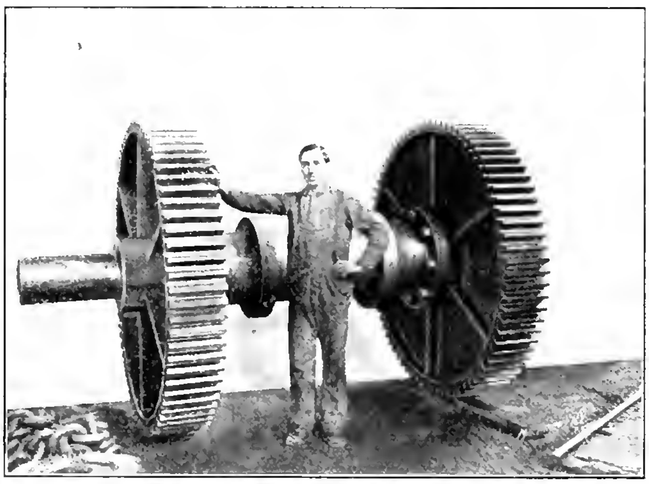

Fig. 6 Bull-wheels.

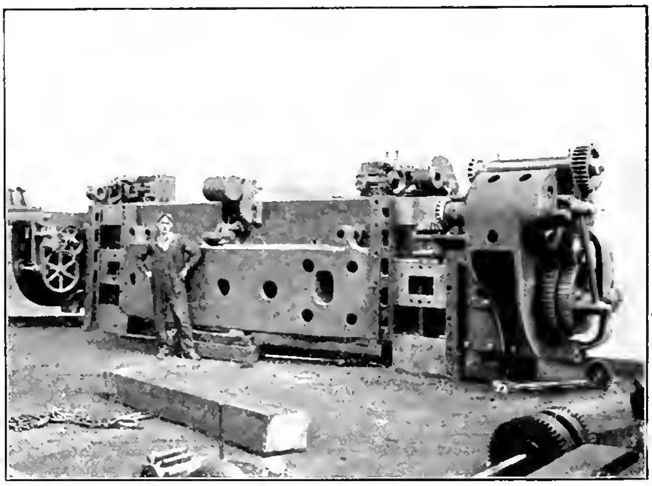

Fig. 7. Cross-rail.

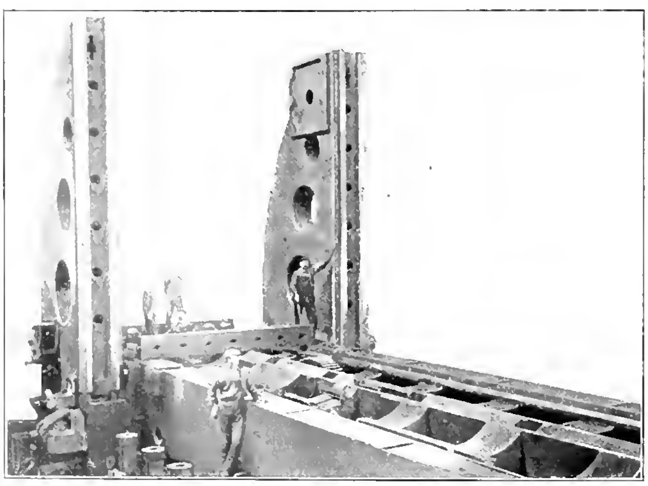

Fig 8 The Uprights Assembled.

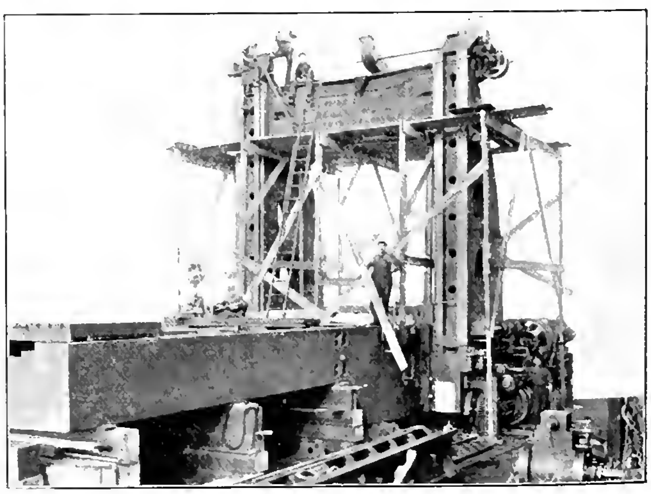

Fig. 9. Erecting the Tie-beam.

of the slotter bar is 8 feet. The cross planing movements of the heads, also referred to above, can be varied as to speed within certain limits, and are also provided with a quick return motion. The movements for slotting and transverse planing make it necessary to throw out the rack driving mechanism of the table. When the machine is used for slot-

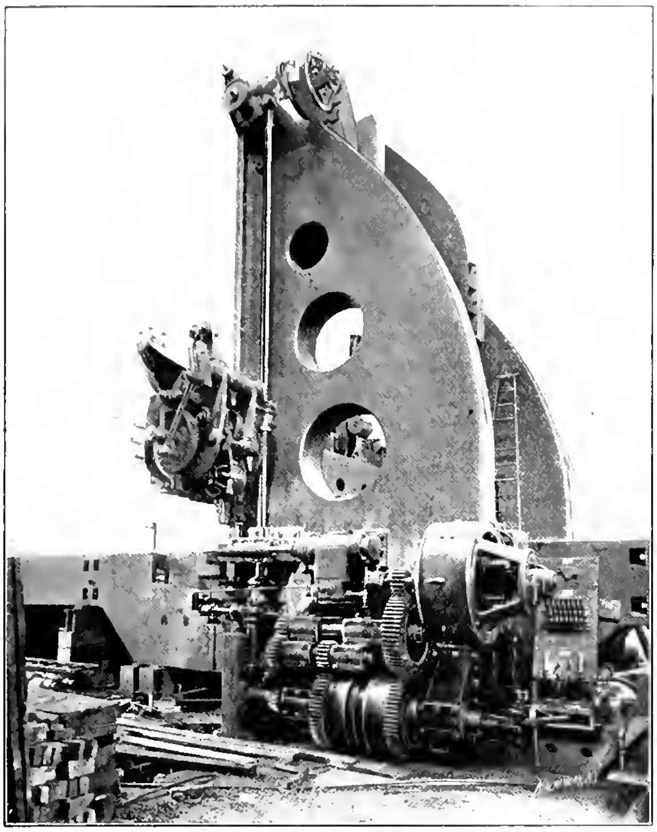

Fig. 10. View showing the 100-horse-power Motor for the Main Drive.

ting or transverse planing, the table is connected to a separate feed motion entirely distinct from the rack feed motion. The throwing out of the driving mechanism is accomplished by simply putting the pneumatic driving clutches into the idle position.

Speeds and Feeds.

The cutting and return speeds are variable through the motor, which has a variation of 1 to 1¼. Changes in speed may also be effected through a range of change gears. The regular cutting speeds are from 14 feet to 25 feet, and the

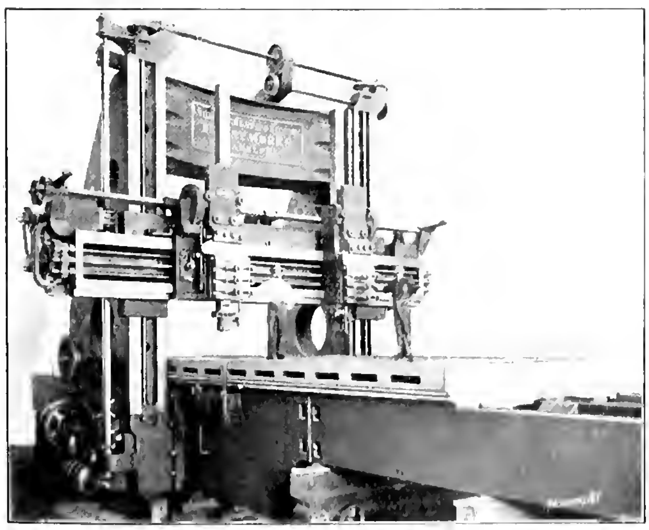

Fig. 11. View of the Slotter Drive.

return speeds are from 52½ to 65½ feet per minute. The slotter bars have a cutting speed of from 18½ to 30 feet, and a return speed of from 57 to 71 feet. Finally, the cutting speed for cross planing is from 11½ to 19 feet, and the return speeds from 35 feet to 13½ feet. The cross traverse feed of the heads is 50 inches per minute. The vertical speed for raising and lowering the cross rail is 26 inches per minute.

The Main Drive.

In Figs. 1 and 10 the main drive from the 100-horse-power motor is clearly shown. The drive is through gearing from the motor to the pneumatic reversing clutches at the base of the right-hand upright. These pneumatic clutches are completely encased, and are made, according to the Niles-Bement-

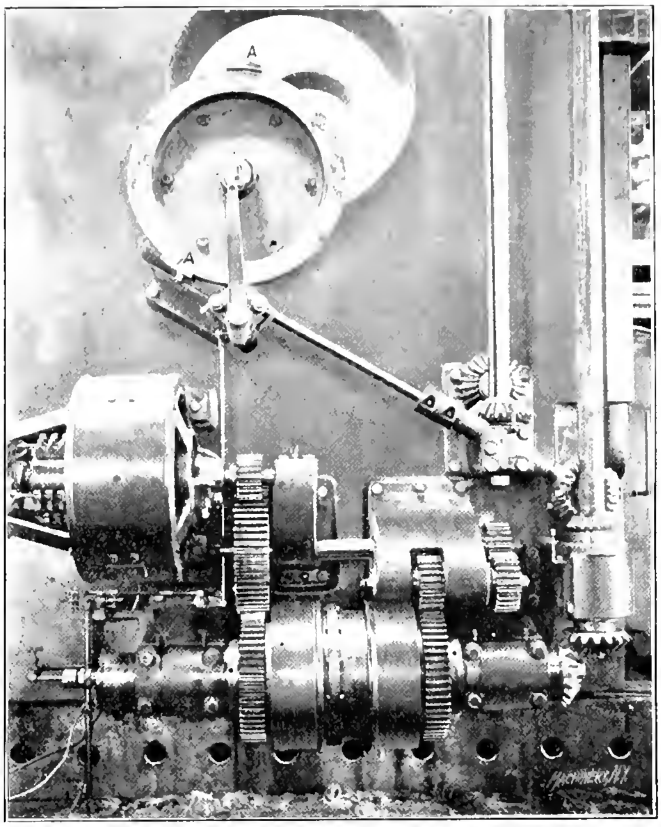

Fig 12. Detailed View of the Slotter Drive.

Pond type, with a large number of friction disks, through which arrangement a large friction area is obtained within a comparatively small space. The stopping, starting, and reversing of the table is controlled through a small valve easily moved by hand. The remaining portions of the drive, from this point on, are practically in every respect the same as those found on other planers, excepting, of course, that the drive distinguishes itself through its enormous proportions. All parts of the drive are made of steel, and the two bull pinions are forged directly on the shaft. They are cut so

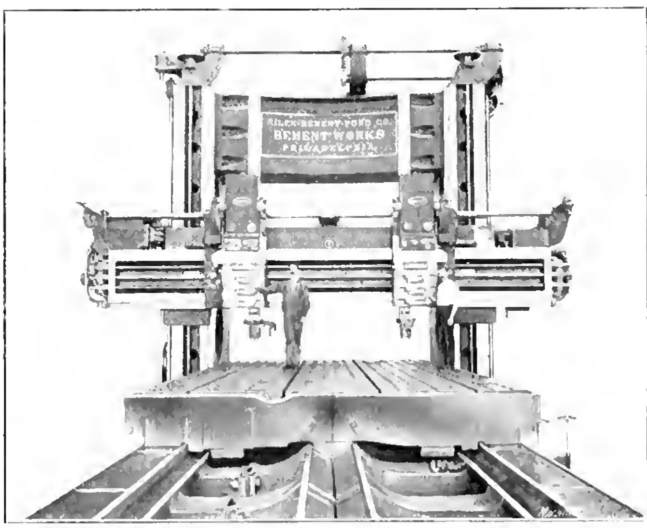

Fig. 13. Front View showing the Three Ways which support the Table

that the teeth of the one are half a pitch ahead of the teeth in the other. This arrangement tends to produce smoothness of action.

The Pneumatic Feed.

The feed of the cross-heads is operated pneumatically. On the side of the upright, just above the gearing, Fig. 10, there is a cylinder with a piston rod extending to the left. In this

piston rod rack teeth are cut which mesh with a pinion near the lower end of the vertical feed shaft. Near the extreme end of this shaft is placed a bevel gear meshing with another bevel gear on a horizontal shaft, which latter transmits motion to the vertical feed shaft on the left-hand upright on the other side of the planer. The movement for these feed shafts is constant at all times, and the variations in amount and direction of the feeds of the heads are obtained by adjusting the connecting-rods in the slotted cranks on the ends of the cross-rail. In order that definite cross and vertical feeds may be obtained, these cranks are graduated. An angular feed can be obtained and given to the tool by using at the same time the slotted cranks for both vertical and cross feeds. This provision is also necessary on account of the fact that the heads are not designed to swivel. At each end of the stroke of the planer table the valve controlling the air

scale. The general arrangement of this drive is the same as for the main drive on the opposite side, up to and including the pneumatic clutches. For the slotter drive the power is then transmitted through bevel gears to a vertical square shaft, from which the power in turn is transmitted to a horizontal square shaft running on the top of the cross-slide, as plainly shown in Fig. 11. A pinion on this shaft drives a large gear enclosed in the gear cover shown at the side of each head. On the same shaft as this large gear is a pinion which meshes with the rack teeth on the back of the slotter bar. The pinion on the square shaft slides back and forth on the shaft, and can be thrown out of mesh when desired, so that either one or both bars may be used. The disk or wheel shown directly above the motor on the left-hand upright controls the length of the stroke of the bar. This disk is driven from the vertical square shaft, and adjustable stops

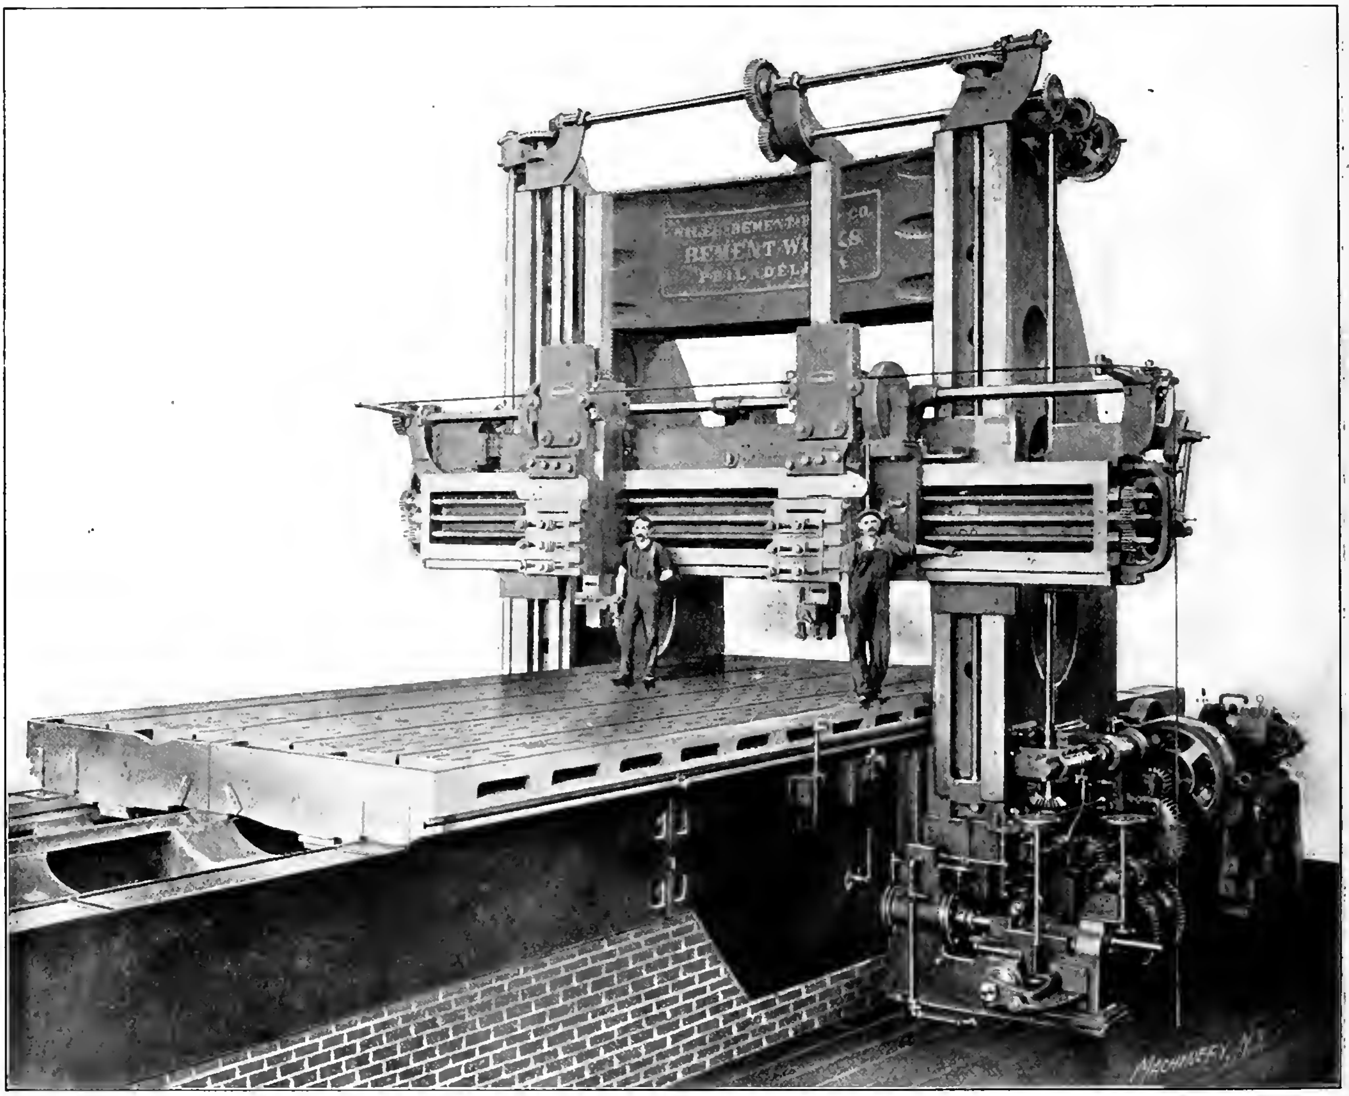

Fig. 14. General View of the Planer showing the Slotting Attachment and the Feed Mechanism.

for the feed cylinder is tripped automatically. The feed is thrown out by the closing of a valve on the main air supply pipe to the cylinder.

The table feed, which is used when slotting or planing transversely, was not put in place when the photograph from which Fig. 10 was reproduced, was taken, but it is shown in Fig. 14 directly in front of and at the base of the upright. The operation of this feed is practically the same as the operation of the feed for the cross-head, previously described, excepting that the amount of feed is obtained by varying the stroke of the piston in the cylinder, an adjustable stop being used for this purpose. This adjustment is made by the right-hand hand-wheel shown in Fig. 14, the left-hand hand-wheel serving the purpose of connecting and disconnecting this feed mechanism to and from the main driving shaft.

Slotter Drive.

In Fig. 11 is shown the slotter drive on the left-hand side of the planer, and in Fig. 12 this drive is shown in a larger

on the outside of its rim can be set at any desired point. These stops effect the reversal in the same way as the dogs on the side of the planer table effect the reversal of the table motion. Near the lower end of the vertical square shaft is seen a bevel gear on the end of a horizontal shaft through which motion is transmitted through the bed and to the other side of the planer, where the shaft is connected to the mechanism operating the valve of the feed cylinder on the opposite side, so that the feeds are available when using the slotter bar as well as when using the main drive for the planer.

Hand Control of Slotter.

In Fig. 14 a vertical shaft will be noticed (at the usual place for the reversing lever) the upper end of which is provided with two sockets, in one of which there is a handle. The upper of these sockets is connected to a shaft which runs down to the bottom lever or crank. This handle is for the hand control of the slotter. The method of connection can

be easily followed, starting from the handle shown in Fig. 14, going through the bed to the corresponding arrangement in Fig. 11, and then following the curved connecting-rod running in back of the upright and out through the upright to the slotter reversing mechanism at the reversing disk previously referred to.

The lower socket in this vertical shaft controls the movement of the table when the planer is used for ordinary planing. The mechanism is then connected by a lever and rods to the reversing dogs on both sides of the planer. It will be noticed that only one handle is furnished for each side of the machine. This prevents mistakes arising from throwing the wrong lever.

The Planer Bed.

It is evident that the bed for a planer of such dimensions as this could not very well be made in one piece, or, at least, an attempt to do so would have been impracticable. To produce and handle such a piece of work in the shop would not only have been attended with the greatest difficulties, if at all possible, but it would also have been a very difficult piece to ship. The bed is therefore made in seven parts, each end section being made in two parts, and the central section being made in three parts. The total weight of the bed is about 275,000 pounds.

The Table.

The table of the planer is made in two sections, the table being divided longitudinally in the center. The weight of the two sections together is about 140,000 pounds. The holes in the table for clamping bolts, etc., run entirely through an upper plate, but below this plate there is a second plate, without openings, extending the full width of the table. In the pocket formed between two plates of the table, all chips will collect. These can then easily be removed through the side openings of the table, clearly shown in Figs. 11 and 14. The table slides on the bed on two flat ways at the sides of the table, and in one V-way at the center, as is shown in Fig. 13.

At the end of the table, as shown in several of the cuts, but perhaps most plainly in Fig. 13, there are finished pads, two over the V-way and to two over each of the flat ways. These pads are intended to carry tool-heads when it is wanted to true up the ways, when worn out of alignment. The method of performing this work is rather interesting and, as far as we know, distinctly new. The table is raised about ¼ inch above the ways, and is supported in this position on sliding blocks which fit the narrow inner auxiliary ways, shown in Fig. 13, which are used for this purpose only. The heads carrying the tools for truing up the regular ways are now fastened to the end of the table, the machine is started up, and the ways are trued up from the center to one end. The heads are then placed on the opposite end of the table, and the remaining portions of the ways are finished. Then the sliding surfaces of the table itself are planed up by placing the same truing heads in pockets provided in the ways in the bed, near the center of the machine. The accuracy of the finished work depends, of course, entirely upon the accuracy of the auxiliary ways, and these are therefore finished on the completed planer with great care.

Fast Traverse and Cross rail Operating Mechanism.

A motor for the fast traverse of the heads is shown at the end of the cross-slide in Fig. 10. The reversing is accomplished through friction clutches, and, in order to prevent the throwing in of the fast traverse and the feed mechanism at the same time, a special safety device is provided. The motor for operating the cross-rail is placed at the top of the right-hand upright, as shown in Figs. 1 and 10. This motor is connected at all times to the elevating screws, and is started, stopped, and reversed from the switchboard. The elevating screws for the cross-rail are firmly held at the top and bottom, and the cross-rail nuts are placed in square pockets against shoulders. It is expected that this will take care, satisfactorily, of the thrust of the slotter bars when in operation, but provisions have been made so that the cross rail can be firmly clamped to the uprights in case any trouble from loosening should be experienced.

FORMULAS FOR CIRCULAR FORMING TOOLS.

When laying out circular forming tools, such as shown in Fig. 1, the cutting edge, as is well known, must be located a certain amount below the horizontal center line of the tool, in order to provide for sufficient clearance for the cut. On account of this, the actual differences of diameters in the piece of work to be formed cannot be directly copied in the forming tool. The distance A in the piece to be formed must

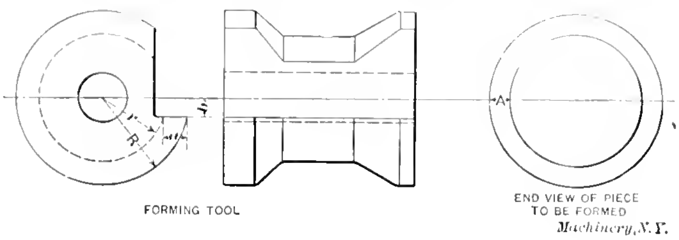

Fig. 1.

equal the distance a on the forming tool, but as this latter distance is measured in a plane a certain distance b below the horizontal plane through the center of the forming tool, it is evident that the differences of diameters in the tool and the piece to be formed are not the same. A general formula may, however, be deduced by use of elementary geometry by means of which various diameters of the forming tool may be determined if the largest (or smallest) diameter of the tool is known, the amount that the cutting edge is below the center, and, of course, the diameters of the piece to be formed.

If R = the largest radius of the tool,

a = difference in radii of steps, and

b = amount cutting edge is below center,

then, if r be the radius looked for,

$$r = \sqrt{(\sqrt{R^2 - b^2} - a)^2 + b^2}$$

If the smaller radius r is given and the larger radius R sought, the formula takes the form:

$$R = \sqrt{(\sqrt{r^2 - b^2} + a)^2 + b^2}$$

Suppose, for an example, that a tool is to be made to form the piece in Fig. 2. Assume that the largest diameter of the tool is to be 3 inches, and that the cutting edge is to be ¼ inch below the center of the tool. Then the diameter next smaller to 3 inches is found from the formulas given by inserting the given values: $R = 1\frac{1}{2}$ inch, $b = \frac{1}{4}$ inch, and $a = \frac{1}{4}$ inch (half the difference between 4 and $3\frac{1}{2}$ inches; see Fig. 2).

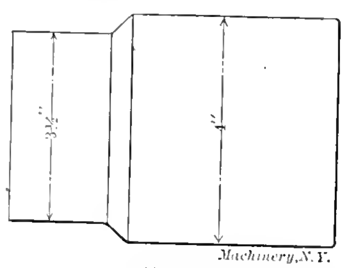

Fig. 2.

Then

$$r = \sqrt{(\sqrt{(1\tfrac{1}{2})^2 - (\tfrac{1}{4})^2} - \tfrac{1}{4})^2 + (\tfrac{1}{4})^2} = \sqrt{(\sqrt{\tfrac{35}{16}} - \tfrac{1}{4})^2 + \tfrac{1}{16}} = \frac{5.017}{4}$$

$= 1.254$ inch.

While the formula looks complicated, by means of a table of squares the calculations are easily simplified and can be carried out in three or four minutes. The value r being 1.254 inch, the diameter to make the smaller step of the forming tool will be 2.508 inches, instead of $2\frac{1}{2}$ inches exact, as would have been the case if the cutting edge had been on the center line.

* * *

The usual plan followed in making punches and dies is to harden the die, leaving the punch soft. The punch is generally finished to exact shape and size by shearing it into the die. An alternative practice which is advocated by some die-makers for such work as armature laminations, is to make the punch hard and the die soft, it being argued that the wear of the soft part, which then is the die, does not tend to raise a burr on the punchings. When the punch is left soft it leaves a burr on the work as it wears, which is very objectionable in the case of armature laminations. If the die is made soft it is not necessary to frequently peen the punch and shear it into the die to overcome the burring referred to.

THE ELASTIC LIMIT AND THE TESTING OF MATERIALS.

H. GANSSLEN.*

The following article is intended to explain in a popular way a subject on which manufacturers, mechanics, and others interested purely in what is called the practical side of the machinery business, judging from my experience, are greatly in need of some definite information. It is not meant to contain any information for specialists on testing materials, although even the specialist may find some valuable data in it, as the diagrams and the figures given are the results of actual tests made by the writer when in charge of the testing department of the E. W. Bliss Co., of Brooklyn, N. Y., and also while assistant to Prof. Bach, the well-known German authority on testing and strength of materials.

The term "elastic limit" has lately become quite popular around the factories and in the sales offices, but I have met very few people who have a clear idea of what the term really means, and of what practical use its application is. I cannot help but cite a case illustrating this lack of familiarity with the subject, even among people who ought to know. A few years ago I made some commercial tests of a special high-grade steel in the presence of the representatives of the two contracting parties and of the maker of the testing machine. The latter was asked by a venerable looking official: "What is elastic limit, anyhow?" After he got half through with what promised to be a fairly good definition of the term, the old gentleman interrupted him with: "You may be all right, but I don't know what you are talking about." There was a complete silence, and I doubt whether anyone present at that time knows any more about that mysterious thing, elastic limit, to-day than they knew then.

Method of Testing Materials.

By means of the following diagrams, the writer will try to illustrate what happens to a round test bar of steel under a load *P*, this load starting at zero and increasing by the bars

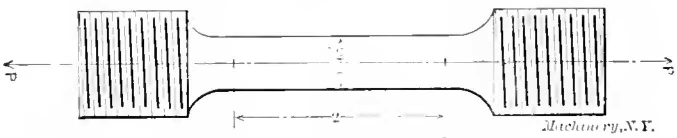

Fig. 1. Piece to be tested.

being stretched with a uniform speed of the machine, say 3/16 inch per minute, until the bar breaks. Fig. 1 shows the shape and dimensions of a bar which is, incidentally, the same as prescribed by the United States Government for certain purposes. The threads on both ends fit the two chucks on a testing machine, the upper one of which is stationary and a part of the machine frame, while the lower one is part of a cross-head moved by gears and screws which exert a tension on the test bar. Besides these parts, the machine consists of a system of levers, similar to the ones on scales, enabling the operator to see the load at any time. The diameter, 0.505 inch, of the test bar gives the latter a sectional area of 1/5 square inch, over which the total load is assumed to be equally distributed. The load on any test bar is, for the sake of comparison, usually expressed in pounds per square inch of its area, and is then called a unit-load. The resistance of the material is, of course, the same as the external force or load. A unit load of 1,000 pounds (external) causes a unit-stress of 1,000 pounds (internal), which holds the equilibrium. A thousand pound load on our test bar, for instance, would, therefore, cause $5 \times 1,000 = 5,000$ pounds unit-stress. After putting a load of 1,000 pounds on the bar, the length under observation, which was originally 2 inches, will then undoubtedly be greater, say 2.0003 inches. The quantity 0.0003 inch is called the elongation at the load of 1,000 pounds. This elongation for 1-inch length would be $0.0003 \div 2 = 0.00015$ inch, and this we call unit-elongation. It is generally assumed that all parts of the 2 inches of the bar under observation take an equal share in this elongation, or, in other words, the elongation is supposed to be equally distributed over the entire length. Elongations are measured with very fine instruments, extensometers, which are working either on optical or mechanical principles. It is a fundamental law that every stress should be accompanied by a deformation, however small it may be, and whatever material we may test, whether steel, iron, copper, brass, stone, concrete, wood, glass, etc., this holds true, but the amount of the deformation of these materials differs very much under the same stresses.

Fig. 2 shows a diagram giving the unit-stresses and the respective unit-elongations of a piece of high-grade steel of

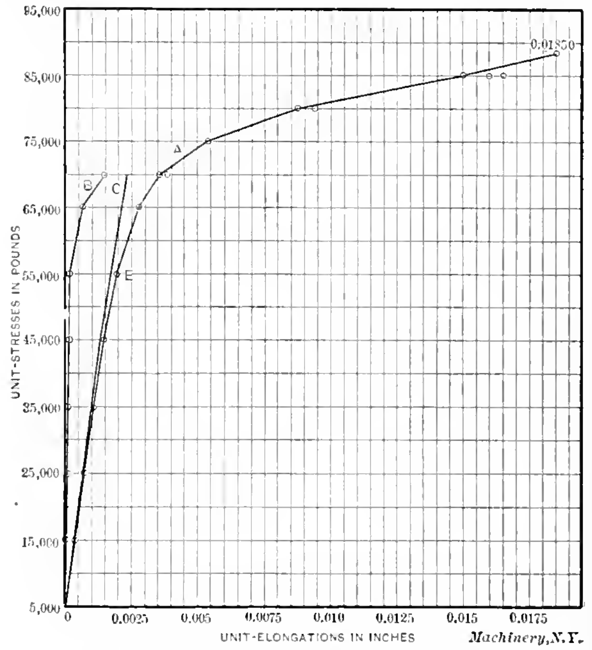

Fig. 2. Diagram of First Part of Test.

the dimensions given in Fig. 1, which I tested some time ago. Curve *A* gives the *total unit-elongation*, as per the accompanying table, *B* the *permanent sets*, and *C* is the curve of the *elastic unit-elongations*, which was arrived at by deducting *B* from *A*. The table gives also the actual record of the test, the load, as indicated on the beam of the testing machine and the corresponding extensometer readings. As seen from the table, a small initial unit-load of 5,000 pounds per square inch was put on the bar, to have all the parts of the testing machine and extensometer in tension. After gradually increasing the unit load to 45,000 pounds, there was a total unit-elongation of 0.00145 inch. At this point the load was reduced to the initial one, and there was noticeable a slight permanent set of 0.00015 inch. The difference of 0.00145 and 0.00015, equaling 0.00130 inch, is called the elastic unit-elongation, as it disappears completely after taking the

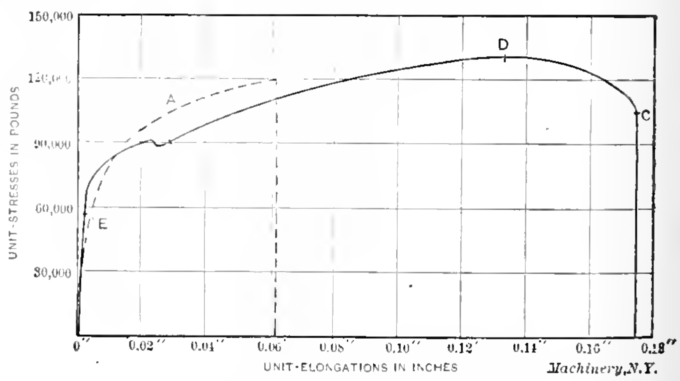

Fig. 3. Diagram of Complete Test.

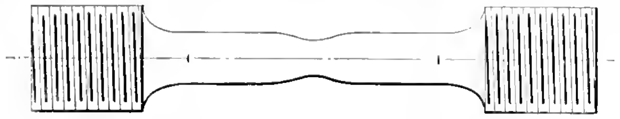
load off. The permanent set at that point and up as far as 55,000 pounds unit-stress (point *E*, Fig. 2), is so small as to be almost negligible. It is due to some extent to the natural error in reading the instrument. Above point *E* the curves of the total and permanent elongations deviate from the hitherto straight line, *i. e.*, the permanent set of the material becomes now more marked. The stress 55,000 pounds is therefore called the *elastic limit* of this particular material, as any higher stress leaves a set in the material after releasing it, or, in other words, stretches the material beyond its elasticity. This test was continued up to a stress of

* Address: 135 Adams St., Chicago, Ill.

70,000 pounds, and then the bar was unloaded down to the initial 5,000 pounds per square inch; the permanent set at that point was found to be 0.0029 inch. Above 70,000 pounds stress the total elongations only were measured, as the elastic elongations are of no further practical value, the material being stretched beyond the range which is of importance for commercial engineering purposes. In Fig. 3 are, however, given the diagrams up to the point of fracture, from which we are still very far away. The material beyond point E goes into a "flowing" state, as small increases in the load produce now much larger elongations than was the case below E. Furthermore, the bar stretches without



Machinery,N.Y.

Fig. 4. Test Bar after having reached the Ultimate Limit of Strength.

increasing the load, as shown by the figures in the table, and also in Fig. 2, at 80,000 and 85,000 pounds stress. Time now becomes a factor. The different elongations given for each of the two loads were recorded within small fractions of a minute. At 88,500 pounds stress per square inch the extensometer was removed, as it had reached the limit of its capacity, and because the elongations could now be measured near enough for the purpose with a pair of dividers. A stress of 93,000 pounds brings us to the most remarkable point of the whole test. The material, without any outward signs visible to the naked eye, seems to utterly collapse; it stretches from

RECORD OF TEST ON STEEL BAR.

Load in pounds.	Stresses, Pounds per square inch.	Elongations, inch.	Unit Elongations, inch.
1,000	5,000	0	0
3,000	15,000	0.0007	0.00035

17,000	85,000	0.0320	0.01600
17,000	85,000	0.0330	0.01650
17,000	85,000	0.0370	0.01850

0.023 inch to 0.032 inch per inch length, and the load which the bar was able to stand in the meantime dropped down to 90,000 pounds, until it reached 93,000 pounds again at 0.032 inch elongation. The stresses 93,000 and 90,000 pounds per square inch are called the *upper* and *lower yield-points*, respectively. In practical life they are frequently, but wrongly, called elastic limit. After this stage the material revives again, and the load can be materially increased, the elongations becoming greater and greater for the same increments in load. The maximum load this particular test bar stood was 131,500 pounds per square inch. This is called the *ultimate strength* of this material. After this point was

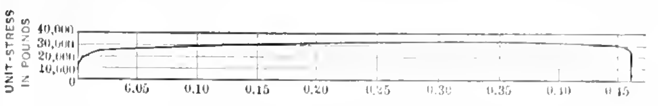

Fig. 5. Diagram of Test on Copper.

passed, the test bar was getting thinner at one point, it contracted more and more, and the load which the material stood became smaller and smaller, as the descending part of the curve, Fig. 3, shows, until the bar broke at point C. Fig. 4 shows the test bar after point D, Fig. 3, was passed, *i. e.*, after the local contraction became plainly visible. The elongation in 2-inch length, measured after the fracture, was 0.354-inch, or $\frac{0.354}{2} \times 100 = 17.7$ per cent. The smallest diameter at the place of contraction measured after the fracture was 0.380 inch, which gives a reduction of area, or contraction, of 43.4 per cent.

By planimetering the area of the diagram, Fig. 3, it is possible to find the work in foot-pounds necessary to tear the material apart. This is sometimes called *resilience*. The amount of work necessary to stretch the bar up to its elastic limit is called the *elastic resilience*, and it can be reclaimed. It is not intended here to further consider this subject, except to show by curve A, in Fig. 3, how little work it took to break a similar piece of steel heat treated in a different way. The test piece has almost the same tensile strength (120,000 pounds per square inch) but only 6.3 per cent elongation and 14.4 per cent contraction. One shock will lead to its fracture, where it would require several shocks of the same kind to break the material described above. The ultimate strength of a material alone is, therefore, no criterion as to its fitness for any particular purpose. It will be noticed from the diagram that there is no yield-point perceptible in this material.

It may be in place here to also explain in a few words a term which is often used—coefficient of elasticity. At 55,000 pounds stress (Fig. 2) there is an elastic unit elongation of 0.0018 inch. The coefficient of elasticity is, therefore $\frac{0.0018}{55,000} = \frac{1}{30,500,000}$. The modulus of elasticity is the value 30,500,000. The coefficient of elasticity is nothing else than the elastic unit-elongation per one pound stress. It is a measure of the

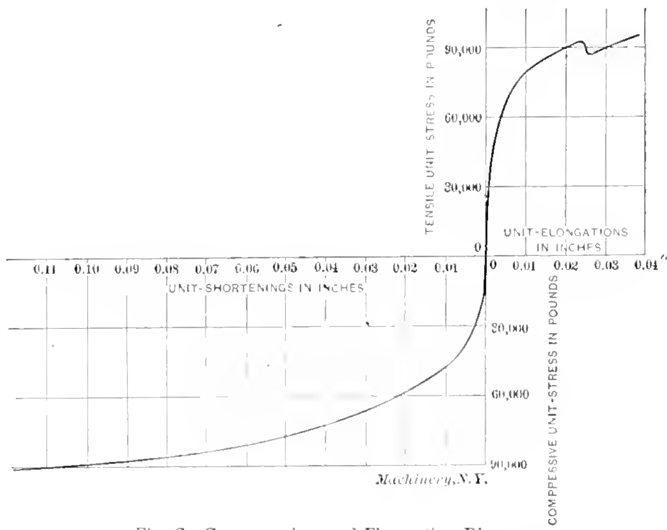

Fig. 6. Compression and Elongation Diagram.

elasticity of various materials. Leather, for instance, is very elastic, wood is less so, and steel still less elastic, their coefficients of elasticity being respectively about

$$\frac{1}{18,000},\ \frac{1}{1,300,000},\ \text{and}\ \frac{1}{30,000,000},$$

the largest coefficient referring to the most elastic material, and *vice versa*. The *degree of elasticity* is something different from the measure of elasticity. It refers to the elastic elongation in proportion to the total one of the same material at the same load; the steel in Fig. 2 at 55,000 pounds stress, for instance, would show this ratio to be $\frac{0.0018}{0.0019} = 0.95$. The nearer this ratio comes to 1 the more perfect the elasticity is, or, in other words, any material showing no set at a certain load, after same is removed, is called perfectly elastic at that load.

Concluding Remarks.

As to the practical application of the term elastic limit, the buyer of materials, especially of steel with a specified elastic limit, should realize that it is very necessary to state what he means by elastic limit, it having become rather customary to use the term wrongly in place of yield-point. It is possible to obtain steel for about 3½ cents per pound, which will, if properly treated, have a yield-point of probably 90,000 pounds per square inch, besides having quite an appreciable elongation, say, 15 per cent. The buyer might, how-

ever, be very disappointed if he would try to treat it so as to obtain an actual elastic limit of 90,000 pounds per square inch, the term this time being used in its correct meaning as given in the above definition, which is generally accepted by engineers. Another factor which makes the word elastic limit a rather uncertain and vague term, is the speed at which the test bar is being stretched during the test. For the test piece shown in Fig. 1, the United States Government in certain specifications requires a speed of the testing machine, that is, an elongation of the test bar, of from ½ inch to 3 inches per minute. Aside from the large margin it leaves the operator of the machine, even the smallest of specified speeds appears much too large for such a short test bar, especially where high-grade steel is used, inasmuch as the load comes on very suddenly, almost like a shock. Under such conditions it takes a very skilled operator to determine the yield-point with any degree of accuracy. The yield-point, as well as the ultimate strength, is greater under such high speed than under slower ones. This difference has been found to amount to as much as 15 per cent. (See C. Bach, Elasticität und Festigkeit, 1898, page 129.) Government inspectors are very strict, as they ought to be, with regard to the margin below and above the elastic limit required. It seems to be an urgent necessity to introduce proper rules regarding the speed of tests, and to the writer it appears that a certain maximum increment of stress per minute for each class of material would be a better way of putting it than the one mentioned above, as this would eliminate the proportions of different test bars.

Fig. 5 shows a diagram of a test of copper under tension, having no yield-point at all; the same applies to the particular steel shown in curve *A*, Fig. 3. Not all materials possess a yield-point. As a criterion as to what stress we should then allow on any part of a machine or structure, we will have to use the curve of the total elongations and permanent sets. For special purposes, as for instance, embossing press work, we are only interested in the curve of the permanent sets of the material to be embossed. Without going further into this subject at this time, there is shown, in Fig. 6, a curve of the permanent sets of a Bessemer steel cylinder under compression (Transactions of A. S. M. E., 1906) as compared with the steel in Figs. 2 and 3 under tension. Whereas, the yield-point of the tension curve is plainly marked, it hardly is marked at all in the compression curve. There we might consider it as being at from 50,000 to 60,000 pounds per square inch, and the material's range of usefulness for embossing lies above these points, below which its applicability for ordinary engineering purposes has already ceased.

* * *

It is less than a decade ago since the first turbine was sold in the American market, but there are to-day about 700 in use throughout the country, aggregating a total capacity of approximately 1,000,000 kilowatts or about 1,350,000 horse-power. This great demand for a new prime mover is, of course, easily explained by the advantages the turbine has over the reciprocating steam engine. An interesting test was conducted recently by the engineers of the New York Edison Company at the Waterside Station near 30th Street, which developed facts hitherto unattained by any steam prime mover in this country. The unit under test was a Westinghouse turbine of 10,000 horse-power capacity. It had been sold under a steam consumption guarantee of 15.9 pounds of steam per kilowatt hour, but the test recorded the phenomenally low steam consumption of a shade less than 14.9 pounds per kilowatt hour. (See MACHINERY, November, 1907, engineering edition.) Apart from the fact that this result gained a bonus for the Westinghouse turbine of over $25,000, it is of interest to all users of steam engines as an illustration of the lowest record for steam consumption which has ever been recorded by a stationary steam engine. This steam consumption figures less than 1½ pound of coal per kilowatt hour. It should be mentioned that the steam supply was superheated, which fact, of course, materially reduces the steam consumption without a corresponding reduction in consumption of heat units.

NEW SHOP OF THE MUELLER MACHINE TOOL COMPANY.

Improvements and new buildings have been the order of the day with most machine tool firms during the last two or three years, and we have from time to time recorded some new shop constructions in our columns. In this issue we show two half-tones of the interior appearance, and a number of line cuts of the plan and elevations, of the new shop of The Mueller Machine Tool Co., Cincinnati, Ohio. This shop has been completed during the year just past, and the machinery and equipment has just been installed. The general arrangement of this shop, as well as some of its commendable constructional features, may prove both of interest and of suggestive value to persons who either directly or indirectly may be connected with the planning of new shops or additions to present plants.

The feature which is most strikingly apparent when one examines the two half-tones showing the interior of the shop is the excellent light afforded by the numerous and large windows as well as by the skylights above. To persons acquainted with shop photography, a good idea of the excellence of the light is afforded by the statement that the photographs from which the half-tones shown were reproduced were taken with a 5 seconds exposure, F-16 stop, at 12:15 P. M. The main shop is a one-story building, but the rear portion of the shop is provided with a basement which, in fact, adds another story for half the length of the shop. This basement has the same advantages of good light from the outside as the main floor, on account of the difference of the ground level at the front and rear of the shop, the slope at the rear end amounting to about 12 feet. In this basement all the unfinished stock and other raw materials are stored. The floor is made of concrete, and wide doors are provided from the yard so that a wagon may drive right into the basement for unloading, a traveling crane being provided for facilitating this work. In the basement is also installed a Stewart combination hot blast furnace, and the forging shop is located here. All hardening, case-hardening, etc., also takes place in this portion of the shop.

The floor level of the main shop is three feet above the street level, which makes it very convenient for loading and unloading machines to and from trucks, the wagons or drays being backed into the building at the drive-way shown in the lower part of the plan view, Fig. 3. The opening into the street from this drive-way is provided with steel rolling shutters which can, without much trouble, be closed, and thus, during cold weather, as soon as the team has been backed into the drive-way, the shutters may be closed during the loading and unloading, thereby retaining the heat in the shop. All machine tools are installed on the rear portion of this floor, one side and the middle of the building being almost entirely given up to the machine tools themselves, while the erection and bench work is done on the other side of the building. In the front of the building are the offices, drawing-room and the shop washroom, which latter is provided with individual lockers for the men. A special stock-room for finished material is located behind the drawing-room, or rather, between the drawing-room and the shop. The main entrance to the building opens into a vestibule from which one may enter either the office to the right or the shop directly in front. At the rear of the building the freight elevator is installed for carrying material between the basement and the main floor. The platform of this elevator is 6 feet by 9 feet, and it has a carrying capacity of 5 tons. The stairs leading down to the basement are located immediately beside the elevator. Near the elevator, also at the rear of the building, is shown a steel chute through which all the chips from the machine operations are dropped. The chute leads to a concrete bin outside of the building, in which the chips are stored until disposed of. The building is steam heated, the steam being generated by an "American" low-pressure boiler. All the benches along the wall are three inches from the brick wall, in order to permit the pipes to be carried near the wall and keep the direct radiation of the heat away from the men working at the benches.

Of the general specifications for the shop the following data

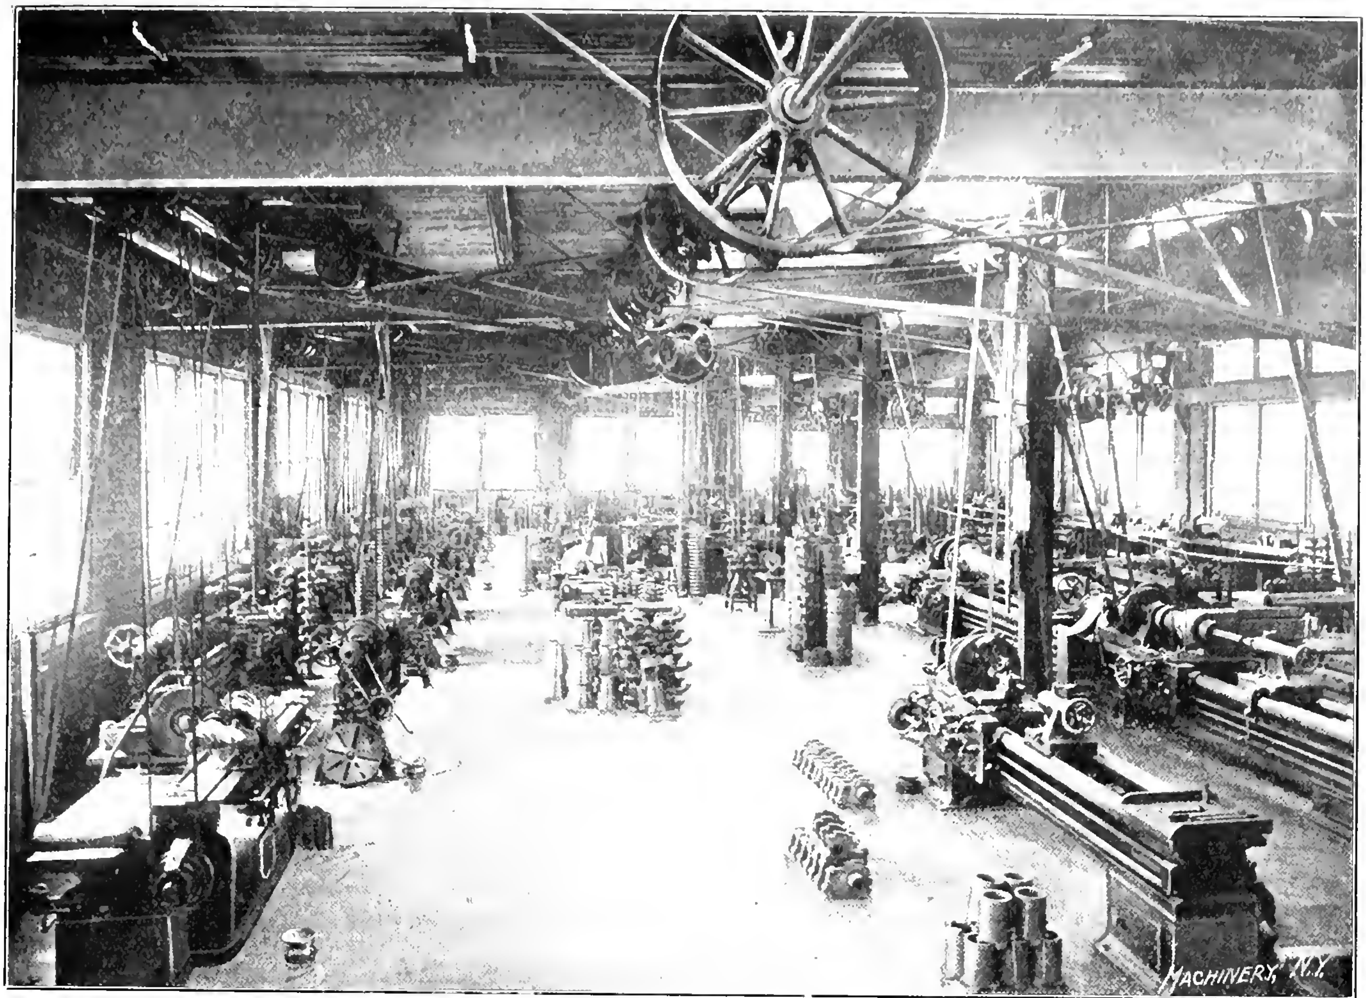

Fig. 1. View of the Machine Tool Department of The Mueller Machine Tool Company.

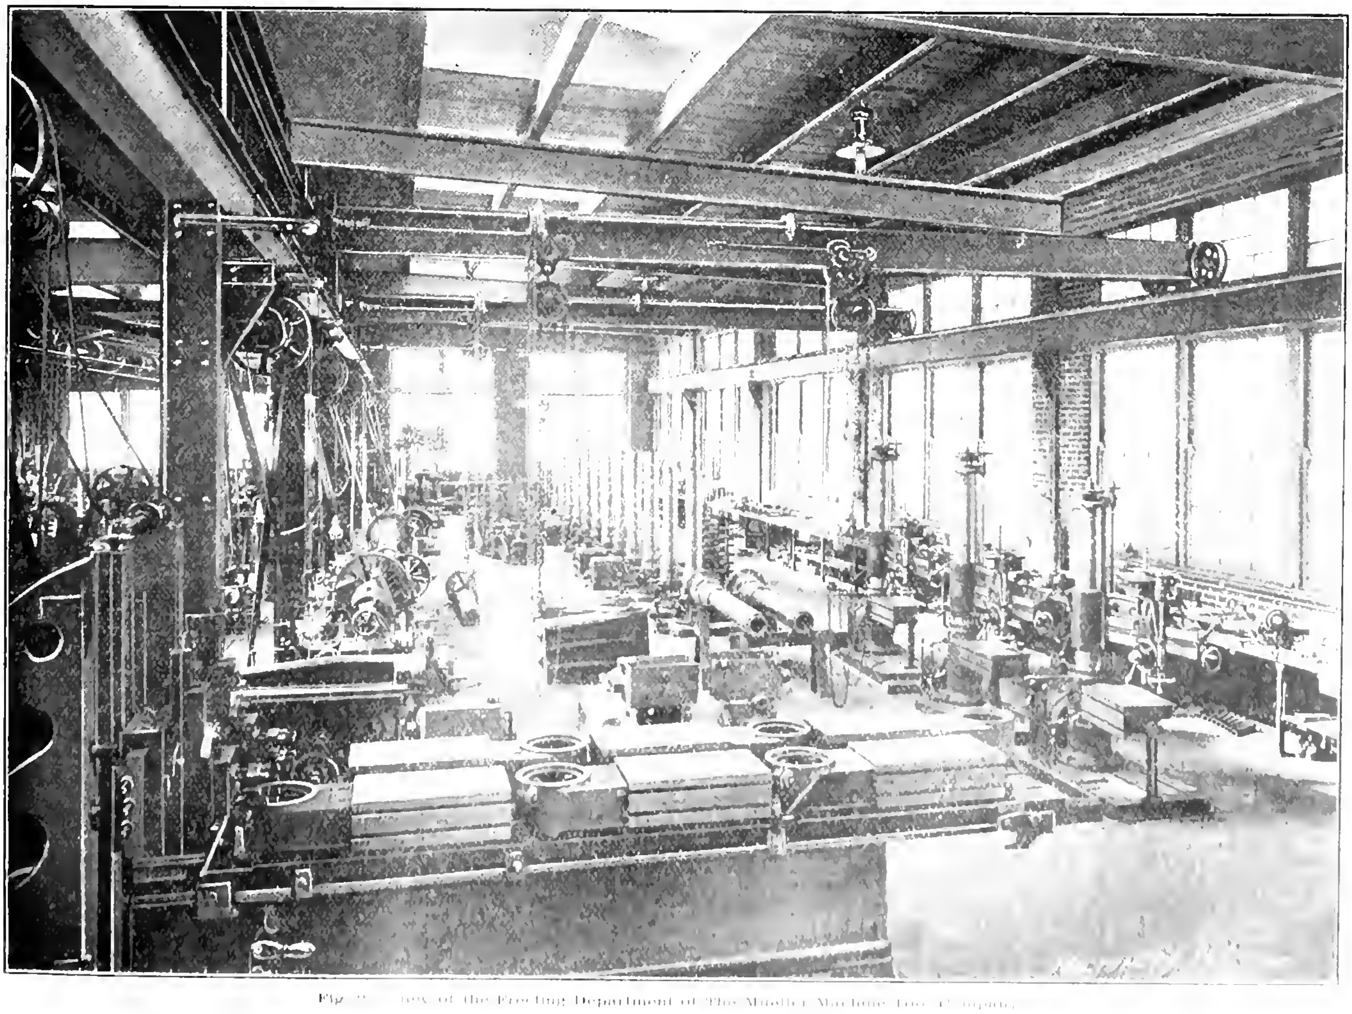

Fig. 2. View of the Erecting Department of The Mueller Machine Tool Company.

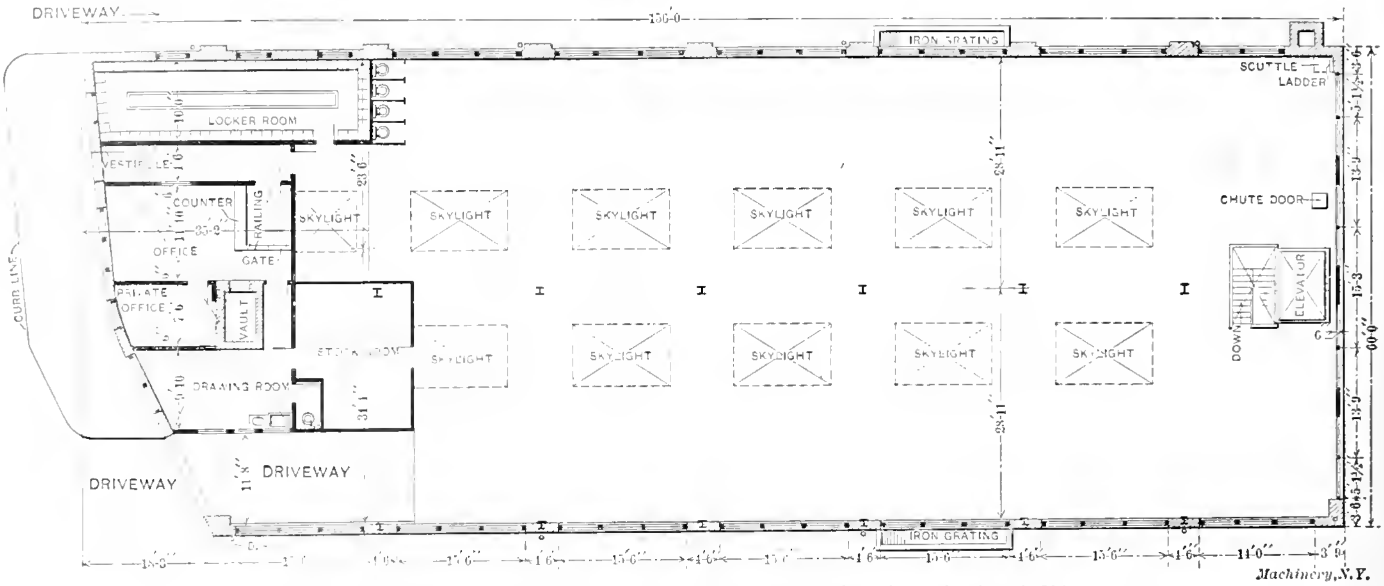

Fig. 3. Plan of the First Floor of The Mueller Machine Tool Co.'s Shop, Cincinnati, Ohio.

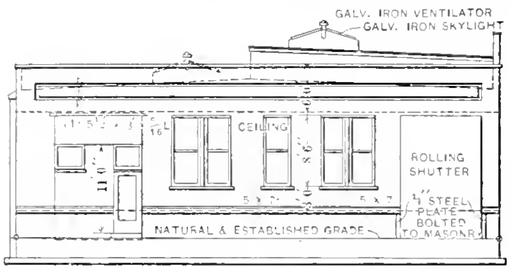

Fig. 4. Front Elevation.

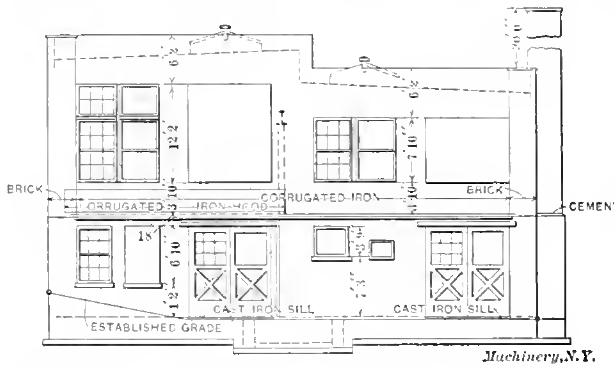

Fig. 5. Rear Elevation.

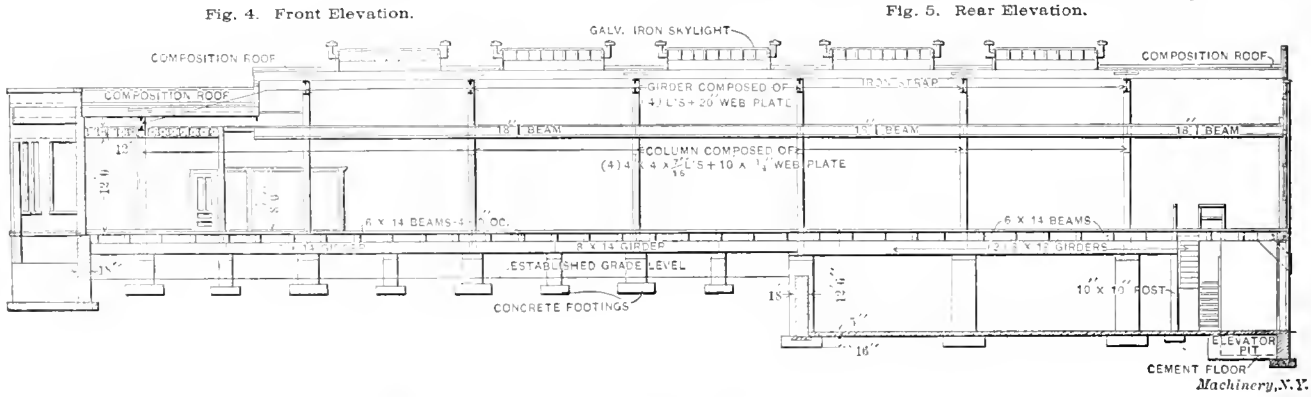

Fig. 6. Longitudinal Section.

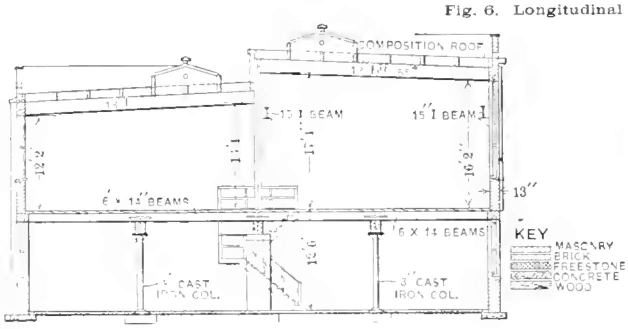

Fig 7. Cross-section through the Shop.

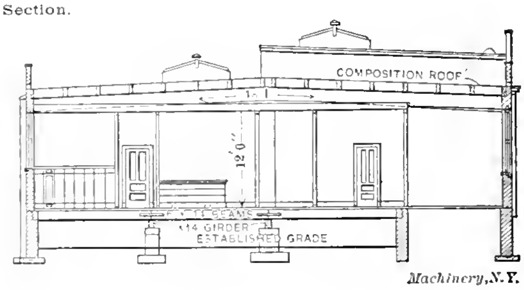

Fig. 8. Cross-section through the Office Partitions.

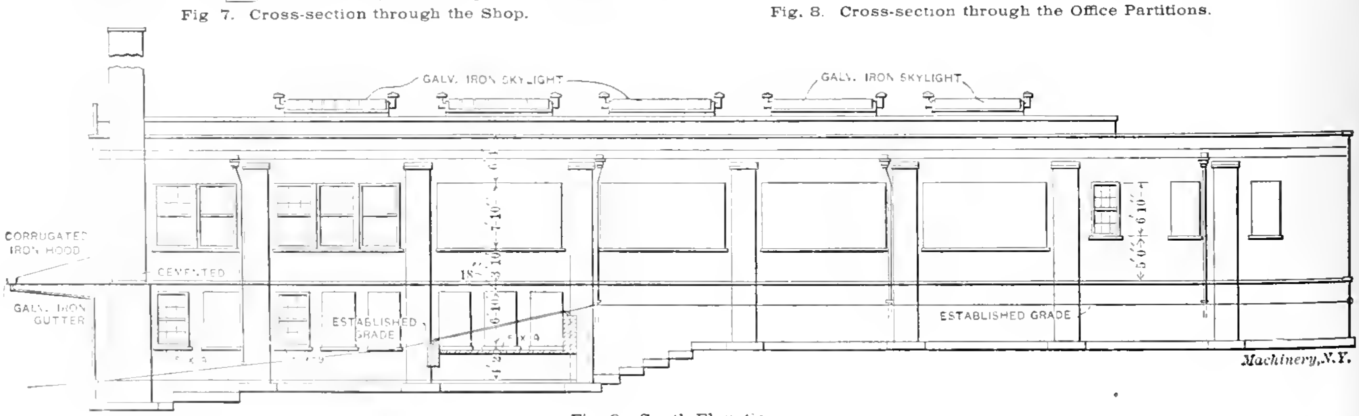

Fig. 9. South Elevation.

may be of interest and of suggestive value. The floor on the upper or main story in the shop is laid diagonally with 2¼-inch tongued-and-grooved pine lumber, and has a top layer, laid diagonally at an opposite angle, of ⅞-inch tongued-and-grooved maple lumber. The steel columns through the center of the building are placed 20 feet apart, and carry 18-inch I-beams which in turn support the roof. The erecting side of the building has a clear height of 16 feet, it being possible to thus obtain a 12-foot lift with the cranes installed, each of which has a capacity of 4 tons. Besides the traveling cranes, there is at the rear wall of the building a 15-foot jib crane, intended to be used by the vise hands when handling parts of machines for assembling, such as heads, arms, tables, etc. The side of the shop, which is exclusively given up to the installation of machine tools, is 12 feet high, this height being the most convenient for the installation of counter-shaft and belting. The skylights, previously mentioned, are ten in number, each measuring 6 feet by 10 feet, projected area. By means of these skylights the middle of the shop is fully as well lighted as are the sides near the windows, and the light over the whole shop is diffused in the most satisfactory manner. The windows all come up close to the ceiling, and those on the north and south sides have transoms for ventilating purposes. Ventilators are also placed one at each end of each skylight.

The line-shaft is motor driven, a Bullock motor and a Renold silent chain constituting the drive. The motor, as will be seen from Fig. 1, is attached to the ceiling, as usual in this kind of installation. The line-shaft is provided with two Dodge clutches, so that sections of the line-shaft can be thrown out if required. All the line-shaft hangers, as well as the counter-shaft hangers, are supported by angle plates bolted directly to the I-beams, thus doing away with all wooden hanger planks. All large machine tools are placed on concrete foundations, while the smaller ones are simply bolted to the floor.

The general construction and equipment of the shop shows care and forethought, everything having been arranged so as to be advantageous for economical manufacturing as well as convenient for the men, and the shop constitutes a good example of moderate sized shop construction adapted to machine tool manufacture.

* * *

HOW A LARGE CASTING WAS PLANED ON A SMALL PLANER.

The photograph for the half-tone cut, Fig. 1, was sent to MACHINERY by Mr. L. T. Wilmarth, of the Wilmarth & Morman Co., Grand Rapids, Mich., to illustrate how a machine frame casting weighing about 1,200 pounds, and of very awkward shape, was planed on a 24 x 24 x 6-foot Woodward & Powell planer. While the method is not new it is of general interest to small shops which frequently are called upon to perform work that is beyond the ordinary capacity of their machine tools.

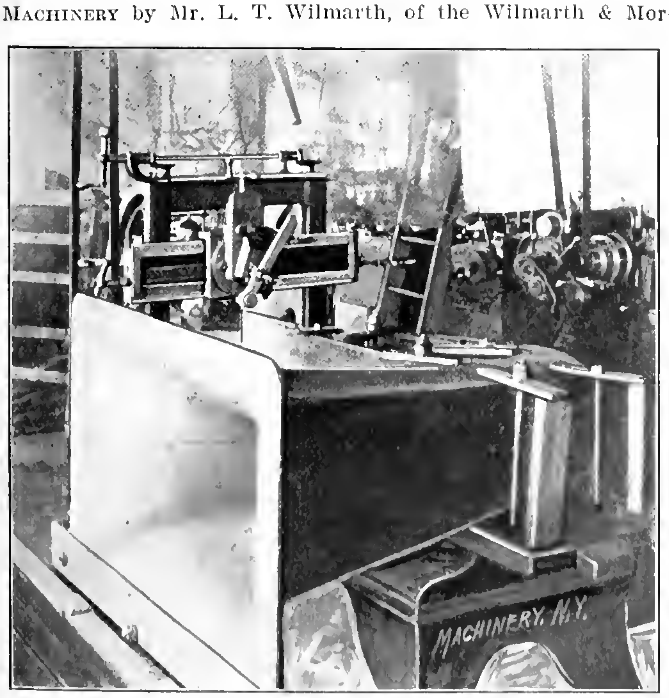

Fig. 1. Method of Planing a Large Casting on a Small Planer.

The surfaces to be planed were the two opposing faces of the jaws indicated by *A* and *B* in Fig. 2, being the upper and lower sides of the projecting arms at the outer ends. The upper surface was 7½ inches long by 14 inches wide, and the lower surface was 9¼ inches long by 14 inches wide. The lengthwise dimensions are in a direction parallel to the direction of the arms. The casting was about 63½ inches long, measured from the end of the lower jaw to the perpendicular through the back edge of the base; the width was 30 inches measured on the base; and the height was approximately 58 inches.

Obviously the casting could not be planed on a 24 x 24-inch planer without allowing the base to over-hang the table. The over-hang was about 3 feet and it was carried on a frame-work partly shown in Fig. 1. Its construction, however, was simple, consisting of three wooden blocks, 12 x 12 x 24 inches, laid on the floor at right angles to the planer bed, on which was placed a 9 x 12-inch x 12-foot timber lengthwise with the planer. This timber was strongly braced sideways to hold it in place, the braces being spiked to the timber and to the floor. A flat iron runway or track was screwed on top of the long timber and upon this track were placed two 2-inch rolls. On account of the unevenness and irregularity of the base, it was necessary to provide a straight-edge bearing for the casting which could be made parallel with the planer ways. This was made with two pieces of flat iron ½ x 4 inches x 4 feet long bolted or clamped to the lower edge of the base.

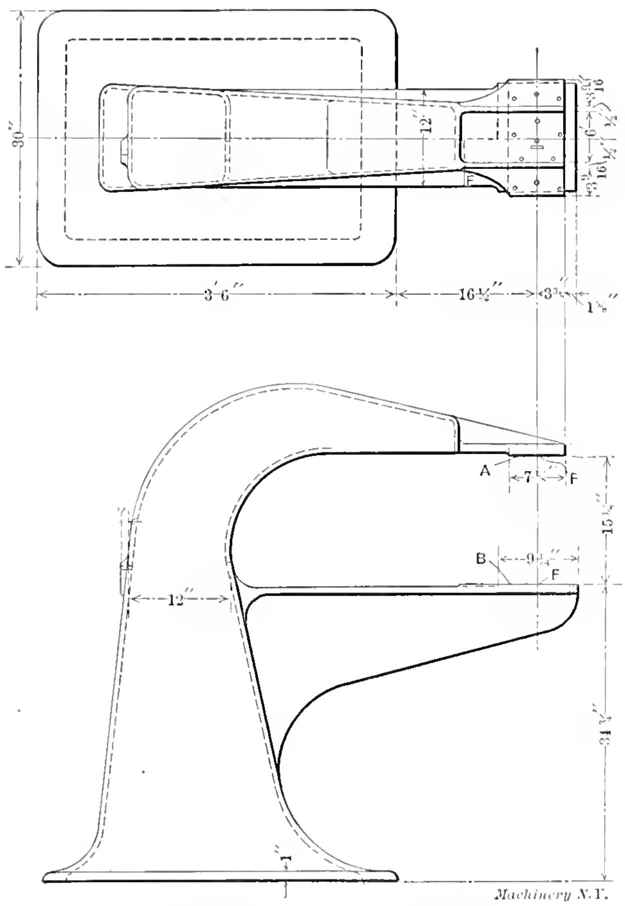

Fig. 2. Elevation and Plan of the Casting.

The time required for getting the outfit together and assembled, and the planing of the first casting was 28 hours; the time required for the second casting was 18 hours, but before the job of 20 castings was completed, the time was reduced to about 12 hours each.

* * *

At the end of 1906 the electric railways in the United States aggregated 36,212 miles. The equipment included 66,206 electric motor cars. Canada had at the same time 1,073 miles of electric railway.

MILLING OPERATIONS ON VISE PARTS.

JOHN EDGAR.*

Most of us are familiar with the flat machine vise, and we put a great deal of dependence upon its being square for the quality and accuracy of a great deal of our machine work, especially that done on the milling machine. The base must be parallel and square with the platen of the machine. The jaws must stand perpendicular with the top of the table, and lie at right angles to, or parallel with, the direction of the feed when the vise is tongued to the table. In order to fulfill all these conditions, and yet have the price of the vise reasonable, considerable planning must be done. The job of machining the parts that require the greatest accuracy is usually done on the planer. These parts are—the base, the slide, and the jaws.

The illustrations that accompany this article show how the different phases of machining these parts are done on the milling machine, and they represent the practice of a New England concern. The vises are manufactured in lots of from one hundred to three hundred. Little rigging up was necessary, and, outside of the cutters, the work called for but little

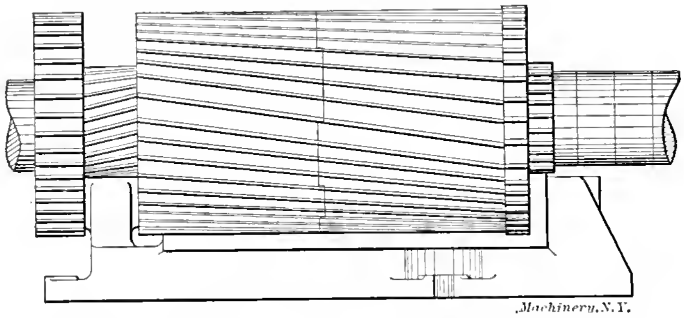

Fig. 1 Rough milling the Top of Base, Jaw Top, Jaw Backing and Screw Bosses with Gang Cutter.

extra expense for equipment. The form of the pieces is such that they are easily held on the naked platen by ordinary means—clamps and bolts. With three exceptions, no fixtures were used. The cutter gangs were for the most part made up from cutters on hand, as in but few of the operations were special gangs necessary. Had the several operations been carried on for a larger number, or for smaller lots, more frequently the case would have been different and special gangs would have been necessary. Of course, in work of this kind, the use of special gangs set up on an arbor for each gang eliminates the necessity of making up a gang and grinding same for the job to be done. However, under the circumstances, the results were, and still are, very satisfactory.

First Operation—Milling the Top of Base, Jaw Top, Jaw Backing and Screw Bosses.

The first operation on the base is shown in Fig. 1. For this, a special gang of cutters was used, as the relation of the sev-

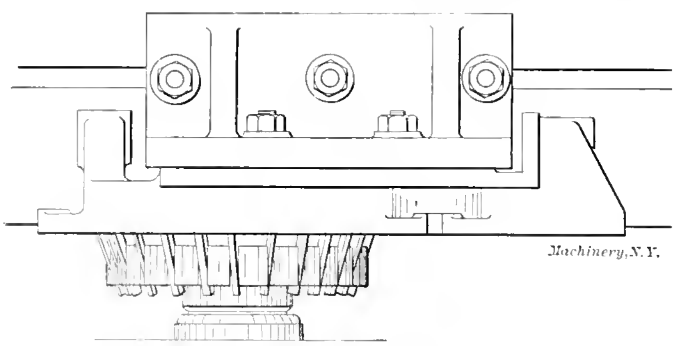

Fig. 2. Roughing Under Side of Base.

eral cutters in the gang made it necessary. This operation is that of roughing off the top of the base, the front jaw, "backing," and the bosses for the screw support. The base casting has a spot on the top of the screw support lug that is machined off so that it comes level with the top of the front jaw backing. The object of having it so is to furnish a bearing on which to rest the base when machining the bottom. The large slabbing cutter in the center of the gang is made interlocking so that the proper distance over all may be preserved. One end of this cutter is made with side teeth for milling the boss. The front jaw backing is milled by a side milling cutter made a trifle larger than the large cutter that lies alongside of it, so that a trough the width of the cutter is cut across the top of the base. The excess in diame-

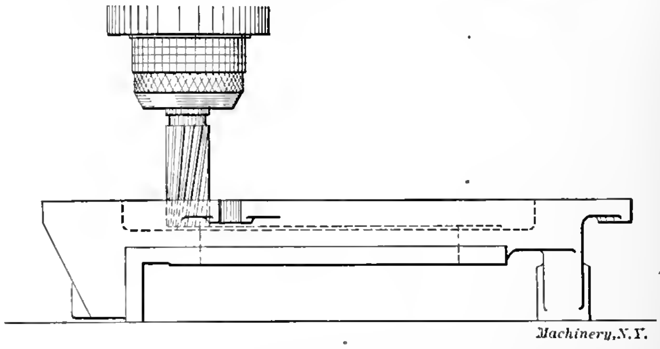

Fig. 3. Milling Under Strap Strips with End Mill, using Vertical Spindle Machine.

ter of the narrow cutter over the other is small, being about 1/32 inch. The reason for this narrow trough will be explained later on.

This operation was done on a heavy slabbing machine, and, while it was supposed to be a roughing cut, care was taken to have the finish fairly good, as the only surface re-milled was the top of the base. The pieces were strung on the platen, which was eight feet long, and were clamped as is ordinarily done on a planer. The feed was about three inches a minute, using high-speed cutters. The chip was light, only enough stock being left on the pattern to insure the removal of all the scale.

Second Operation—Roughing Under Side of Base.

The second operation was the machining of the under side of the base. This was accomplished on a horizontal milling machine, as shown in Fig. 2. The piece was held against an angle-iron bolted to the table. The reason for using the large inserted tooth cutter is that such a cutter will remove a greater amount of stock for the same expenditure of power, and will not strain the machine or holding devices so much as would a slabbing cutter. The face mill does not heat the work to the extent that a slabbing cutter does. The feed can

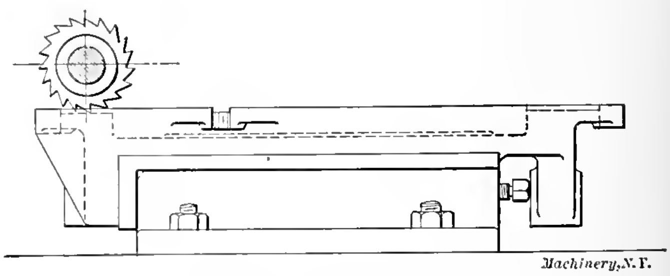

Fig. 4. "Tongueing" the Base.

be forced much faster than with the plain cutter, and the surface will not show the effects of such forcing. In all, a much better surface can be obtained with a mill of this kind on a broad surface than with the slabbing cutter. The feed, in this case, was forced to seven inches a minute, and the surface produced was all that could be desired. The feed was then dropped to five inches per minute, in order to save the cutter from repeated grindings. The bottom surface of the pattern for this piece is cut out considerably in the center, which, of course, counts for considerable in time of milling the resulting castings.

Third Operation—Milling Under Strap Strips with End Mill.

For the next operation we find ourselves among the vertical millers. Here we have the base turned bottom upward, and an end mill machining the strips for the binder straps to ride on. There are two of these strips, one on each side of the center line. Each strip has a slot running nearly its full length, through which the screws pass. The advantage of the vertical milling machine on this operation is apparent. The cut is in full view, and the ease with which the cutter can be dropped in to the proper depth is easily imagined. This

* Address: 7 Webster St., Hyde Park, Mass.

is the class of work for which the vertical spindle machine is peculiarly adapted. The proper depth for each piece is obtained by means of a gage block which is set under the micrometer "set" screw on the side of the head. The screw is then adjusted until the cutter just touches the bottom of the base. The block is then removed, and the head is lowered until the screw strikes the shelf.

The milling cutter is as small in diameter and as short as is convenient, so that a high speed and a fine "quick" feed may be obtained, leaving a surface tnat is easily scraped. In

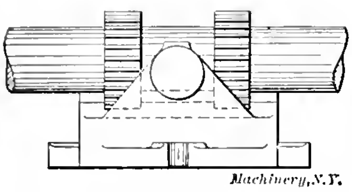

Fig. 5. Milling the Slots for the Movable Jaw.

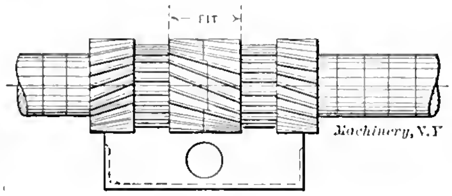

Fig. 8. Milling the Bottom Surface of the Slide and forming the Grooves.

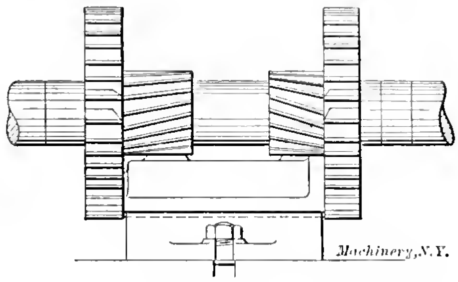

Fig. 9. Milling the Top of the Sliding Block.

this position, we use the spot spoken of in the early part of the article. The casting is clamped to the table by ordinary clamps and bolts.

Fourth Operation—Milling the Tongue Slots.

We now come to an operation, shown in Fig. 4, that requires a little care. This operation is milling the tongue slots—the most important feature of the flat vise, because should they be out of line or out of square the vise cannot be used with satisfactory results. The slots lengthwise of the base must be square with the front jaw, and the slots across the base

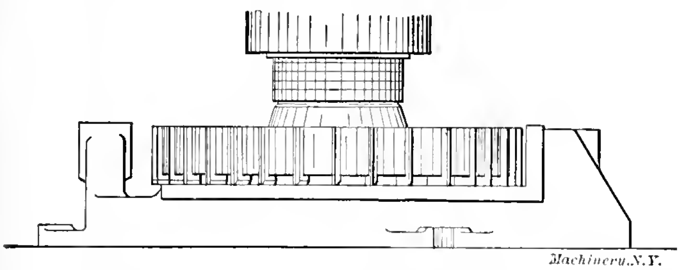

Fig. 6. Finishing the Top of the Base for the Movable Jaw.

must be parallel with that jaw and, of course, at right angles with the other slots. To procure good results in this case, the casting is set bottom up on a specially adapted block which is made perfectly square with the direction of the feed and parallel at one end with the axis of the cutter arbor. The top of the block, of course, must be parallel with the top of the table. The block is fitted with a set-screw which is brought to bear against the boss on the screw support lug, thus forcing the vise base home against the lining surface of the block. The casting is clamped to the block by means of

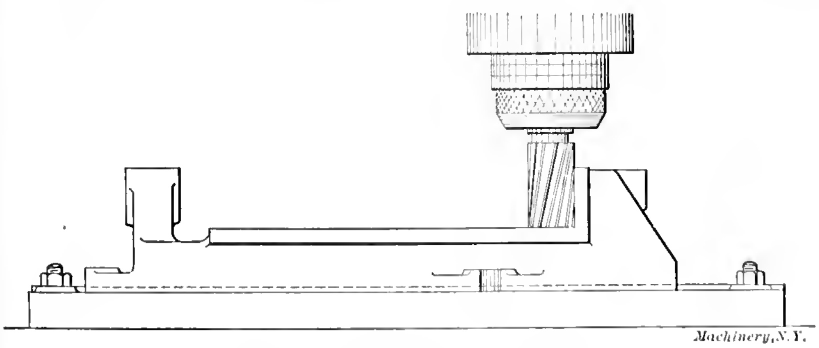

Fig. 7. Finishing the Jaw Backing Surface.

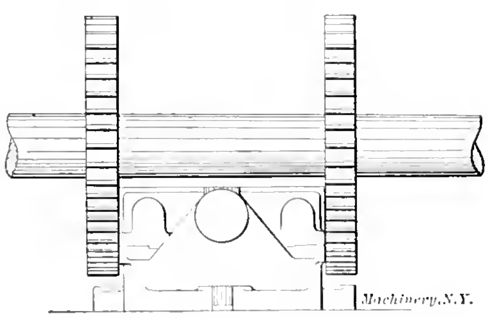

Fig. 10. Finishing the Sides of Base and Movable Jaw.

tap bolts through the slots in the casting and tapped into the block. A similar block is used to mill the cross slot, the only difference being in the location of the tongue.

The cutter used to slot the casting in this operation is a plain cutter with outside teeth. The slot is narrow, and, with the cutter properly hardened, little trouble is experienced from the corners of the teeth wearing excessively or breaking. A side milling cutter under such conditions would be under size after the first grinding. The cutter is made small in diameter, and is run at a correspondingly high speed, making it possible to obtain a good reasonable rate of speed, and still not overdo the matter.

Fifth Operation—Milling the Slots for the Movable Jaw.

The next operation, shown in Fig. 5, is also one that requires care, and on it depends the accuracy of alignment of the sliding jaw with the front jaw. This operation is that of milling the slots in the top of the base for guiding the slide. In order to reduce the labor, the guides are made to fit on the inner side of each slot only, and a clearance is left on the outer side. The work, in this case, is clamped to the table, using tongues in the table slots to line it up. The base thus rests in a natural position, and the accuracy of alignment of the machine is the only feature upon which we place any dependence. Naturally the machine used for this work is previously tested for error. The statements regarding the cutters, in the last operation, apply with equal force here.

Sixth Operation—Finishing the Top of the Base for the Movable Jaw.

The work is again placed on the vertical milling machine, and, with a large inserted tooth face milling cutter, the top of the base is given the final cut. The operation is shown in Fig. 6. The cutter used in this operation is kept in good condition, exclusively for this work; it runs very true. The speed and feed of the cutter in this operation are rather above and below—respectively—that which would be considered correct for ordinary work, surface and finish being the main object of this cut. The teeth of the cutter are broad, and the clearance is small, insuring a smooth cut. This operation takes out any twist that may have been caused by releasing the scalė on the bottom. For that reason the operation was delayed until this time.

It was for convenience in this operation that the trough was milled across the top of the base, as explained in connection with the first operation. The large face mill is set to depth so that it just scrapes the bottom of this trough, and also so as to clear the jaw backing as shown. It is obvious that should any attempt be made to mill both surfaces by a single operation, poor results would be obtained. The strain would cause chattering. By the method described, the top is milled independent of the vertical surface, and yet no corner is left that the milling cutter passes over. It also avoids the obvious difficulty of making a large cutter, screwed onto the spindle nose, run perfectly true on its periphery.

Seventh Operation—Finishing the Jaw Backing Surface.

More as a precaution than as a necessity, the operation shown in Fig. 7 is taken. The object is to straighten up the backing for the front jaw, and also to insure its being square

with the tongues, but here, again, we have to depend on the alignment of the machine. Probably it would be as well to omit this operation, for, when all conditions are looked into, the risk of throwing already accurate work out of square is great.

Eighth Operation—Milling the Bottom Surface of the Slide and Forming the Groove.

The operation of milling the bottom surface of the slide is shown in Fig. 8. This operation forms the tongues that fit the slots formed as shown in Fig. 5. The fit mentioned in dealing with that operation is indicated in Fig. 8. The cutters used in this operation are a special gang kept for the purpose. The block is clamped to the table by ordinary means.

Ninth Operation—Milling the Top of the Sliding Block.

The operation of milling the top of the sliding block is shown in Fig. 9. For this operation a casting was provided, having slots corresponding to the slots in the top of the vise base, at right angles to the tongue on the under side of this casting for lining same with the slots in the machine table. This course insures that the backing for the sliding jaw will be parallel with the line of the front jaws.

Tenth Operation—Finishing the Sides of the Base and Movable Jaws.

Fig. 10 shows the operation of milling the sides of the vise base and slide, the latter being put in position on the base and clamped to same. This operation mills the sides of both pieces so that they will be flush. This method was adopted rather than that of making special fixtures and special cutters for milling each piece separately.

As examples of operations wherein the milling machine has "butted" into the planer's territory, the above are well worth attention, and it is regretted that photographs were not available instead of the scanty line cuts. However, even these show the milling machine's superiority for such work to good advantage. They furnish, also, examples where equipment has in no way been a main point, and show that a large range of work can be handled with the ordinary means available. The various operations also show the different kinds of milling, and both styles of machines.

* * *

MOVING A SHOP.

B. HARDIE.*

It is sometimes necessary to move a manufacturing plant, particularly one renting quarters, from one place to another, either because the present place has to be vacated to give room for somebody who is willing to pay higher for the lease, or because cheaper and better quarters can be obtained elsewhere. This moving time is one of uncertainty of hours for all employed, and it makes the young apprentice swell with pride to have the superintendent approach him and ask him to work to-night, and he feels under moral obligation to tell every one he meets that "we are moving now, and I will have to work to-night."

At a time of such a shop moving, the most important thing is to have everything about the moving settled beforehand. The men in charge must determine upon exactly where every bench and machine should be placed in the new building in order to provide for the greatest convenience. The first thing to do is to obtain a drawing of the place, either from the owners renting it, or, if the place be bought, from the previous owners, or by having the draftsman sketch it up. In these plans particular attention should be paid to columns, height of ceiling, and location of cross beams, as well as the location of the windows. The location of the cross beams is very necessary in order to be able to arrange the counter-shafts correctly, and as for the columns, it is plainly in evidence that it would be inconvenient to have one of them located right in between the ways of a lathe. The same applies to the planning of closets in front of the windows, which mistake is often made in the drawing, if the windows are not plainly marked. When all these data are obtained, a plan should be laid out to as large scale as convenient. It is preferable to paste the paper on which this plan is laid out on the drawing board itself. Templets corresponding to the various machines in the shop should then be cut out of stiff cardboard, these templets being made as close to scale as possible of the actual floor space occupied by each machine. Particular attention should be paid in this instance to proper clearances, and the pasteboard pieces should be large enough to cover all projections or overhanging parts of the body of the machine, as these parts often will require larger space than do the columns or feet of the machine. Templets should also be made for benches, closets, and all other fixtures required to be installed. When this is done, the superintendent and the foremen in charge should arrange the templets as they consider best for carrying out the work in the most economical manner. When the templets have been arranged in a manner satisfactory to everybody concerned, thumb-tacks may be stuck to each templet as it is placed in position, and then another layout can be drawn up very easily, a tracing made, and blue-prints taken, so that everybody concerned in the moving can use one of these blue-prints as a guide.

One of the greatest troubles met with is the lining up of the shafting and the placing of the counter-shafts, which, if not properly done at first, will cause an endless amount of trouble later. A great deal of this difficulty is, of course, avoided in the more modern shops, where individual motor drive obviates this difficulty. Another very important point to be considered when all machines, benches and shafting are placed in position is the arrangement of the lighting fixtures, whether the lighting be by gas or electricity. This work should not be entered upon before everything else is in place, as one of the most important things in regard to light is that it be placed exactly where it will be needed the most, and this cannot very well be determined in the drafting room, but should be determined directly in the shop, when all the machines are in place.

Some shops will think it advisable to hire a few extra hands for the moving, but generally this is bad practice if it is possible to go along without extra movers. Hiring outside help for moving gives the men in the shop a chance to say that they "were not hired for moving," and may retard the work rather than facilitate it. Besides, in the case of moving it is a difficult matter to have too many men to look after, and the experienced old hands will probably know more about how to do the work properly than would extra hands. When everything is arranged right, each machine should be moved from its old place and put directly into its place in the new shop in the same order as it is moved. It is a great deal better to have each machine put in place at the time of moving than to have them all piled up and sorted out later, and if a man with a blue-print of the layout of the floor is appointed to superintend the placing of the machines in position as soon as arriving in the new place, it is an easy matter to attend to. The entire operation of moving can be more quickly accomplished if two crews are employed, one to take the machines from the floors and place them on the wagons at the old shop, and one to take them off the wagons and put them down in their place in the new shop. Thereby the time lost by the men traveling forth and back between the two shops is saved. If the moving is carried on along the lines indicated, and superintended in a proper manner, the interruption in business will not be noticed by outside customers, as each machine can be kept in running order up to the time of its removal, and be put in running order within a short time of its being placed in the new shop.

In the case of moving a shop, it is, perhaps, more necessary to create a spirit of cooperation among the men than it is at any other time, and to obtain this, many firms offer a bonus to the men for every day under a certain time that the shop is in running order, the bonus to be divided between the men in proportion to the work and responsibility assumed by each at the time of moving. This never fails to impart new energy to everybody, and even the office boy is imbued with new vigor in getting a shop cat into a bag to be taken to the new place. After the shop has been moved, the office quietly goes the same way as the shop. The main point to be considered in moving the office is to keep track of all records, as it often happens at the time of moving offices that old, and presumably useless, records are thrown away and lost.

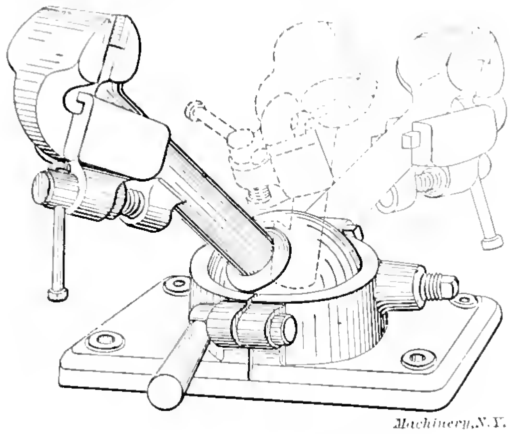
ITEMS OF MECHANICAL INTEREST.

UNIVERSAL VISE OF UNIQUE DESIGN.

At the Olympia Exposition in London, which took place during the latter part of last year, a vise of unique design was exhibited by Wadkin & Co., Leicester, England. The accompanying cut gives an idea of the manner in which this vise may be used, the general principle of the vise being plainly in

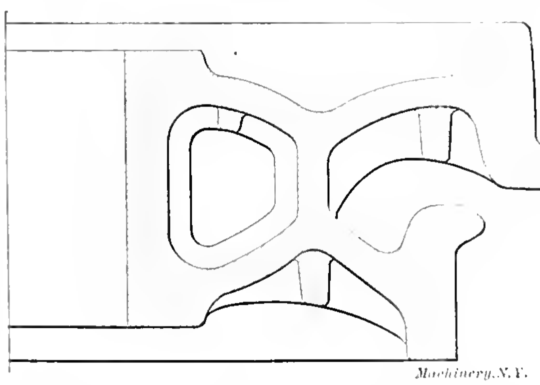


Universal Vise of Unique Design.

evidence. It can be swiveled around to almost any position, and tightened in place wherever desired. Considering its universal features the vise is said to be unusually rigid and effective for all ordinary bench work. The jaws are carried on the upper end of an arm, the lower end of which is fitted into a base having a ball and socket joint. It is of great advantage when working on irregularly-shaped pieces, as it is not necessary to change the grip of a piece in the vise or to work at the vise in an uncomfortable and awkward position, but the vise itself can be swiveled around to bring the piece clamped into the position required for convenient application of the tools used.

NEW IDEA IN CAR WHEELS.

The accompanying cut, taken from the *Railroad Gazette*, November 8, 1907, shows a new car wheel patented by Mr. P. H. Griffin, president of the New York Car Wheel Co., Buffalo, N. Y. The purpose of this wheel is to divide the destructive effects of heavy wheel loads and the wear and heating action of the brake shoe between two similar treads, and thus more than double the life of the wheel. The outer tread, as shown in the cut, is of large diameter, and rolls on the rails, carrying the load. The inner tread, of smaller diameter, is used only for braking purposes. This construc-



Car Wheel having Extra Tread for Braking Purposes

tion requires a longer hub than the ordinary wheel and adds between 200 to 250 pounds to the weight of a 700-pound wheel, or approximately from 30 per cent to 35 per cent. The objections to this wheel, however, cannot be lightly dismissed. The weight of car wheels already adds considerable to the dead weight of a car or a train, and so considerable an addition to the weight as necessary in the car wheel described naturally is an important objection. There is also another point worth considering. The wear on the tread of a car wheel caused by its rolling on the rails soon forms a groove in the tread, and the action of the brake shoe has helped to eliminate the continual deepening of this groove by wearing evenly over the whole surface of the wheel. Dividing the action of the rail and the brake shoe will eliminate the beneficial action of the brake shoe in preventing a groove to be formed on the tread of the wheel, and it is likely that the tread rolling on the rails will have to be trued up a great deal oftener than would be the case in ordinary wheels.

DIFFERENTIAL DRIVE.

The accompanying cuts, taken from an article in *Der praktische Maschinen-Konstrukteur*, show the principle and application of a differential drive, or what might be called a geared counter-shaft. While the principle in itself is by no means new, the present construction is of some interest. If we first

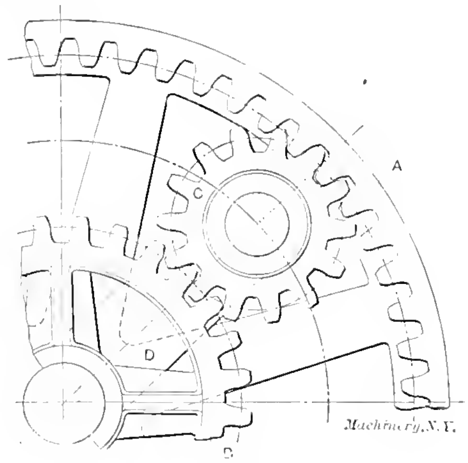


Fig. 1. Differential Drive of Interesting Construction.

refer to Fig. 1, it is clear that three cases for the use of this device may be conceived of. In the first place, the internal gear *A* may be stationary, and the gears *B* and *C* revolved; the gear *C*, of course, is simply rotated loosely on a stud fastened to an arm *D*, so that, in fact, it is the motion imparted by the arm *D* that is transferred to the gear *B*, or *vice versa*. In the second place, the arm *D* may be stationary, in which case either the internal gear *A* or the gear *B* may be the driver. Finally the gear *B* may be stationary, the power being transmitted in either direction between gear *A* and arm *D*. Fig. 2 shows a practical application of the principle. In

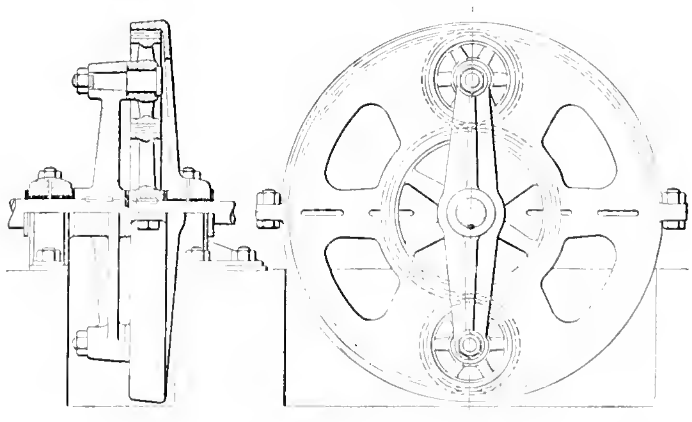

Fig. 2. A Practical Application of the Principle.

this design there are two gears corresponding to *C* in Fig. 1, mounted on an arm which in turn is keyed to the end of a shaft. The internal gear is stationary, forming part of a casing inclosing the gears, and the central gear is keyed to another shaft and drives this at a speed different from that of the driving shaft. This arrangement is a compact one, and is valuable, where space is limited, for the driving of a shaft directly in line with another shaft, but to be run at a different speed.

* * *

It is stated in *Copper and Brass* that aluminum bronzes containing less than four per cent of aluminum can be easily worked, but a greater amount produces a metal that is very hard to machine.

DESIGN—CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

49-55 LAFAYETTE STREET, CORNER OF LEONARD,

NEW YORK CITY.

Alexander Luchars, President and Treasurer.

Matthew J. O'Neill, Secretary.

Fred E. Rogers, Editor.

Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Associate Editors.

The receipt of a subscription is acknowledged by sending the current issue. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

JANUARY, 1908.

PAID CIRCULATION FOR DECEMBER, 1907, 23,327 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

THE LIGHTING OF DRAFTING ROOMS.

In no part of the office is the absence of direct shadows more to be desired than in the drafting room. High studding, with windows on the north side reaching to the ceiling, or a saw-tooth roof with the glazing facing the north, give the best and most uniform light. With the former, the arrangement of tables for a left-shoulder light is more vital than with the latter. Prismatic glass in the upper window sash is often of inestimable value in lighting distant corners, but it must be avoided when it would receive the direct rays of the sun. The tone color of the walls should be warm and restful to the eye, with the maximum reflective power. Plaster is usually much to be preferred to wood. The method of artificial lighting to be employed depends largely upon the character of the work. If large drawings are the rule, the light must be thoroughly distributed, as may be best accomplished by properly shaded overhead enclosed arc lamps. If the drawings are small, calling for little change in the area to be lighted, local illumination is very satisfactory, such for instance as by means of a single 32-candle-power lamp, swung from the back of the table upon a double-jointed bracket. This light, well shaded, and usually below the level of the eye, gives maximum intensity and lighting efficiency. The general appearance of the room is much better than with suspended lights in any form.

* * *

BORROWING TOOLS.

One of the little things in the shop which causes a great deal of lost time to the employer, and much annoyance to the more thrifty and careful of the men, is that of borrowing tools. Some men seem to think it perfectly proper to have their fellow workmen supply them with almost any tools they may happen to need, from a screw-driver to a micrometer. They have always some excuse to offer why they have not supplied themselves with a certain tool, and are always saying, "Guess I will get one myself," but they seem to forget it the next minute. When the rightful owner is in need of his tools, they are not on hand, as the habitual borrower seldom remembers or cares to promptly return what he has borrowed, and sometimes does not know what he did with it. The result is a constant searching for tools, with the consequent loss of much time. Sometimes the tools are entirely lost, and the borrower will assert that he has returned them. These matters may seem trifling as a subject for editorial comment, but we are convinced that if the time lost through this practice of borrowing tools could be estimated, and expressed in dollars and cents, the aggregate would be staggering in amount, particularly in large shops with a great deal of floating help.

It is true that the machinist has to supply himself with an expensive outfit of tools if he wishes to be well supplied—so expensive, in fact, as to be rather out of proportion if compared with the average income of machinists as a class; but that is no reason why one man should take advantage of his fellows. Tools cost one workman as much as another, and the borrower usually can afford to buy them just as well as the lender. Borrowed tools are not always handled gently, and it is an imposition to expect a man's friends to pay for the tools he uses. If each man tries to be independent of the other in this respect it will add materially to the efficiency of the entire force, and when it is really necessary to borrow, or help of any kind is needed, the infrequency of the necessity will induce a greater spirit of cooperation.

* * *

ON KEEPING THINGS SEVEN YEARS.

"Keep a thing seven years and you will find a use for it" is a current saying, for which almost any one can find warrant in his own experience. People who believe thoroughly in this principle have their desks and their houses filled with a collection of articles of more or less value which they are saving for the seven years period, with the reasonable expectation that a use will be found for some of it, at least, within that time. Such collections may be arranged in orderly fashion or heaped in wild confusion, depending on the characters of those responsible for them.

This same condition may sometimes be seen in a shop where the superintendent is imbued with this idea of preservation. In such a place there will be found, in more or less orderly arrangement, large collections of scrap, which from time to time furnish material for use in repair work, and from which old pulleys and gears are dug out to be worked over into special machines. Carrying out the same idea, old machinery, which has outlived its usefulness so far as continuous production is concerned, is kept in commission for the sake of the occasional odd job for which it is particularly suited.

Now, is not this idea a fallacy, however successful it sometimes may appear to work out in practice? It takes valuable time to search through a collection of such material for the one article needed, and the material itself requires valuable room if carefully and systematically laid away. If scattered indiscriminately over the shop, as is usually the case, it is a source of confusion, and interferes with the work, and such wreckage lying around loose cannot fail to have a demoralizing effect on both superintendent and workman.

The question to be considered is whether order and system, and the ability to do the work properly, are not of greater value in the long run than the money represented by an occasional useful article which has to be sacrificed for its price as scrap.

* * *

Probably reinforced concrete building construction requires just as careful designing and supervision as any other form. An engineer connected with one of the prominent contracting engineering companies of New York says that the apparent ease with which a reinforced concrete building can be erected has caused the business to be taken up by a large number of inexperienced contractors. Essentially, a reinforced concrete structure requires careful designing and engineering, and in addition, a most thorough and conscientious system of intelligent inspection, while in course of construction. Reinforced concrete, as well as any other form of construction, should be executed only by contractors experienced in that particular line of work.

UNIFORMITY IN SHOP FORMS.

Before the advent of the cost accountant and the betterment engineer, with their cost index and numerous blanks, most shops displayed a heterogeneous collection of shop forms, devised by different individuals, suited to the needs of different departments, and printed at different times by different printers. The trend is now decidedly toward uniformity in material, size, and type. Variety in color of ink and paper is by no means as necessary as sometimes appears. Judicious selection, and reduction to the least number of varieties, will permit of greater economy in printing, inasmuch as a number of different shop forms may be run together on the same stock, or in the same color of ink. The same is true of the sizes, which may be made in multiples, so that a similar grouping will reduce cost in printing. There is always a strong tendency to make a system absolutely complete by providing a printed form for each type or class of report. This results in great and often unnecessary multiplicity. Particularly in the case of index cards always retained in a given department, all printing may be omitted when the meaning of each item or notation is perfectly clear to those who habitually refer to the cards. It is often the case that expensive ruled sheets are required for monthly or annual reports. The number is so small that carefully hand-ruled sheets, or blue-prints will serve fully as well, with a material saving in the cost as compared with type composition, printing, and machine ruling. A careful consideration of the conditions under which they are used, and a realization of the fact that they are not made for strangers to the system, will frequently result in a decrease in the number of printed forms, and a material economy in the entire expense of shop stationery.

* * *

THE DECEMBER MEETING A. S. M. E. PAPERS.

Contrary to our usual custom, we have not made a general abstract of the papers read before the December semi-annual meeting of the American Society of Mechanical Engineers. The number of papers presented would have necessitated brief paragraphs of a somewhat perfunctory nature had the abstracts been confined to ordinary limits of space, and the general character of the papers makes them of minor interest to the majority of our readers. No disparagement is intended, nor is it merited. The papers on the whole were of a high grade, and they constitute a notable lot of contributions to engineering literature; but we cannot help feeling that they possessed too little variety. Out of a total of nineteen papers presented at the December meeting, all but two were either on power production and closely kindred subjects or foundry practice. The December proceedings are rich in material for the power plant engineer and the foundryman, but rather dry picking for the machine shop superintendent or machine designer.

Undoubtedly the most effective results for a favored group can be obtained by these symposiums on given subjects, but it should be remembered by the committee on papers that the membership is made up of men representing a great variety of engineering interests. The production of power is important; in fact, it is a basic art on which all other industries depend. The manufacture of castings in a sense is also a basic art and the foundation of nearly all machine work, but there is a vast multitude of other things of interest to the mechanical engineer which also possess great importance. We should like to see more variety in the papers presented, and more of the lowly things that we all can understand and talk about. Power plants, superheated steam, gas engine development, and foundry practice are subjects of perennial interest, no doubt, but let us also have papers on machine work, machine shop practice, the drafting-room, notable examples of machine production and even shop kinks. In the same way, other fields of mechanical engineering activity can be treated so as to give the papers a diversity of interest that will make every member of the A. S. M. E. feel that his membership is profitable to him, and that it has a direct vital connection with his business.

BALANCED INDUSTRIAL CONDITIONS.

In time of peace, prepare for war! This maxim has been repeated so many times that it is now nearly universally accepted, although the feeling is growing that if we did not prepare for wars we should be less likely to have them. Whether this maxim be true or not in regard to peace and war, it is not open to denial that a similar expression can be applied to industrial conditions, and dealing with times of prosperity and of depression. As thus applied, the maxim would naturally read: In time of prosperity, prepare for depression. This, however, is a pessimistic view of industrial conditions, and the value of the suggestion is somewhat negative. We would prefer to phrase the maxim: In time of depression, prepare for prosperity. This is the optimistic view—a positive expression looking forward to increased possibilities and development, and expressing a different attitude towards the establishment of balanced industrial conditions.

Our industries, and in particular the machinery industry, have developed so rapidly that truly balanced conditions have not yet been fully accomplished. But it is no exaggeration to say that an increased confidence in the future, permitting, in times of less active business, necessary preparations to be made for the returning tide of business development and prosperity—which we all know to be ahead of us as soon as the temporary ebb has passed by—would greatly tend to balance industrial conditions. If improvements were carried out in dull times instead of being curtailed, not only could they be installed for a smaller outlay, but they would be available when active business required. We have all seen cases where our shops were unable to take proper care of their orders in good years, and time and money were wasted trying to turn out work with inadequate facilities; and while there is a natural reluctance to invest more capital in a plant when business is dull, foresight and provident business management often demand it in order to take advantage of prosperous times when they return. In every sound business the approximate relation between present expense and future requirement can easily be judged, because there can be no doubt of the ultimate return of prosperous conditions.

One of the great differences between European and American industrial management is to be found in the conditions under consideration; and it may be that the balance generally maintained on the Continent depends somewhat upon the manner in which most European shops add extensions. Unlike many of our own manufacturers—who are often forced, we admit, by the unprecedented demand for their product—European manufacturers usually add improvements when times are dull and when labor and materials, as well as interest, are low, and the demand on their facilities is light. In good times they devote themselves exclusively to the manufacturing business, being then equipped to take care of all the trade they obtain, and naturally making a larger profit on their product.

The additional expense of carrying a building or two, not yet equipped to its full capacity, for a couple of years, they claim is amply justified by the certainty of increased returns later. There is, perhaps, a lesson in this for us, which could be applied to our present conditions. Instead of increasing our plants when times are prosperous and everything expensive, and completing the installation of the equipment about the time when trade begins to fall off, would it not be possible, to some extent at least, to prepare for increased trade before the demand exists? The question has but one answer. If we look far enough ahead, we can see the tide turning, and now is the time to prepare for it, rather than to lose heart on account of present conditions.

* * *

In a report recently presented to the General Managers' Association of Chicago, it is stated that on American railroads the number of locomotives has, in the last ten years, increased by 12.8 per cent. In the same period the weight of some types of locomotives has increased 82.8 per cent, and the average weight increased 28 per cent. The number of freight cars has been increased by 51.5 per cent in this last decade, their total capacity 95.3 per cent, and average capacity 30.6 per cent.

ENGINEERING REVIEW.

CURRENT MECHANICAL EVENTS—LEADING ARTICLES OF THE TECHNICAL PRESS.

According to *Industritidningen Norden*, an international exposition will be held in Turin, Italy, in 1911. This exposition will be large in its scope, and will be devoted particularly to industrial products and agriculture.

It is reported from Washington that the Postmaster-General has imposed on a number of railroads the penalty stipulated in their contracts for failure to deliver the mails on time. The Great Northern Railroad has been fined more than $26,000 for slow deliveries from points in Minnesota to points in the state of Washington.

The inventor of the mono-rail gyroscopic railway car, Mr. Louis Brennan, has been granted a sum of $30,000 by the Indian government, in order to enable him to proceed with his experiments with a full-sized mono-rail car which he is now constructing for that government. The principle of Brennan's mono-rail car was described in the August issue of MACHINERY, engineering edition.

A company has been organized, and a factory for the manufacture of glass telegraph poles has been built at Grossalmerode, a town near Cassel, Germany. The glass mass of which the poles are made is strengthened by a reinforcement of steel wires. One of the principal advantages of these poles is their use in tropical countries, where wooden poles are soon destroyed by insects and where climatical influences are ruinous to wood.

Contracts were closed some months ago for the construction of floors, interior partitions, and roof of the Pennsylvania Railroad's new passenger terminal in New York City. The material used will be absolutely fireproof, and porous terra cotta has been selected as the only material that could stand the required tests. This material will be used in form of hollow blocks as a complete covering for the steel frame of the building.

A Canadian correspondent to the *Times Engineering Supplement* states that on the new National Transcontinental Railway, known also as the Grand Trunk Pacific, a section of the line, 70 miles long, will be constructed without a curve, and also without a rock cut, no obstruction being met with except rivers to be bridged. The longest tangent on any railway in the world is to be found in Argentina, where, on one road, there is in one place 175 miles of straight track.

Platinum has recently been discovered in California, and according to the *Railway Age*, the United States Geological Survey is at the present time investigating these discoveries. The investigations have gone on for a year or more, and it has developed that there is platinum in 120 places in the United States. The increased commercial use for platinum and the high price of the metal, owing to its scarcity, make these investigations very valuable. Should the natural deposits of platinum in the United States be found to be of any considerable amount, they would constitute an addition to the known natural resources of the country of no small importance.

A contributor to the *Engineering News* tells of a neat method he has followed for lettering maps and drawings which are to be reproduced photographically by the zinc process. Instead of spending the time to do the lettering carefully by hand, he has the various names, titles, etc., set in suitable type and has proofs taken on gummed paper. Strips containing the words and titles are cut from this gummed paper and pasted on the drawings. These labels do not appear in the finished cut, nothing being reproduced except the printing. This gives neat, uniform lettering at a less expense than would be required for work of a similar quality done by hand.

It is stated in the *Engineering Record* that the preservation of ties by crude oil has been successfully tried by the Atchison, Topeka & Santa Fe Railway. The company some years ago treated a few ties with California crude oil containing about 75 per cent asphaltum base, the remainder being light oils, the greater part of which vaporized when heated. The oil was heated to 180 degrees F., and forced into the wood under 150 pounds pressure per square inch, the ties taking up from 4 to 8 gallons each. They were placed in the track at the section where untreated ties will not last over two or three years, but the treated ties, when examined after having been in service for 4 years and 9 months, were found perfectly sound.

The increasing application of internal combustion engines, fed with coal gas, blast furnace gas, and other gases, has, says *Engineering*, unfortunately, been accompanied by a large number of cases of gas-poisoning. In Germany both the Imperial Insurance Office and the Board of Health have drawn the attention of manufacturers and engineers to this source of danger. The attendants of gas engines should be cautioned, and be instructed as to the measures to be adopted in accidents. The most dangerous constituent of the gases is the carbon monoxide, and cures can be effected by making the victim inhale oxygen. Oxygen cylinders provided with suitable valves should be kept where gas engines are used, and some attendants be duly trained by medical men in applying the first aid.

A feature of special interest at the Olympia exhibition in London was that of a line of compressed paper pinions, manufactured by the British Insulated & Helsby Cables Co. These pinions are intended to compete with the raw hide pinions, and it would seem from records of the samples shown that they are likely to come into great popularity. The specimens exhibited were pinions which had been in use under hard load conditions and unfavorable surroundings for periods long enough to prove their ability to stand up in hard service. The makers claim that these paper pinions are unaffected by moisture and oils. The makers have had a successful experience with compressed manila paper for insulation of cable work, and, judging from this experience, it is reasonable to expect that the paper pinion has been evolved on thoroughly firm ground, and with reasonable assurance of successful working.

In an article in the *Zeitschrift für Angewandte Chemie* a new method for manufacturing copper tubes is described. This method is in operation at the works of Langbein & Co., in Leipzig, Germany. The copper is deposited on a revolving mandrel as in the Cowper Cole's process, but the high rate of revolution of this latter process is dispensed with. The density and smoothness required in the deposit are obtained by suspending in the solution some siliceous material such as sand or quartz, which is unacted upon by the electrolyte, and which supplies the necessary degree of friction to the surface of the mandrel to remove all gas bubbles and inequalities in the deposit. Tests of the tubes made by this process have shown that the tensile strength is twice as great as that demanded by the specification for copper tubes drawn up by the authorities of the German Marine. The method can be applied to the production of plates and tubes of other metals than copper. In fact all metals that are liable to electrolytic deposition in a spongy and porous state can be obtained in a dense and coherent deposit by use of this method.

It is stated in the *Brass World* that the most frequent cause of the cracking of aluminum castings is the overheating or "burning" of the aluminum while melted. The most generally used aluminum alloy for castings, at the present time, is one which contains aluminum and zinc, and occasionally copper. The presence of zinc renders the casting more liable to crack,

but, on the other hand, the greatest strength in the metal is obtained by using zinc. If the following rules are adhered to, less trouble will be met with in aluminum castings. In the first place, the metal should be melted with a slow fire, so that the top of the metal will not be burned before the remainder of the metal is melted. When the whose mass is melted, care should be taken not to overheat. The ingots should be packed in the crucible as compactly as possible, so that portions of the metal will not stick up and become exposed to the action of the flame, and the most important rule may be said to be not to have the aluminum melted before the mold is ready. Non-observance of this last requirement is perhaps the most common source of burned metal, and consequently the most frequent cause of the cracking of aluminum castings.

The English government, according to the *Times Engineering Supplement*, is at the present time making preparations for introducing oil for fuel for steam raising purposes in the navy, on a large scale. Oil storages have been provided for in several localities. Among liquid fuels considered, is one known as "masut," which is one of the by-products of the distillation of raw petroleum, and which is now used to some extent by the Russian, German, and Italian navies. As it appears to have a high calorific value, and is said to produce but little smoke, it has some of the chief requisites for a fuel to take the place of coal. The relative cost of production of masut and of coal would probably be disadvantageous to the former, but this would be offset by the decreased cost of transportation and the conveniences attending the use of fuel in a liquid form. It is likely that the future will pay more attention to liquid fuels than has the present. The natural supply of liquid fuels is abundant, it being stated that Australia has immense deposits of oils which can be used for fuel purposes, which have as yet not been exploited at all.

In an editorial in the November issue of MACHINERY we found occasion to touch upon the future of the automobile, and we also mentioned that we expected that before long the more or less useless pleasure vehicle would be followed by vehicles for actual commercial use. It is gratifying to find that this sentiment is now voiced by automobile manufacturers themselves. In a recent issue of the *Horseless Age*, the manager of a well-known concern is quoted as having said: "I feel more and more strongly drawn to the commercial end of the business, and am convinced that in time we shall make trucks exclusively. Nevertheless, I do not think it advisable to give up the sale of pleasure cars at the present time." It is also stated that this awakening to the possibilities of the commercial vehicle is general, and that there is scarcely a company of any prominence connected with the industry which has not begun to take a more or less active interest in motor cars for trucking and general use. Some have designs under way, and others have various experimental vehicles on the road.

It is well known to anybody who has attempted to make a good photograph from a machine having bright polished surfaces as well as dark painted portions, that the bright portions cause trouble, and there is difficulty in showing these portions in a proper manner, the work of exhibiting the machine clearly being largely involved upon the retoucher. If the exposure is made of such duration that the bright portions will be clear, there will be under exposure of the dark painted portions, and if the exposure is made to suit the darker portions, then the bright portions are usually not plain, and sometimes entirely indistinguishable. In *Industritidningen Norden* we find mentioned a method for so preparing the bright portions of a machine to be photographed that a satisfactory picture can be taken, which will show all details with an equal degree of exactitude. This method consists in subjecting the bright surfaces to vapors from sal-ammoniac, which gives to the surface a fine covering which takes away the brightness of the surface. If the sal-ammoniac is pure (neutral) the vapors have no effect whatever on the machine, or on the surfaces themselves, and the covering can easily be wiped off with a cloth without using either oil or other means for removal.

FORMULAS FOR GAS ENGINE CRANK-SHAFTS.

During the last few years, although manufacturers of gas motors have materially increased the diameters of the crankshafts of their engines, these have still proven themselves too weak in many cases for the stresses imposed on them, owing to the higher compressions and heavier fly-wheels in present-day designs. While a few years ago, in gas motors, an explosion pressure of 250 pounds per square inch was seldom exceeded, in present practice 400 pounds per square inch is not uncommon. The stresses on this class of machinery are always more or less uncertain, and therefore calculations of strength are difficult, and dimensions have largely been determined by experiment, or, in other words, by trial and error. For this reason some remarks by Mr. Michael Longridge, as published in the *Mechanical Engineer*, are worth noting. According to his opinions, while reliable theoretical formulas are not deducible, the sizes which experience has shown to be desirable can be expressed fairly accurately empirically. If C is the diameter of the cylinder, D and d the diameters of the shaft and crank-pin journals, respectively, r the radius of the crank, and L the distance between the inner edges of the shaft journals, that is, the distance over-all of the crank webs, all expressed in inches, then for engines below 12 inches diameter of cylinder the value of the expression

$$\frac{C^2 (L + d)}{D^3}$$

should not exceed 12 for engines with two bearings and overhung fly-wheels, or 14, if three bearings are used. Furthermore the value of the expression

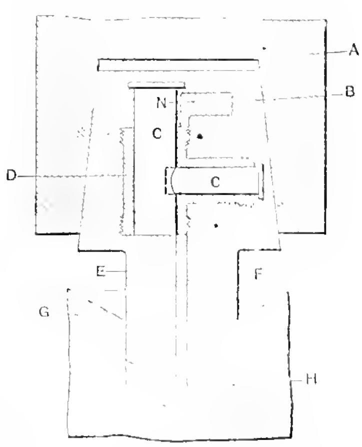
$$\frac{C^2 r}{d^3}$$

should never exceed 10. Besides, the crank webs should always be joined to the fly-wheel shaft with large fillets, as sharp corners have proven to be a common and serious source of weakness.

CASTING METALS UNDER PRESSURE.

The Mechanical Engineer, November 16, 1907.

By the process of producing castings under pressure, it is possible to make the castings of complicated shapes and with such details produced by the casting process as it has not heretofore been possible to form excepting by finishing with special tool. The processes of casting metals under pressure are divided in two groups. In the first of these groups the pressure exerted upon the material being cast is produced by means of gas, while in the other case the pressure is exerted by mechanical means. The device illustrated in a schematical form in the accompanying cut shows the appliances used in a process patented by Mr. F. Ljungström, Flemminggatan 8, Stockholm, Sweden.



Arrangement for casting Metals under Pressure

Referring to the cut, A is a piston operated by hydraulic pressure, at the lower end of which the mold B is inserted. The mold is intended for a T-pipe, C being the core of the pipe. The mold is provided at its lower end with a piston-like extension E provided with a taper at its lower end, and also with an internal passage F. This extension fits into the hole H in the part G. The hole or cavity H is filled with molten metal, and the piston A with the mold B is moved downward so that E enters H, and thus exerts a pressure upon the molten metal. The metal will then rise into the cavity D, and the desired casting will be formed under pressure. As the mouth of the passage F is located at the lowest level of the end of the piston-like extension E, the layer of oxide collecting on the surface of the molten metal in H will not enter the

passage. If, however, a few particles should penetrate into the passage they will collect in the pocket N, branching from the actual form of the piece to be cast. The advantage which is claimed for this method is that the mold does not need to be heated before the molten metal is introduced, and for this reason the frame of the mold can be made out of metal, so as to give the required streugth required by high pressures. In previous designs of this kind it has been necessary to heat the molds, before introducing the molten metal, to a temperature as high as the molten metal itself, and in cases of metals at a high fusion temperature, it has not been possible to make the molds from metal or alloys, but they have been made from plaster of paris, asbestos and similar materials which could not stand high pressure.

A YEAR'S EXPERIENCE WITH GAS ENGINES.

Abstract of paper by Mr. Paul Winsor, read before the American Street and Interurban Railway Engineering Association at Atlantic City, N. J., October 16, 1907.

The author of this paper is chief engineer of motive power and rolling stock of the Boston Elevated Railway Co., and is therefore well acquainted with the subject in hand. The gas engines in question were installed in the plant of this company early last year at the Somerville power station, the equipment consisting of two 600 B.H.P. 2-cylinder 4-cycle gas engines with generators and gas producers. The plant was started in May, 1906, and since then has given continuous, reliable, and satisfactory service, the engines being run sixteen hours per day. The fuel used for gas generation has been soft coal, the coal used per kilowatt hour averaging 2.034 pounds or 1.404 pound per B.H.P. hour. Some trouble was experienced with ignition. The igniters had originally platinum tips, and these were rather expensive to replace. For this reason the plant has been run for four months without any platinum tips, and less trouble has been experienced. During the first months, pre-ignition and back fires were rather frequent, but by lowering the compression in one of the cylinders, and changing the igniters, these troubles have been greatly reduced. The reliability of the service has proved one of its strong points. The plant can be started up at any time in less than five minutes. The gas engine station used only 46.1 per cent of the coal used at one of the steam plants of the same company per brake horse-power. For this reason the author concludes that a gas engine plant equipped with gas producers will operate fully as reliably as a steam plant, and will require from 30 to 60 per cent less fuel. The drawbacks to be considered would be the first cost which is about $200 per kilowatt when rated so as to have 33 1/3 per cent overload capacity, and also the present small size of gas engine units.

THE CRYSTALLIZATION OF STEEL.

Walter Rosenhain, in the *Times Engineering Supplement*, November 6, 1907.

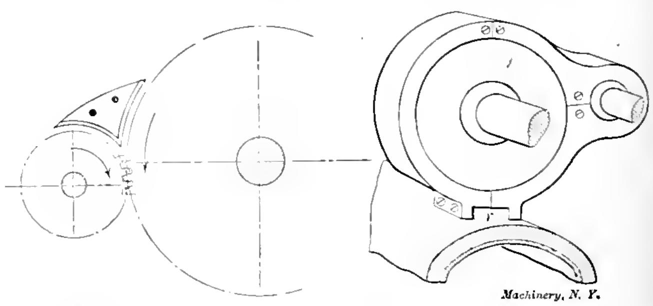
In our issue of MACHINERY, engineering edition, December, 1906, we published a short statement regarding the crystallization of steel, in which it was contended that steel does not crystallize by use, but that in cases where steel, having given away under stress, shows a crystalline structure, this crystalline condition has been inherent in the steel, and the use of the steel simply separates the faces of the crystals. In the present article the author sustains the same theory. The author states, in the first place, that microscopic study has proved beyond doubt that all metals possess, in any state, a truly crystalline structure, and that, therefore, ordinary materials of construction, particularly iron and steel, cannot be said to possess the fibrous structure, as so often has been contended. One cause of misconception regarding the character of metals lies, no doubt, in the fact that we are accustomed to regard crystal as brittle bodies, easily broken or split. This brittleness, however, is only the property of one class of crystals. It has been shown, for example, that under suitable conditions such a perfectly crystalline substance as marble can be caused to flow under stress and undergo drastic deformation without fracture. Ice is also a typical crystalline body which shows a great amount of plasticity. The fact that metals are characteristically crystalline is, however, not in any way in conflict with our knowledge of their ductility and strength. When fibrous fractures appear, it is simply because the crystals have been subjected to deformation, before the fracture occurs, by the application of the stresses in a certain manner, while on the other hand, when sudden and intensely local forces develop, the crystals will split or cleave along their natural cleavage before any amount of deformation has taken place. In such cases, we have the fractures which are claimed to have occurred on account of the crystallization of the metal, although the crystalline or fibrous character of the fracture is dependent not as much upon the character of the metal itself as upon the manner in which the fracture has been produced.

The author finally concludes that inasmuch as metals, in their normal condition, already have a truly crystalline structure, it is evident that exposure to vibration cannot produce such a structure, although it might modify the character of the crystals already existing; but there is, as far as the author knows, at the present time, no evidence at all that any change in the size or arrangement of the crystals of a metal can be produced either by vibration or fatigue. The decisive and final abandonment of the "crystallization" theory thus is evidently unavoidable, and some of our cherished misconceptions will have to be abandoned. At the same time, it must of course, be admitted that fatigue fractures reveal more clearly the crystalline structure existing in the metal, and it is also evident that fractures would appear at sudden stresses more easily in metals of coarse crystalline structure. This is in itself a point of considerable practical importance, and it explains to a great extent the prevalence of the crystallization theory, for it gives us the reason why faulty conclusions have been arrived at.

GEAR GUARDS.

Zeitschrift des Vereines deutscher Ingenieure, August 10, 1907.

In an article about the development of German machine tool design, the author, Mr. Ruppert, devotes himself also to the influence on the design of machine tools of the German laws for protecting employes from injury. He calls attention to the fact that these laws, while at first not considered to be of any consequence to the machine tool builder in any other respect than that he had to safeguard dangerous gears and belts in his own shop by a piece of stiff sheet-iron or wooden board, finally have proved to give a distinct characteristic to machine tools on which every gear and projecting revolving part is covered with a suitable guard. The law covering compensation to injured employes is far more detailed than that of the United States, and it probably is for that reason

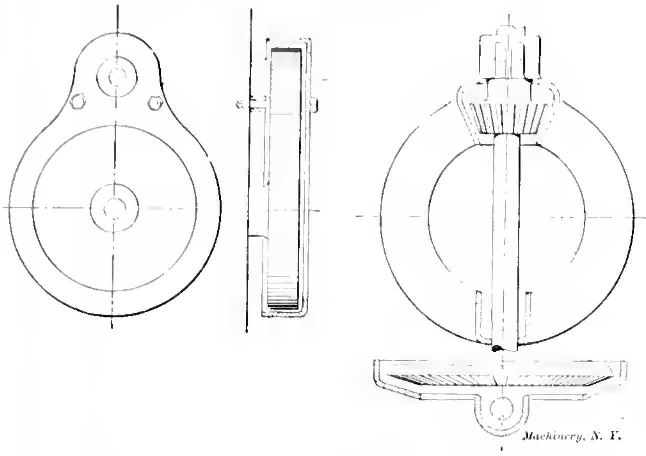


Figs. 1 and 2. Showing Old and New Forms of Gear Guards.

that foreign machine tools until lately always have been far better protected than American tools as a rule have been. The German law stipulates that the owner of any machine is responsible for any injury inflicted upon any person in his employ working with his machine. While at first, as mentioned, it was not expected that this law would influence machine tool building to as great an extent as it has, it was soon realized that machine tools had to be provided with suitable safeguards in order to sell as well as other machines well safeguarded, but not superior in other respects.

The first crude form of gear covering as used in Germany is shown in Fig. 1, and was not unfamiliar to American products a few years ago. It consists simply of a small piece of bent sheet iron, or at best, a thin casting covering the portion where two gears engage with one another. This inefficient

guard was probably adopted for economical reasons, it being considered too expensive to cover up the whole gearing. If the gears, however, are running in a direction as indicated by the arrows this guard is really almost as dangerous as the unprotected gearing, as the fingers may be pulled in



Figs. 3 and 4. Guards which cover only the Toothed Surfaces of the Gears.

between the gear and the guard almost as easily, or perhaps more easily, than they would be liable to be drawn in between the gears themselves.

A few neat designs of a more recent date, however, are shown. Some of these are not merely covers but brackets which serve as support and bearings for the gear shafts, as well as for safeguarding covers. In Fig. 2 is shown a cover which completely encloses the gears, and in order to facilitate assembling, it has been necessary, in this case, to make the gear case in several parts. The design is a remarkable example of a gear guard made up from several parts, and still giving the impression of a uniform and neat design. In Fig. 3 is shown a guard of fairly similar design. This guard encloses completely the outside of the toothed surface of the gears, while it is open on the inside and in the central portions on the outside so as to permit of easy assembling of the machine. Fig. 4 shows a cover for bevel gears in which the cover also completely encloses the toothed portions of the gears. In Fig. 5 is shown the neatest and most modern design for covering miter gears. In this, the guard itself and the bearings for the shaft carrying the gears are cast in one integral piece, the gears being assembled from the outside of the guard, which is left open. After being assembled, a cover, as shown by the dotted lines, is placed over the opening, thus completely enclosing the gears. These forms of guards for gearing are not new, but they have a particular interest as they show the development of the idea of the necessity of making the risks of industrial workers as small as possible, and some of them may contain an idea that can be employed in other cases similar to those shown

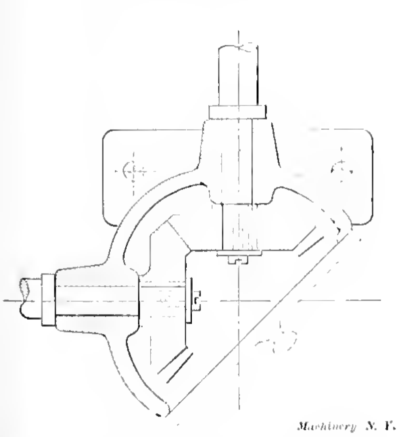


Fig. 5. Miter Gear Guard, with the Guard and the Bearing for the Shaft cast in One Piece.

as well. The designer of to-day is required to keep in mind the proper guarding of revolving machine parts, just as much as he is required to keep in mind the proper ratio of the gears themselves; and the cheapest and best guards for gearing are those which can be made up in a uniform style with the machine itself, and be designed so as to form integral parts with the machine. Wherever a guard becomes such a part of the machine it will serve its purpose to the fullest extent, inasmuch as there is then no risk of its being left off because of being inconvenient to the man operating the machine.

NOTES ON ROPE DRIVES.

Thos. Hart in the *Mechanical World*, October 11, 1907.

At the beginning of this article, the author lays down the rule that one should try to avoid arranging rope drives at

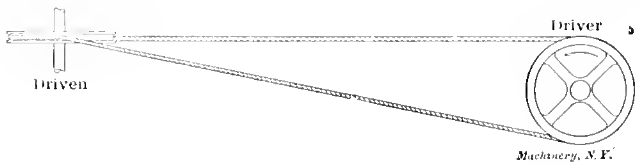

Fig. 1. Half-cross Drive.

right angles or around corners, whenever it is possible to arrange the drive so that it may run straight. A rope drive transmitting power around the corner reduces the power probably by 50 per cent, while its life is shortened by even a greater amount. From this it is evident that this kind of drive is not economical, but there are cases where such drives are imperative, and the author has attempted to show the best methods of arranging these drives.

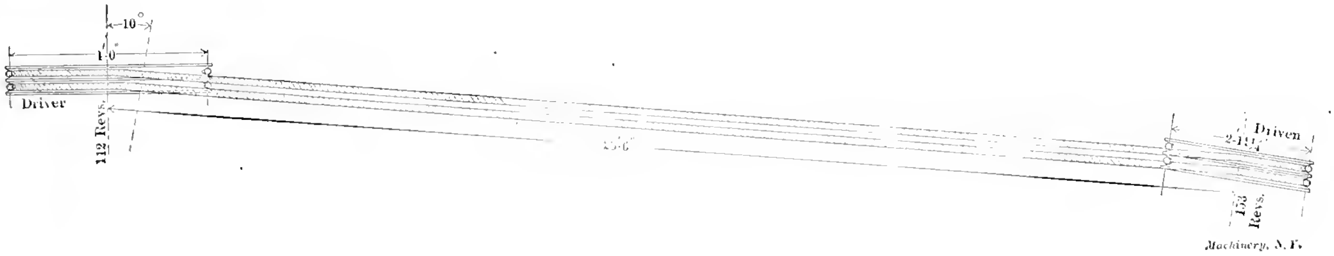

Fig. 2. Rope Drive with Shafts at an Angle of Ten Degrees.

Half-cross Drive.

Fig. 1 shows what is called the half-cross drive. In arranging such a drive, the fundamental rule is that all the angle should be given to the tight or driving side of the rope, and the slack side should run straight. If the slack side took the angle, the sagging would cause it to leave the groove at the point of entry. When installing such a drive it is often good practice to fix one pulley and to let the other one loose on the shaft for a few minutes. It will then find for itself the position in which it will work the best. It is difficult to arrange this class of drive for more than one rope, and therefore this type of drive is seldom used excepting for small powers.

Drives between Shafts which are not Parallel.

Drives where the shafts are not parallel with each other are frequently met with, but there has as yet not been any positive answer to the question of the greatest angle at which the ropes can be made to keep in the grooves and do effective work. It has been stated that where shafts form an angle with one another of three degrees or less, a rope drive may be arranged which will run well without any special arrangement, but for larger angles special deviations from the standard shape of groove must be made. In Fig. 2 is shown a rope drive where the two shafts form an angle of 10 degrees

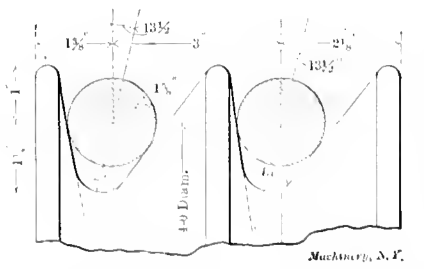

Fig. 3. Shape of Grooves for Rope Drive in Fig. 2.

with one another. It will be noticed that at the point where the rope commences to leave the groove, it requires more freedom than it can obtain in a groove of the ordinary shape, and for this reason the grooves have to be shaped in a special way. Fig. 3 shows the shape of groove adopted for the rope drive shown in Fig. 2, which is one that has been running satisfactorily for two years. In general, it may be said that rope drives of this character will give greater satisfaction if it is possible to have the pulleys of approximately the same diameter; if the distance between the pulleys is not too long, so that the sag of the slack side of the ropes becomes too great; and, finally, if the speed is not too high.

Drives at Right Angles.

The author understands drives at right angles to be drives around corners. In these, more than in any of the types previously discussed, is it necessary to assume that a great deal of power is lost through the bending of the rope in its passage from the driving to the driven pulley. In this class of drive, the driving and driven pulleys may have their grooves parallel to each other, although the ropes pass around the corner as shown in Fig. 4. This kind of drive offers no difficulties as far as the design or arrangement is concerned. A different problem is encountered in the case shown in Figs. 5 and 6. It is easily seen that the idlers here require different setting, and that careful thought is necessary to place them in the correct position. In Fig. 5 only the actual center of the driving and driven pulleys can be set true with the idler. Therefore, the greater the number of ropes, the greater is the tendency of the ropes to leave the grooves. Drives of three ropes seem to run satisfactorily with this arrangement, but when five ropes are used the first and fifth often cause

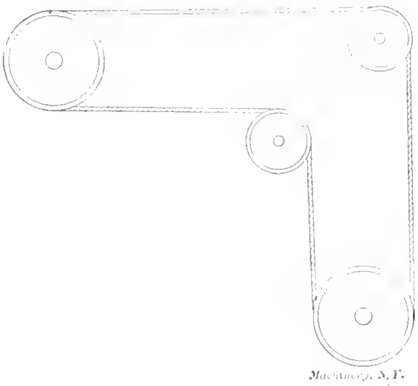

Fig. 4. Right Angle Drive, with Grooves Parallel.

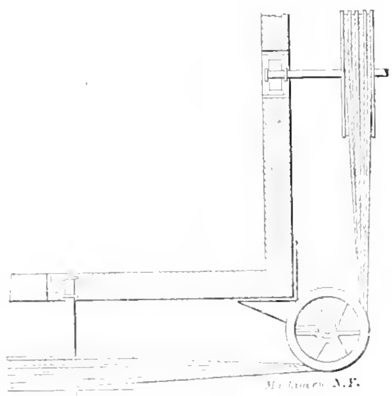

Fig. 5. Right Angle Drive, with Grooves at 90 Degrees.

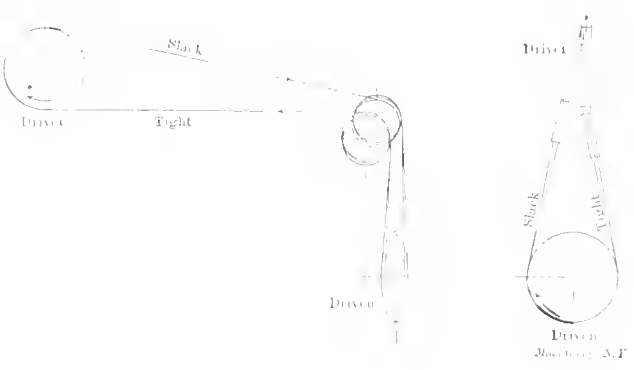

Fig. 6. Form of Drive with Two Idlers on Shafts at Different Angles.

difficulties, and they will run out of the grooves on the slack side of the drive. It is therefore advisable to make the shape of the grooves to resist the tendency of the ropes to leave the driving or driven pulleys in such cases. If one does not want to make the grooves with an inclined center line, it is well to make them very deep, as shown in Fig. 7. In Fig. 6 is shown a drive where the idlers are placed on two separate shafts in order to permit a proper position to be obtained for each of them to carry the ropes between the driving and the driven pulley. The grooves in the idler pulleys should be wide and round at the bottom, and the sides should be shaped so as to accommodate the rope at the position which it will naturally take in the groove. In the earlier days of rope drives, experiments were made with idler pulleys having no grooves, but having a flat bottom and outside flanges made to any angle suitable for the drive, as shown in Fig. 8. At first sight it appears as if this idea would be favorable to the types of drive under discussion, but on account of the sag of the ropes, particularly on the slack side, it often leads to one rope fouling the others, and possibly throwing them off the pulley altogether. The idlers should be made as large in diameter as possible, and should run in well lubricated bearings.

Loss of Power with Angular Drives.

The author concludes his notes on rope drives with repeating his reference to the loss of power in angular drives, and in that connection he refers to an actual case occurring in his practice. In this case, the drive was one of two ropes, each $1\frac{1}{2}$ inch in diameter, in a spinning mill, arranged to drive around the corner on account of an objection to using bevel gears at this point. The trouble was that the ropes stretched considerably, and after tightening, quickly wore out, all this indicating overload. An inquiry showed that the two ropes were set to transmit about 60 horsepower. This load would have been easily carried in an ordinary straight drive, the speed being 4,500 feet per minute, but, on account of the angular drive, the ropes absolutely failed to carry this load in the case referred to. In another case five ropes of $1\frac{1}{4}$ inch diameter on a straight drive performed a certain work, but, owing to some alterations, it became necessary to alter the position of the engine, and to install a right angle drive. This was installed in the most practical manner possible, but it soon became necessary, in order to transmit the required power, to increase the ropes to a diameter of $1\frac{3}{4}$ inch, and still the life of the ropes was very much reduced.

Fig. 7. Deep Grooves for Angular Drives.

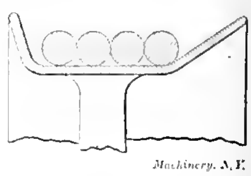

Fig. 8. Idler Pulley without Grooves.

For this reason it cannot be too strongly pointed out that drives such as those discussed should only be used under circumstances of great necessity.

BALL BEARINGS.—2.

Abstract from paper by Mr. Henry Hess, read before the American Society of Mechanical Engineers, May meeting, 1907.

Correct Ball Bearing Mounting.

The following requirements are based on correctly mounted ball bearings:

a. The proper size must be selected for the load and conditions in question. Rated capacities are usually for steady loads and speeds, but variations from these conditions demand a cutting down of the listed capacity.

b. Bearings must be lubricated. The often repeated statement that ball bearings can run without a lubricant is not correct.

c. Bearings must be kept free from grit, moisture, and acid. No lubricants developing free acids should be permitted.

d. The inner race of the bearing should be firmly secured to the shaft. This can be done by a light driving fit, reinforced by binding the race between a substantial shoulder and a nut.

e. The outer race must have a sliding fit in its seat. These conditions should under all circumstances be adhered to, and a failure to do so will result in very unsatisfactory bearings.

The two following conditions are frequently disregarded, and while the disregard of these conditions is not so serious as of those mentioned before, it is safe engineering to follow them, and a disregard of them is a standing invitation to trouble.

f. Thrusts should always be taken up whether in the same or opposite directions by the same bearing.

g. Bearings should never be dismembered, or at least never more than one at a time. That will avoid the danger of mixing the balls from different bearings; such balls from different bearings are very apt to vary more than is permissible for the individual bearing.

Illustrations of Correct Mounting.

The development of ball bearings being so recent is probably the cause that so little information as to correct mount-

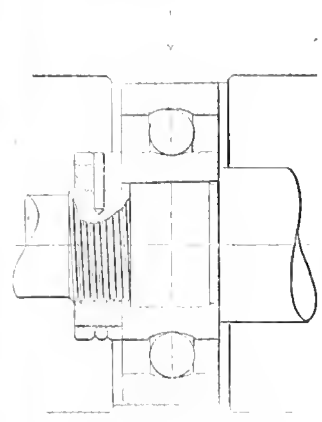

Fig. 16. Free Mounting for Radially Loaded Bearing.

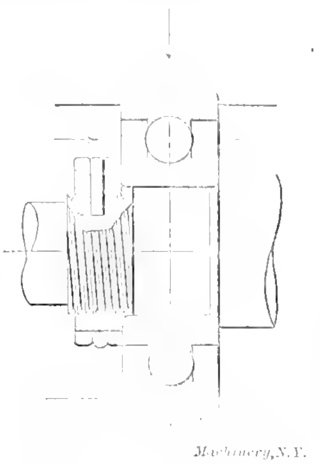

Fig. 17. Radially Loaded Bearing held against Longitudinal Motion

ings for various conditions is available. The experience of the author of this paper has been that faulty mountings are very general, and for this reason he has given illustrations of correct mountings, going more into details than would be considered necessary for a more familiar mechanical subject.

Fig. 16 shows a bearing in which the inner race has a light driving fit on the shaft, and is securely clamped between a shoulder on the shaft and a nut. The shoulder on the shaft should be high enough to get a firm grip on the surface of the side of the race. It is good practice to make this shoulder about one-half as high as the race thickness, perhaps a little less for large bearings and a little more for small bearings. The outer race has a tight sliding fit in the housing, so that the bearing as a whole may be able to respond to relative shifting of the shaft and housing without being subjected to end thrust through the balls.

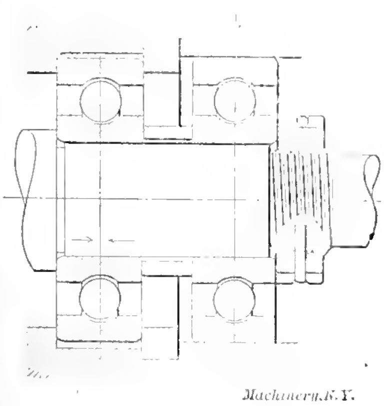

Fig. 18. Separate Radial Bearings for Radial and Thrust Loads.

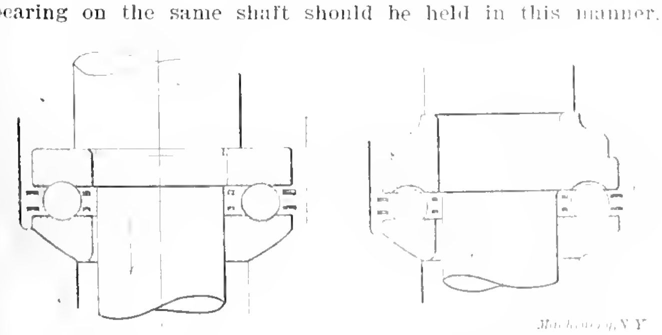
Fig. 17 shows a radially loaded shaft held against endwise motion in either direction. This bearing is capable of carrying thrust load in either direction, but never more than one bearing on the same shaft should be held in this manner.



Figs. 19 and 20. Thrust Load in One Direction on Collar Bearings

This bearing differs from the preceding mounting only therein that it has the outer race secured between shoulders in the housing. This arrangement and the preceding one are usually found combined on the same shaft, which is then held endwise at one point only, so that temperature changes, or deflections of the shaft can cause no cramping.

Fig. 18 shows separate radial bearings for radial and thrust loads. This type of bearing is used when it is desirable to take thrust load on bearings of the radial type, although the space available does not permit of a single radial bearing of sufficient diameter to take both loads. One bearing is then mounted entirely free circumferentially so as to take the radial load, while the other bearing is mounted between the shoulders, and takes the thrust load.

Figs. 19 and 20 show thrust loads on a collar bearing in one direction only. Here the stationary race is provided with a spherical seat so that it will distribute the load over the complete circle of balls. In order to permit compensating shifting, the fixed seat must be radially free of the shaft or of the housing. The shoulder on the shaft should be large enough so as not to permit any bending strains on the rotating race. When it is inconvenient to provide a large enough shoulder on the shaft, a washer can be inserted between the shoulder and the race, as shown in Fig. 20. In Fig. 21 is simply shown a modification of the bearings in Figs. 19 and 20. This bearing takes thrust loads in two directions on two collar bearings. Fig. 22 shows an arrangement by which thrust load in two directions may be taken up by a single collar bearing. This arrangement is one which economizes space, cost of bearings, and number of parts. Fig. 23 shows an arrangement where a radial bearing is used for taking the radial thrust, and a collar bearing is used for taking the end thrust. Fig. 24 shows an arrangement for taking up radial load as well as thrust load in two directions, these loads being carried on one radial bearing and two collar bearings. In this design attention may be called to the distance piece inserted for binding the inner race of the radial bearing against the shoulder of the shaft.

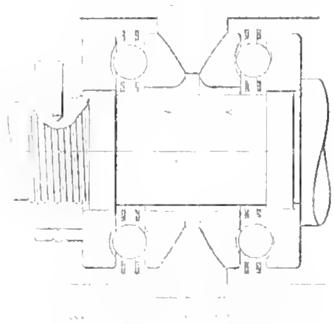


Fig. 21. Thrust Load in Two Directions on Two Collar Bearings.

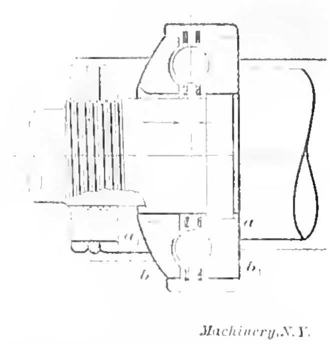

Fig. 22. Thrust Load in Two Directions on One Collar Bearing

It is occasionally inconvenient to arrange the bearing so that the parts of the inner races can be clamped to the shaft, or it may be desirable to have a shaft sliding through the bearing. In such cases a sleeve may be introduced on which the inner race of the bearing is firmly clamped endwise, the shaft simply resting in this sleeve. This gives a long bearing to the shaft, which would not be possible if the shaft was directly mounted in the ball race, because the peening effect of the vibrating loads would, even if the race itself was prolonged, be concentrated on a narrow zone of the shaft. A bearing of this kind is shown in Fig. 25.

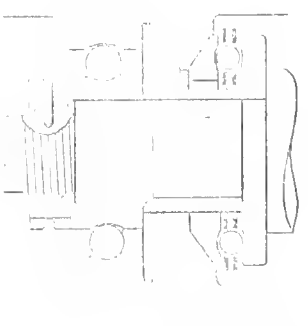

Fig. 23. Radial Load and Thrust Load in One Direction

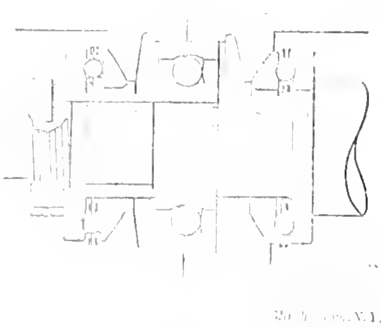

Fig. 24. Radial Load and Thrust Load in Two Directions

In Fig. 26 is shown a bearing which is intended for shafting which may not be fully to standard size. The inside of

the ball race is tapered, and a split bushing, tapered on the outside as shown, will, when tightened, bind the shaft as well as the race to it, and will compensate for all variations in size. The nut should not be used to draw the bushing in, but should merely act as a lock to hold it in place after it has been driven home with a soft hammer.

Ball bearings should always be enclosed so that lubricant will not be lost by leakage, and so that foreign matter will be excluded. Fig. 27 shows an efficient way of enclosing a ball bearing without using any packing. At the end where a shaft passes out of the enclosure, a flange should be bored out about 0.020 inch larger in diameter than the shaft. This flange should be separated into two lips by an angular groove, either cored or bored, as shown at *A*. These lips should not be less than 1/8 inch wide and should have sharp edges. The groove should be provided with a hole or narrow slot *B* at its lowest point to communicate with the bearing oil space. The groove itself should have a width of not less than 3/16 inch,

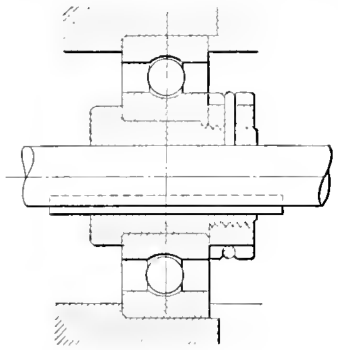

Fig. 25. Shaft Free in Longitudinal Direction in Inner Race.

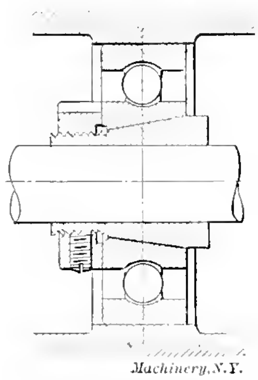

Fig. 26. Adapter Bearing for Shafting varying from Standard Size.

and a depth of about 5/16 to 3/8 inch, and should not be filled with packing material. Fig. 28 shows an arrangement of a similar kind, excepting that here is introduced a second groove and a third lip. This arrangement is employed where water may be occasionally encountered, and will prevent its entrance. What little may find its way past the outer lip into the outer groove is soon drained out again through the holes provided.

Where much grit is encountered, as in grinding machinery, a packing may be necessary, and filling the outer groove with a fairly consistent grease will provide such a packing without introducing friction. A bearing of this kind is shown in Fig. 29. A grease cup of the spring loaded piston type will automatically maintain the integrity of this packing. In some cases felt ring packings may be used, but these ought to be soaked in good soft paraffine, and a spring wire ring should be placed around the felt washer so as to force the

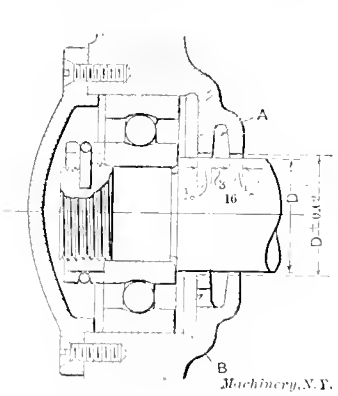

Fig. 27. Example of Enclosed Bearing.

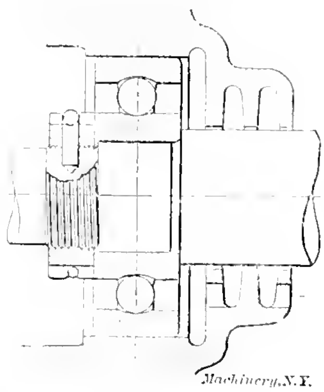

Fig 28. Bearing Enclosure with Double Groove.

outer edges of the washer outward, which will cause the felt to come into more intimate contact on the sides. Felt washers may also be applied as shown in Fig. 31. Here the washer is tapered on one or on both sides, and the sealing of the enclosure is made entirely against the sides of the surfaces against which the felt washer bears. The felt washer is pressed inwards by means of springs on the outside. The two modifications shown in Figs. 30 and 31 are intended to be inserted between the faces of the stationary boss and the rotating hub. The modification in Fig. 32, however, is enclosed entirely within one or the other. A felt ring is set into a counter bore and held in place by a light metal cap sprnng into position.

The author concluded his paper by saying that, on account of the time and space available at the society's meetings and in the society's transactions, much has been omitted in regard to ball bearings that might have been well considered, and

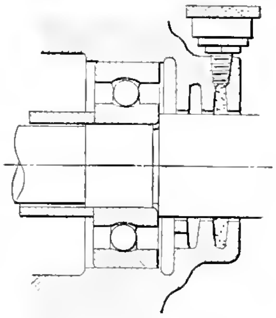

Fig. 29. Enclosed Bearing with Grease Packing.

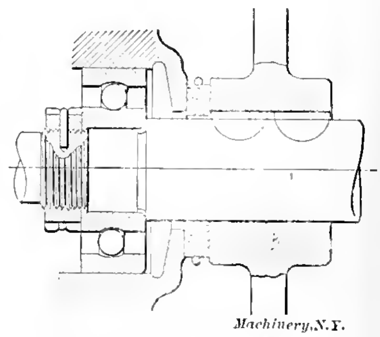

Fig. 30. Felt Ring Packing.

the author hoped in the future to make such contributions regarding the development of ball bearings as would appear to be of general interest.

In a paper regarding the economy attainable by the use of pneumatic tools, in preference to hand labor, for such operations as chipping, calking, drilling, riveting, etc., in British practice, Mr. C. P. Whitcombe states that the following comparison of the relative speed of turning out work by pneumatic tools and by hand labor has been compiled from actual results. It is not claimed that these speeds are applicable to all classes of work, but that they can be generally attained and sometimes even exceeded:

	Speeds.	
Description of Work.	By Hand.	By Pneumatic Tool.
Heavy chipping	1	2 to 4
Calking	1	3 to 4
Drilling	1	3 to 4
Rimering	1	4 to 6
Riveting	1 (3 men)	$1\frac{1}{2}$ to $2\frac{1}{2}$ (2 men)

Figures recently prepared by a leading English firm for their own information showed that a weekly saving of more than \$2 was being effected in wages for every \$1 of running

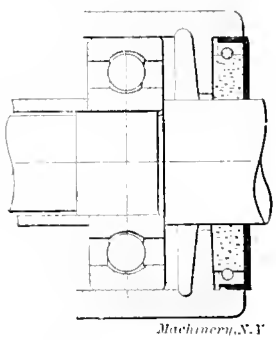

Fig. 31. Angular Felt Ring Packing.

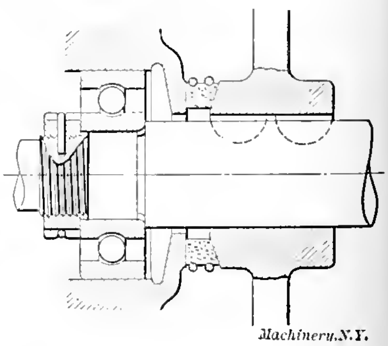

Fig. 32. Modification of Felt Ring Packing in Fig. 30.

cost of the pneumatic plant, the latter including interest on capital outlay, depreciation, power charges, maintenance and repairs.

A new example of the reliability feature of motor cars is given by the recent trials of a six-cylinder Hotchkiss car, which, according to the *Practical Engineer*, during its tests accomplished 21,250 miles, the longest trial on record, being 6,250 miles more than has been attempted by any other car. Of this distance, 10,474 miles was covered without a single involuntary stop.

TESTING THE DIVIDING HEAD OF THE CINCINNATI MILLING MACHINE.

The matter of inspecting work properly is a difficult problem to deal with, whether that work consist of parts of machinery, finished machines, drawings, calculations, or what not. There are so many ways in which a thing may be wrong that it is easily possible to neglect looking for one of the many in the course of a long day's work. Again, it is remarkably easy to follow another man's mistakes. Besides this, it takes remarkable strength of will to inspect as carefully and honestly at the end of nine or ten hours of work as at the beginning, or at the end of a year's work as at the commencement of it. The greatest aid an inspector can have in passing on the correctness of machine parts, machines or drawings is a regular laid out schedule telling him what to look out for, and establishing, in the case of machinery, the allowable limits of error. With a carefully planned schedule of this kind, the inspector can examine and check off each point item by item, and thus be able to do this work acceptably with no greater strain than the expenditure of that degree of care and intelligence which must be part of his equipment, if he is at all fit for his position.

Fig 1. A Sample Inspection Sheet for Cincinnati Dividing Head.

We illustrate and describe herewith the method pursued by the Cincinnati Milling Machine Co. in inspecting its dividing heads for workmanship and accuracy. The method of inspection pursued involves not only the regular schedule of investigation of which we have just spoken, but a carefully laid out series of inspection operations as well, with appropriate tools provided for the purpose.

The printed schedule is shown in Fig. 1. As may be seen, this is divided into two sections, the first of them dealing with items of fitting and workmanship which have to be checked by both the assembler and inspector; the second part gives a list of the maximum errors allowed in certain measurements and alignments, with a blank column in which the inspector records the results of his tests of these various dimensions. We are told by the manufacturers that this inspector's test sheet was drawn at random from a lot of fifty, it being the result of the inspection of a 10-inch dividing head examined on September 18, 1907. The inspection is made as nearly as practicable in the order listed on this sheet.

As previously stated, attention is first of all given to the workmanship on the different parts of the mechanism, each of which must come up to the required standard before the workman passes the head on to the inspector. At first glance, it might appear that these items need not be on the test sheets, since any good workman would naturally give these details his attention when assembling the head. However, experience has proven that it is best not to leave this to the workman's memory, it being better to remind him of the standard of excellence required and the test to be made on each of these parts by detailing each item on the test sheet. It is evident that the accuracy tests cannot be made until all of the mechanism has passed inspection.

For the tests relating to accuracy, various special tools are provided, with carefully worked out methods of procedure. The first test relates to the accuracy of the front taper hole in the spindle. Fig. 2 shows the operation with the special devices used. A test plate or table is provided, having a T-slot accurately made to standard size, into which the tongue of the dividing head fits. This table has a rearward extension provided with a knee the use of which will be explained later. In the front taper hole of the spindle is inserted a hollow test bar, with a taper shank carefully fitting the standard taper to which the hole is finished, and carefully made so that it is known to be straight, true to diameter and concentric, far within the usual limits of error in such work. The gage used is one of the American Watch Tool Co.'s test indicators—used on all their other accuracy tests as well. It is graduated to read to thousandths of an inch, and the graduations are so far apart that it is easy for an experienced workman to estimate halves and quarters of a thousandth. The shank of the hollow test bar having been carefully cleaned and lightly driven into the carefully cleaned taper hole of the diving head spindle, the indicator point is brought to bear on its outer end at a distance of 18 inches from the nose of the spindle. When the bar is revolved through the indexing mechanism, the error may be read direct from the indicator dial. The maximum error allowed is 0.0015 inch. In the present instance, the head showed an error of 0.001 inch, that is to say, 0.0005 on each side of the true position.

The second test determines the truth of the front taper hole by resting the indicator point against the side of the hole, the reading being taken in the same manner as before. The maximum error allowed on this test is 0.00025 inch, and in the present case the head tested within this limit.

The third test relates to the alignment of the spindle with the T-slot on the table. A little thought will show that in measuring this from the test arbor there is danger of introducing into the measurements the error of the untruth of the taper hole, previously determined, unless some provision is taken to eliminate that error. This is done very simply. First the test arbor is rotated with the indicator bearing on its side, until the "high point" is found. This position having been located, the spindle of the head is rotated 90 degrees, so that in Fig. 3 the "high point" would be at either the top or the under side of the bar. Under these conditions it is obvious that the two sides of the bar are for all practical purposes parallel with the axis of the spindle. The special standard on which the test indicator is mounted in Fig. 3 has a tongue which engages the T-slot of the fixture table. Readings with the indicator are taken at different points on one side of the bar. The difference between the largest and smallest of these readings gives the amount by which the arbor (and therefore the taper hole in the spindle) is out of alignment. In the present instance this error was found to be 0.001 inch in 18 inches. The maximum error allowed is 0.001 inch.

This is followed by a test to determine whether the center of the spindle is in the same vertical plane with the center of the T-slot. It is a repetition of the preceding test, except

that in this case the readings are taken at several points along both sides of the bar, the base in which the indicator is mounted being turned around in the slot to bring the measuring point on the other side of the spindle for this purpose. The readings on both sides for each position are noted and their difference taken; the difference determines the error. In the present instance there was an error of 0.001 inch in 18 inches, while a maximum of 0.002 inch is allowed.

Following this, comes a test to determine the alignment of the head- and tail-stock centers. This is shown in Fig. 4, and is a repetition in most respects of the test shown in Fig. 3, except that in this case an accurate test bar 12 inches long is held between centers. The tail-stock has a reversible center bar with a large center on one end and a smaller center adapted for the lighter classes of work of small diameter on the other end. Both of these are tested for alignment, and in the present case showed an error of only 0.0005 inch.

Since it is expected that the dividing head will sometimes be used with the work spindle clamped in any position between the limits through which it may be swiveled, a test is also made to determine whether or not the spindle swivels in a plane perpendicular to the top of the table. In this test the head is set so as to bring the spindle in a vertical position. The test bar is inserted in the spindle as shown in Fig. 2. The indicator is then mounted on a stand similar to that shown in Fig. 3. This is rested against the face of the vertical surface of the test block, and by taking several readings along the side of the test bar, the parallel relation of the bar with the face of the vertical surface of the test block is at once determined. In the present instance the error found was 0.001 inch, while the maximum allowed error is 0.0015.

Perhaps the most ingenious and interesting of the tests is that used to determine the accuracy of the indexing. To test this, the apparatus shown in Fig. 5 is used. An arbor is placed in the taper hole of the spindle and on this arbor are clamped two disks, having nicely finished ground edges of the same diameter, matching each other so as to form an unbroken surface. To the testing plate is fastened a bracket carrying a marking device which, by the operation of the

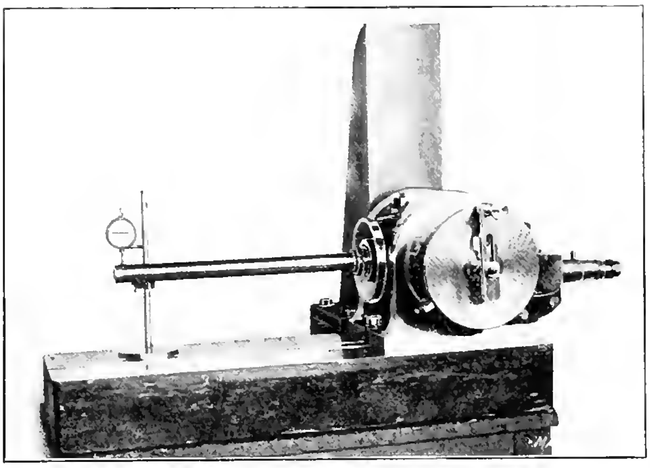

Fig. 2. Does the Taper Hole run True?

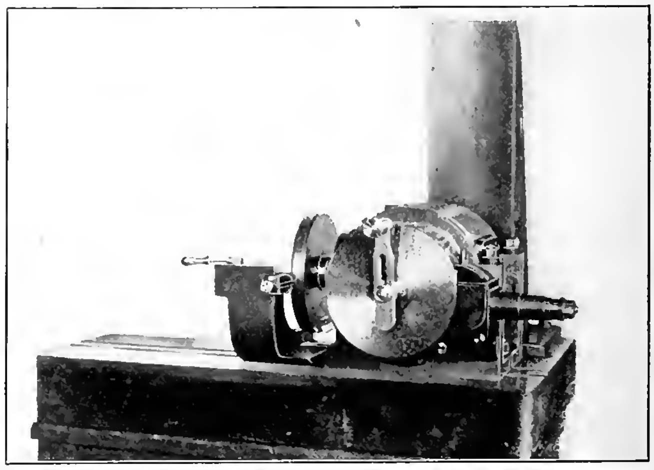

Fig. 5. How Accurate is the Index Worm-wheel?

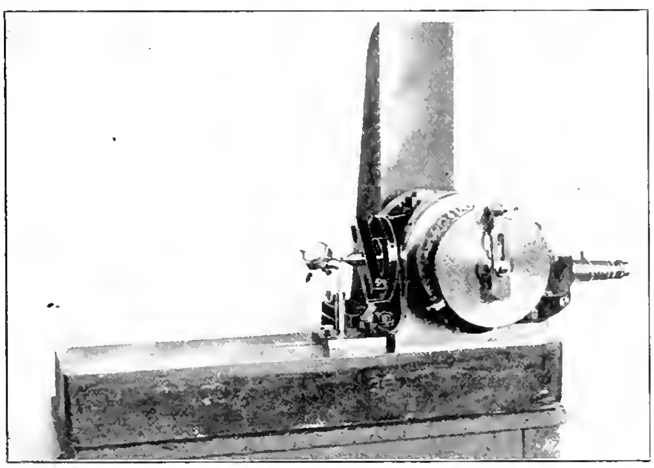

Fig. 6. Does the Center run True?

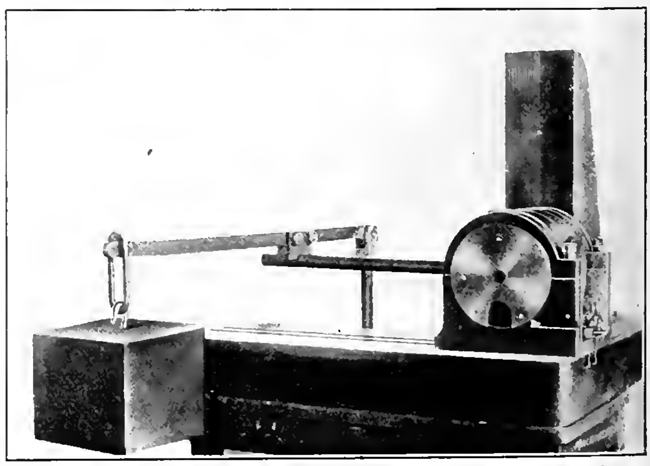

Fig. 7. Do the Clamp Bolts hold the Head firmly from Turning?

small lever shown, scribes a fine line of uniform thickness across the edge of the two disks. The spindle is indexed for forty divisions and a line scribed after each indexing. Then the arbor holding the disks is removed from the dividing head, grasped in a vise, the clamp bolt is loosened, and one of the disks is rotated successively to seven different positions, each one-eighth of the circumference ahead of the preceding one so that in each case the first line scribed on it exactly matches the line on the other disk, corresponding with the selected position, and for each position the lines in the one-fourth of the circumference immediately ahead are examined for alignment under a strong magnifying glass. Their non-alignment indicates the error in the index mechanism, and may be estimated by an experienced man to very close limits. In the present instance the maximum accumulative error found in any one-fourth of the circumference of the disks was 0.0005 inch.

The above method of testing is frequently checked by the following plan: Instead of scribing hair lines across disks in Fig. 5, slots 1/4 inch wide and 1/4 inch deep are milled into them. Pains are taken to make these slots exactly to gage. Then the work is removed from the dividing head and the slots are compared by lining up any two of them the same way as in the previous test, except that in this case it is done by inserting a standard gage of sufficient length to fill both slots. The alignment of the other slots is then compared by testing with special gages. These gages are made 0.00025, 0.0005, 0.00075, 0.001 inch, etc., below standard, and obviously the amount that any given gage is below standard indicates the error or amount of non-alignment of those two slots into which it fits snugly.

Since accuracy in the other parts of a dividing head is of no great value when doing work between centers unless the head center itself runs true, this part is also tested, as shown in Fig. 6. This is a repetition of former tests, except that here the indicator point rests against the point of the head center, and when this is revolved through the index mechanism, the error may be read from the indicator. The maximum error allowed on this test is 0.00025 inch.

Besides these thorough inspection tests, others are made of the separate parts in the course of manufacture, and in the preliminary stages of the assembling. One of the most interesting of these, shown in Fig. 7, is employed for testing the rigidity of the clamping device by which the head is held at the proper angle. As shown, a bar 24 inches long is placed in the hole of the work spindle. A lever carrying a 200-pound weight on one end is then brought to bear on this bar at a point 22 inches from the swiveling center. The arms of this lever are in the ratio of 3 to 1, so that the total pressure brought to bear on the bar is 600 pounds, at a point 22 inches from the center of swivel. Every head must undergo this test without any evidence whatever of failure on the part of the clamps to rigidly hold the swivel block in position.

The dividing head is a most important part of the equipment of the milling machine, particularly in the case of the universal type. Its accuracy is trusted implicitly in many operations, and on its accuracy depends the accuracy of the work. We think it will be agreed that dividing heads that have successfully passed the tests outlined above are worthy of reliance in all ordinary operations.

* * *

There is very little literature on drop forging or "machine blacksmithing," which seems strange considering the importance of the art. The editor would gladly receive a good contribution on the subject. Any reader of MACHINERY who feels that he could write such an article will please communicate.

* * *

There are some curious misnomers in common use as, for example, "cork" legs, the name commonly applied to artificial limbs, which are not made of cork at all, but wood, the qualifying adjective being the name of the inventor. John Cork made the first wooden legs in the early part of the 19th century, his product being the first successful substitute for the "peg-leg." No artificial legs are made of cork, elm or willow being almost always used in preference to any other material.

TESTING THE LEAD OF TAPS AND SCREWS.

ERIK OBERG.*

In cases where there is no necessity of ascertaining the exact error in the lead of a screw or tap, and when only a limited number are to be tested, a fairly good test is afforded by simply screwing the thread into a female gage. The threaded portion of this latter should then, however, be fairly long, so that errors in lead, which are liable to be very small in a short distance, may be detected by taking account of the error in the comparatively long length. Ordinarily, however, when quantities of taps are to be tested, the errors in lead are most easily ascertained by some device particularly in-

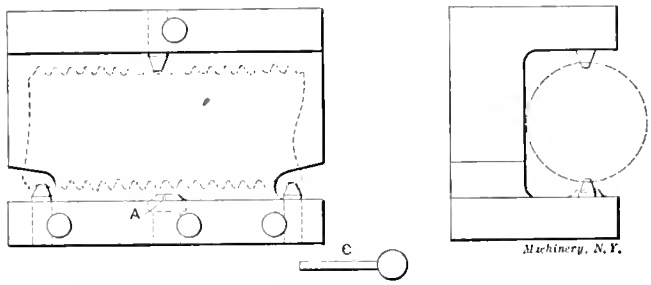

Fig. 1. British Gage for Simultaneous Testing of Lead and Angle Diameter.

tended for the testing of the lead of a screw thread alone. Some devices which test both the lead and the diameter within certain limits are also in use. Of these latter, two examples are shown in a report on British standard systems for Limit Gages for Screw Threads, presented to the Engineering Standards Committee of Great Britain.

Testing the Lead by Gages.

The first of these gages is shown in Fig. 1. In this gage, allowance is made for a permissible error in angle diameter and lead. As is plainly shown in the cut, the screw thread enters between three fixed points, shaped like the thread, two of which are located in the lower jaw of the gage, and one in the upper. The distance between the two points on the lower part of the gage should be equal to about twice the diameter of the screw. The fixed point in the upper jaw should, of course, be placed midway between the points in the lower jaw. At *A* is shown a ground flat face which is so adjusted that the small cylinder *C*, of such diameter that it will touch the thread about half way down its depth, will barely enter between the flat face and the thread of the bolt for the *minimum permissible* diameter, but will "not go" as a general rule. This device then gives a practical test for both diameter and lead. If the lead were out too much, the screw would not enter the gage, because the two points in the lower jaw would not fit the pitch of the thread, these points being, of course, set to a standard gage. If, again, it could be conceived that the diameter was so much smaller than the standard that the screw or tap could be placed in the gage in spite of the lead being an appreciable amount long or short, then the feeler *C* would enter so freely between the face *A* and the screw as to indicate that the screw was not within permissible limits. It will be noticed that provision is made for getting the points entering the threads placed exactly in the center of the screw. In the end view, the screw is indicated resting up against the back of the gage with one side, the distance from the back of the gage to the center of the points being equal to half the diameter of the screw. It is

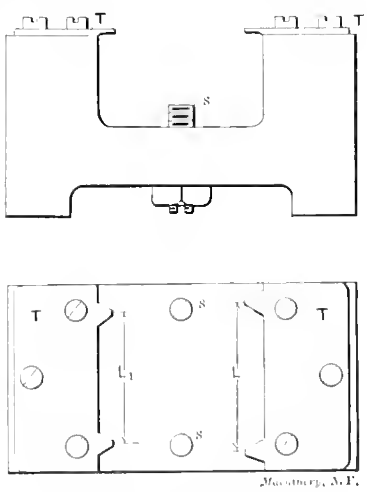

Fig. 2. Maximum and Minimum Gage for Lead and Angle Diameter

* Associate Editor of MACHINERY

evident that gages of this kind will have to be made for each separate diameter and pitch.

Another form of gage intended to deal with shorter lengths of thread than the one just described is shown in Fig. 2. In this case, two separate gages are applied, one minimum and one maximum. The screw is supposed to enter into the one and refuse to enter into the other. In this gage the top plates T are made of hardened steel and contain V-teeth set as shown, the distance L representing the next even number of threads immediately above the number contained in a length of screw equal to the diameter of the thread, while the distance L_1 is one thread shorter. The plates are screwed, and preferably doweled, to a base plate, and are, of course, made and adjusted to a standard plug. At s are shown screws which can be so adjusted that the measurement can be made exactly at the center of the screw, the distance from the faces of screws s to the center of the gage plates being equal to one-half the diameter of the screw.

Comparators for the Lead of Taps and Screws.

When it is wanted, however, to determine the errors in pitch with some exactitude, and not only to find out whether the error is between certain limits, then the instrument termed thread comparator is used. This consists, in its simplest form (see Fig. 3), of a fixed block A and a sliding block B provided with ball points. The sliding block operates a pointer C, which on a large scale indexes the errors of lead. The manner of using this instrument is as follows. A standard plug is first placed against the device so that the ball points enter in threads, say one inch apart. The position of the pointer on the scale is noted when the standard plug engages the ball points, the free block B adjusting itself to the thread into which its ball point enters, and carrying with it the pointer C. Next, the tap or screw to be tested is placed in position against the device. If the lead of this screw or tap is correct, and is the same as that of the plug, the pointer will evidently occupy the same position in relation to the scale as in the case of the plug. If the tap or screw is long or short in the lead, the pointer will show the amount on the scale by swinging either to the left or to the right. The scale should, of course, preferably be graduated so as to show thousandths of an inch.

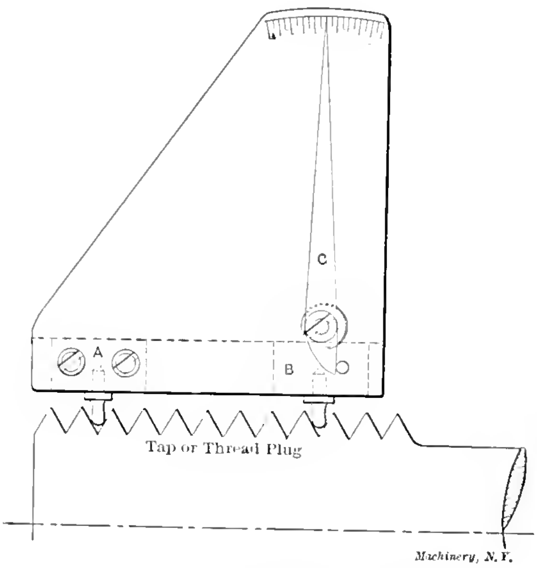

Fig. 3. Simple Form of Comparator for Lead of Screw Thread.

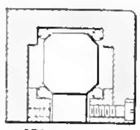

SECTION IN S-S

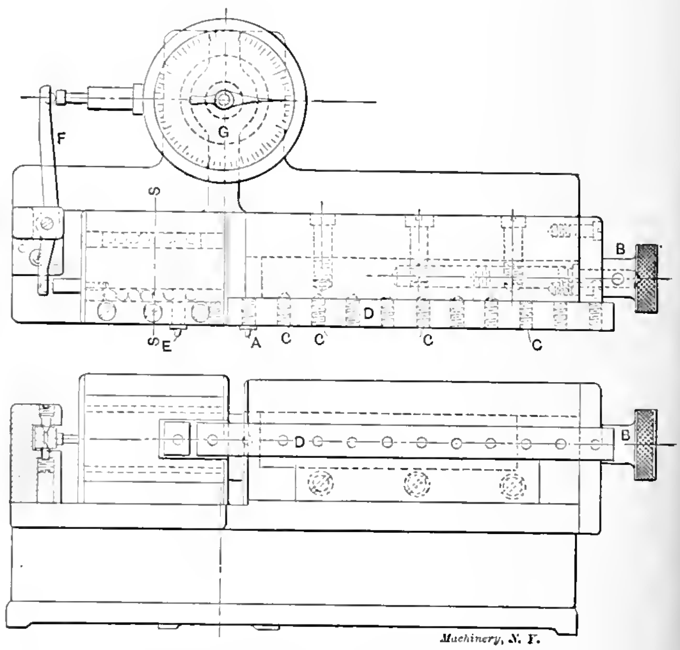

Fig. 4. Comparator for Testing Lead of Taps and Screws.

A more elaborate device for measuring the errors in lead of taps is shown in Fig. 4. Here one ball point A, which we may call the fixed, is mounted in a slide D, which latter is operated by a knurled head screw B. Ball point A may be screwed into any of the holes C, which may be ½ inch apart; thus one may, with this device, measure the lead in one inch, or in any length up to six inches, as may be desired, by moving the ball point A to different positions in the slide D. The ball point E is inserted in a movable block resting on a ball bearing. This block, in turn, is connected through the lever F with the indicator or sensitive gage G, which should be so arranged and graduated that each thousandth inch can be easily read. When the standard plug is placed against this device, the ball points entering between threads in the same way as in the former device described, the slide D can be so adjusted by the knurled head screw B that the indicator points to zero. When the screw or tap to be tested is placed against the ball points, any error will then be apparent by the motion imparted by too long or too short lead to the movable ball point E. This motion, of course, is, through the lever arm F, carried to the indicator. If the latter is graduated in thousandths of an inch, the graduations below or above zero will indicate the amount in thousandths of an inch that a tap or screw is short or long in the lead in the distance originally measured on the plug, *i. e.*, the distance between the ball points when the plug was placed in position against the device. In the device shown, the length of the lever F, between its pivot and that end which is operated by the movable block, is half of the length between the pivot and the end operating the gage. Consequently, if the gage be graduated to show movements of 0.001 inch on its own plunger, it will indicate a motion of 0.001 inch on the movable ball point by moving two graduations on its own scale. Very close measurements are consequently possible.

Of course, this device is only one modification of the many possible for obtaining the same results. Very likely there are others equally good, but this one is shown as an example of a satisfactory design, and at the same time as an indication of the principles involved in the design of comparators for the lead of screw and tap threads.

* * *

MACHINERY'S REFERENCE SERIES.

In the advertising section of this issue, announcement is made of a series of valuable reprints from MACHINERY. During the past fourteen years a large number of articles on machine design and shop practice has been published in its columns, all well worth preservation in permanent form. A number of well-known books first appeared by installments in MACHINERY, but these represent a comparatively small part of the valuable technical material that has appeared therein. The remainder represents the shorter contributions of many designers and others connected with the best constructive work. In order to make it generally available, we have selected the representative articles and divided them into groups, each group devoted to one subject, which will be published in 6 x 9-inch pamphlets, ranging from 32 to 48 pages. These pamphlets will contain only such articles as are considered to be of the most practical use, and they will be edited and condensed so as to be "all wheat."

LETTERS UPON PRACTICAL SUBJECTS.

REDUCING THE DIAMETER OF TOOL STEEL UNDER THE STEAM HAMMER.

It is often necessary to reduce the diameter of a piece of tool steel from its original size to perhaps one-half that diameter. This is very common in the making of taps and reamers of large diameters, where it is wanted to have the shank of considerable smaller diameter than the main part of the tool itself. It is evident that it is a great deal cheaper to forge down the diameter of the shank in such cases, than to use solid stock of the full diameter of the tool, and reduce it by turning, but it is necessary that the work of reducing the diameter under the steam hammer is done in the proper manner. Many blacksmiths do not seem to know how this work should be properly accomplished. I have seen many of them take a bar of steel, put it into the fire, leaving it there until the bottom side had arrived at a red heat, and then turn it and leave it in the fire until the other side got heated, paying no attention to the uniformity of the heat of the piece. The work is then taken to the steam hammer and reduced by continually rolling it around on the sides until it is reduced to the size wanted.

The result of this procedure is always a forging with a spongy or "piped" center. When this sponginess is finally detected in the tool, the steel is blamed as being poor, but as a matter of fact, in most cases, the steel has been satisfactory to start with, and the fault is to be found in improper treatment in the blacksmith shop.

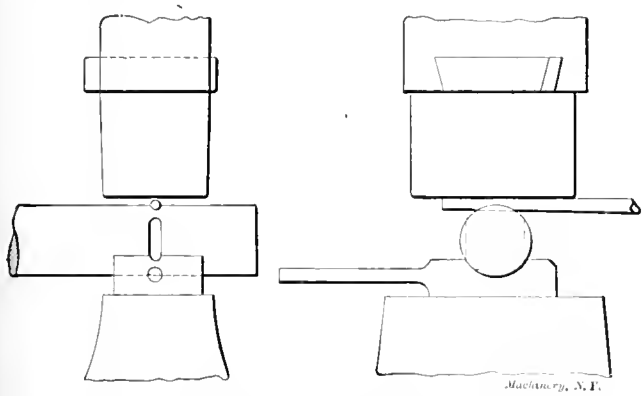

Fig. 1. First Operation in reducing the Diameter of a Tool Steel Bar under the Steam Hammer.

The proper way to reduce the diameter of a piece of tool steel is to first heat it uniformly, and then place it in the steam hammer as shown in Fig. 1. The blacksmith then proceeds to mark the bar on all four sides with a $\frac{3}{4}$-inch round machine steel bar, long enough to hold by the hand. This marking is intended to give a guidance as to the amount of reduction necessary. When the four sides have been marked as in Fig. 1, then proceed to mark the four corners in the same manner. The piece is turned around from one side to the diametrically opposite, receiving a blow each time, until a groove all around the piece is made to the proper depth. Then the diameter is reduced by hammering first on one side, and then on the opposite side of the piece, until a square of the size wanted is produced, as shown in Fig. 3. Then the four corners are hammered in a uniform manner until the piece gets an octagon shape, as in Fig. 4. Next the eight corners of the octagon are hammered down, making sixteen sides, always making sure that the next corner hammered down is diametrically opposite the one just operated upon. Finally, if a swage of the proper size is on hand, the piece can be rounded with this; otherwise when all the corners have been reduced so that they are hardly visible, it is possible to round the piece nicely with even hammer blows until the correct size is arrived at. In Fig. 2 are shown the consecutive shapes assumed by a piece of steel worked down in the manner described.

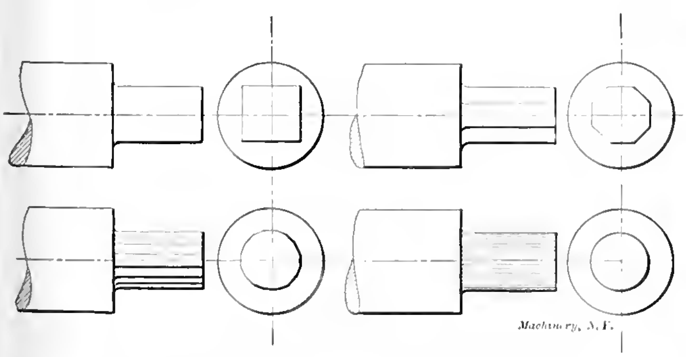

Fig. 2. Successive Steps in reducing the Diameter.

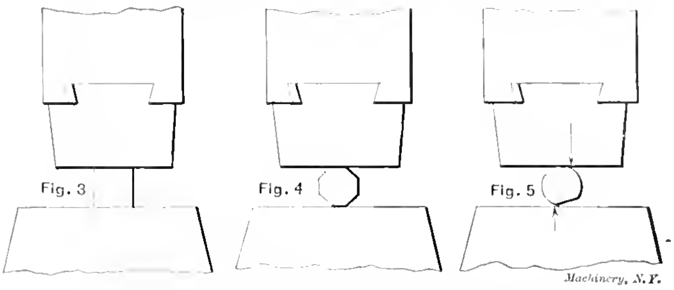


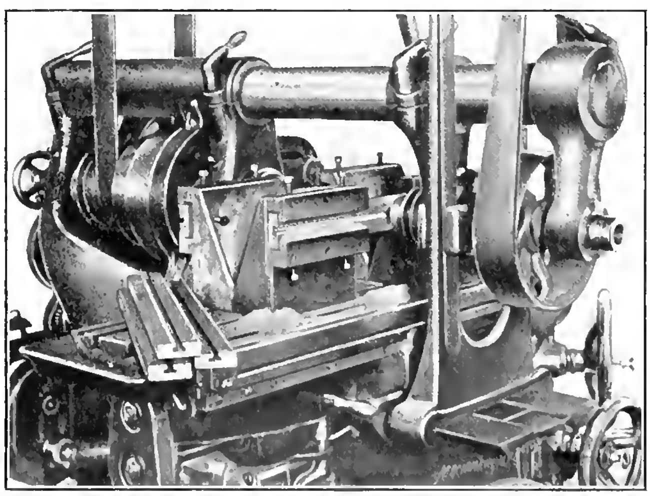
Figs. 3, 4 and 5. Illustrating Corrrect and Incorrect Methods of reducing the Diameter.

It is evident that by rounding continually after the first blow is struck, the blow, as shown in Fig. 5, is not directed on a point that has a firm support directly under it, and a kind of twisting action takes place, causing one-half of the bar to have a tendency to slide in relation to the other half of the bar, the result being that the center of the bar is spoiled, and a spongy or, perhaps, a piped center results. In some cases this hollow center is of no consequence, as, for instance, when a hole is drilled through the piece, but it is evident that all efforts should be directed to avoiding results of this kind.

Decatur, Ill. GEO. T. COLES.

DOUBLING THE CAPACITY OF THE MILLING MACHINE.

The half-tone shows an improvised duplex milling machine. The machine, a Becker-Brainard No. 3, was provided with two arbor supports so designed that the arbor passed through them allowing the supports to be adjusted close to the cutter. The extra spindle is journaled in the outer arbor support, and in addition to this there is an inner journal which is supported by a bracket which is clamped to the knee of the machine. In this way the spindle is rigidly supported. This inner journal, and the bracket which is clamped to the knee, is clearly shown in the illustration. The spindle was taken from a heavy vertical milling attachment, and it was driven by the pulley as shown. An extra pulley on the counter-shaft was, of course, needed. This rig gave much satisfaction, and it was entirely a shop get-up. Few of us who profess to be machine designers would ever think of any such rig as this. The man on the job simply had so much work of a certain



Attachment for Milling Two Pieces Simultaneously.

class to do, that he sought for some way of doing the work more rapidly, and this attachment was the result.

The work, as can be seen, was that of milling tee-slots in strips which were used for holding trip dogs. These strips were about 20 inches long. The fixtures for holding the work are also worthy of mention. They are simple, but effective, as they hold the work securely. Because of their simplicity, they are easily operated, and they are not likely to get out of order. The work which is not finished on the edges, is milled on the top and slotted. The fixture is so arranged that this milled surface is used to line the work up sideways. The screws, which are shown in the illustration, are used to adjust the work lengthwise until the slot is parallel with the table. This work might be done on a vertical machine, but there is an advantage in having it in the position shown, as the cutter can more readily free itself of chips. This advantage is more marked when the cutter is fed in such a direction that it cuts into the metal from underneath so that the teeth carry the chips up over it and drop them in its wake, instead of contiuually dragging them into the cut, as would be the case should the cutter run over and into the work.

Work, other than that shown, might be done to advantage in this way, as the fixture is quite inexpensive even when made specially for the work, the only parts necessary outside of the regular equipment, being the spindle and pulley. I trust that some of the readers of MACHINERY have been looking for something of this kind; if not, it may suggest something else which will prove to be a time saver, and give just as good satisfaction. JOHN EDGAR.

Hyde Park, Mass.

[A similar scheme for doubling the effective capacity of small milling machines was illustrated in the article "The Manufacture of Colt's Automatic Army Pistol," May, 1906, issue.—EDITOR.]

NOVEL METHOD OF PRODUCING THREADS.

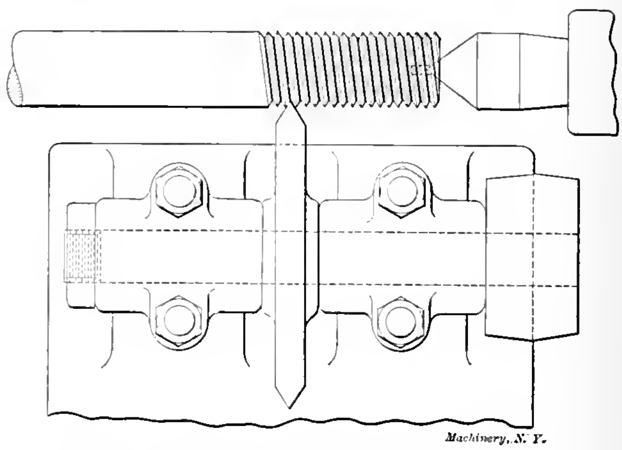
The accompanying cut illustrates a method used for threading studs, pins, etc., of manganese steel, this material being so hard that it cannot be cut by any kind of tool steel. A plain, hardened tool steel disk, having the edge made according to the angle of thread, is employed. This disk is revolved at a high speed, and at the same time forced into the work, which is revolved slowly. Due to the friction between the edge of the disk and the work, and the softening of the material, owing to the heat generated by the friction, the disk wears away the stock, and, by means of this, creates the thread. The stock is coming off in very small, thin scales like chips, which to some extent remind one of the scales of a fish. An ordinary lathe has been rigged up for the purpose of removing the tool-post and top-rest, and substituting for them the fixture shown in the cut. The disk must be driven independently by an overhead drum, or some similar arrangement.

The peripheral speed of the disk is usually between 3,000 and 4,000 feet per minute. The operation is unavoidably slow and expensive, and the method is used only when no other way is possible. The writer thinks, however, that the efficiency can be increased to some extent by increasing the peripheral speed of the disk, perhaps as high as 24,000 feet per minute, same as used on friction saws.

It is likely that high-speed steel would be preferable to ordinary tool steel as material for the disks, but, as the process described is necessarily slow, and is used only when no other way of threading is possible, it has not as yet been developed to the limit of its capacity. There is a certain point in the gradual development of the method above which it becomes economically preferable to employ high-speed steel for the disk, but below this point of development, although high-speed steel may be the best, the ordinary tool steel disk, owing to its smaller first cost, is economically the one to be preferred. A preference for the one or the other kind of steel is influenced by a number of factors, *viz.*, the number of pieces to be threaded per unit of time; the peripheral speed of the disk; the pressure between disk and work; and the efficiency of the system of cooling.

The question of cooling is in itself an interesting one. The reason why the heat does not draw the temper of the tool steel in the disk while the heat is so great that it softens the metal of the work, is that the disk is revolving at a high speed and the work only revolving very slowly, so that a unit of length of the periphery of the disk is in contact with the work but a very short time, while every point on the work, at the place where it is cut, is in contact with the disk a comparatively long time. Owing to this the disk has ample time to cool off, while the work accumulates the generated heat. The high speed of the disk also throws the film of air nearest to the disk outward, owing to the centrifugal force, and new cool air comes constantly in at the center, a current of air thus at all times tending to cool the disk.

The cooling thus obtained is found to be satisfactory at the present speed at which the disk is run, but at a higher speed



Cutting Thread by a rapidly revolving Hardened Steel Disk.

a system of cooling by an air jet, or still better, perhaps, by water, could be employed to advantage. This would also increase the limits within which an ordinary tool-steel disk could be used to advantage. For increasing the peripheral speed of the disk as previously mentioned, undoubtedly the best way would be to increase the diameter of the disk, permitting the number of revolutions to remain the same as before; but at the present stage of the development of this device there are some limitations to the size of the disk, inasmuch as it is used in an ordinary lathe, and the space possible to utilize for the disk is not very great. Another difficulty in increasing the diameter, rather than the number of revolutions, is that for a large diameter disk it is necessary to arrange the disk on an inclined angle in relation to the work in order to get a perfect thread, and this necessarily means a more expensive rigging.

The principle involved in this method of cutting threads is the same as that involved in the friction saw. But the principle of the latter machine cannot be carried out to its full extent in the present case, because the steel to be threaded must not be heated more than to a certain degree. Above this limit, increased heating would mean injury to the quality of the steel. The heat also must not be so high that it burns the thread.

If the call for threaded parts of this kind of steel would be great enough so that a special machine would be warranted to be built, then the efficiency of the method could be increased by a careful taking care of all the points previously referred to, but, at the present time, the demand is not large enough to warrant the expenditure of building such a machine.

High Bridge, N. J. OSKAR KYLIN.

TEMPERING DROP FORGING DIES.

It has always been a source of wonder to the writer, why so many drop forging dies are cracked in hardening, because it is not at all necessary that this should happen. Uneven heating, and uneven cooling with consequent uneven contraction is the cause of the trouble.

If drop forging dies are made from machine steel, they should be packed in No. 1 raw bone and fine wood charcoal, three parts charcoal being used for each two parts raw bone. They are then heated in an oven for eight hours, at a temperature of 1600 degrees F., and are then dipped the same as

described in the following for tool steel. When the dies are made of tool steel, let us first notice that the heating of dies or any kind of tools made from high carbon steel in an open furnace, even if covered with coke, is very injurious to the steel, especially so in the case of drop forging dies, as the carbon leaves the surface of the steel, and the dies will not harden on the outside, but will be harder further in. This

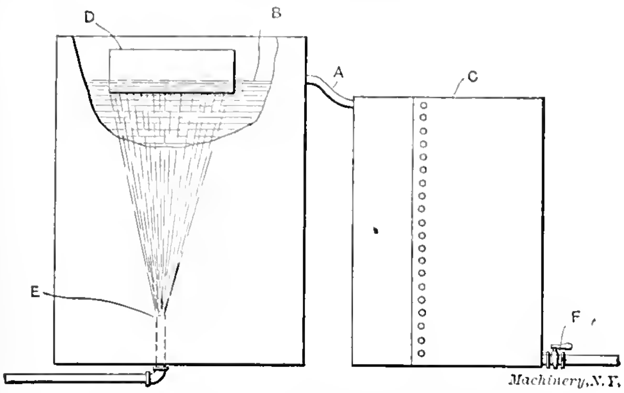


Fig. 1. Arrangement of Brine Tank for Hardening.

does not matter so much with tools that are to be ground to size after hardening, but it is a poor practice with any kind of tool-steel tools. Tool-steel dies should be packed in fine wood charcoal in a box large enough to allow plenty of charcoal between the die and the box walls, say about two inches or more. Seal the cover on tightly with asbestos cement, place the box containing the die in the furnace, and, if a pyrometer is attached to the furnace, hold the furnace at about 1,500 degrees F., leaving the die in for at least four hours. For a small die, shorter time will be sufficient, but a die weighing 50 pounds or more should be allowed four hours to heat slowly and uniformly. Then, instead of dumping the

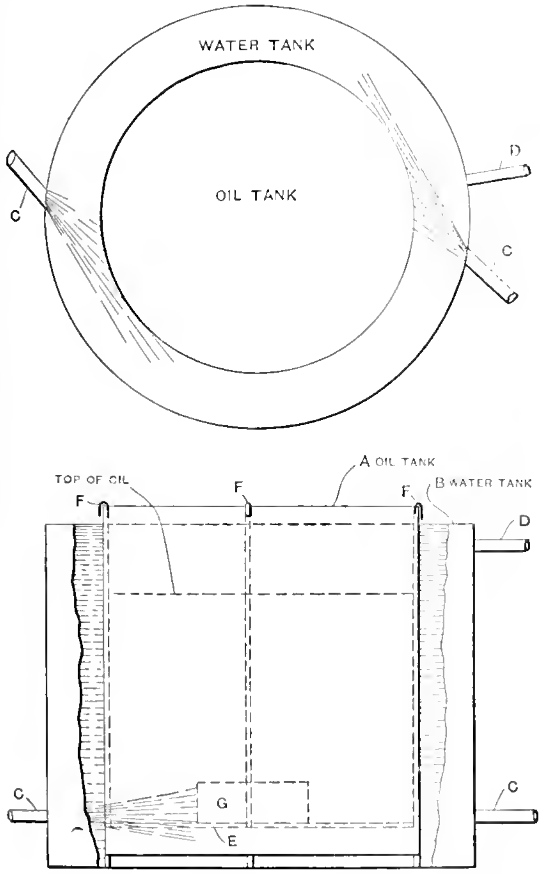

Fig. 2. Oil Tank for Hardening Room

whole die in a tank of cold, clear water, have two tanks, a large one and a smaller one, as shown in Fig. 1. An overflow pipe or hose *A* from the water line *B* in the large tank should connect it with the small tank *C*. When ready to dip the die *D*, place the face only in the water. Plenty of salt should be well dissolved in the water, about 4 pounds to the gallon; this extracts the heat from the die quicker than clear water, and prevents steam formation on the face of the die. A water pipe *E* should be carried in at the center of the large tank at the bottom, and should be supplied with water at fairly high pressure. When placing the die in the bath, open the valve of the pipe *E*, thus forcing the cold solution against the face of the die, while the warm water passes into the smaller tank. The solution collecting in the smaller tank, when cool enough, can be used for smaller tools, and, when so desired, can be run off by outlet *F*. Another bath, in an oil tank, inside of a water tank, as shown in Fig. 2 should be provided. The size of the tanks must be determined by the size of the dies to be hardened. Fish oil should be used in this latter tank, and the tank should have two water inlets *C*, at opposite sides of tank, and so arranged as to allow water to flow around all sides of the oil tank as indicated in the plan view. Pipe *D* is the overflow. A coarse mesh sieve *E* is suspended in the oil tank, and held by rods *F*. The oil tank should have four legs about 6 inches long, to allow water underneath the tank. When the die face has been cooled in the salt water solution, remove the die quickly to the oil tank, and lower it until it rests on the sieve (see *G*, Fig. 2). Let the die remain in this position until cold. It requires no further attention than removal from the oil. Dies hardened in this manner will not crack.

Lansing, Mich. J. F. Sallows.

BORING DRIVING BOX BRASSES.

The jigs illustrated in the accompanying cuts are used for holding driving boxes while their brasses are being bored. It is not claimed that these jigs, or the methods of boring boxes, which will be described, are the best in use, still they are preferable to the tools and methods employed in many shops for doing this work. Fig. 1 shows a jig which is used on a vertical boring mill. This jig is composed principally of two castings in the form of angle plates. The distance between these angle plates, or jaws, is made to suit the largest box in use, and the jaw to the left is made adjustable so that the jig can be used for the smaller boxes. When the jaw is to be adjusted, the four cap-screws which hold it are

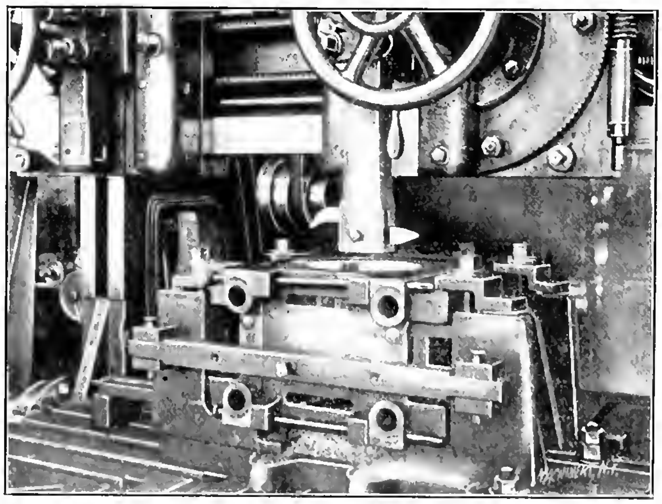

Fig. 1. Jig for Boring Driving Boxes on a Vertical Boring Mill

removed, the angle piece moved in, and the cap-screws inserted into another set of holes which were previously drilled and tapped in the proper place. The jig is provided with two tie bars, one across each end. These tie bars, one of which is shown in Fig. 1, are for the purpose of taking the end thrust when heavy cuts are being taken, and they also facilitate the adjustment of the box. The forged lugs, which hold the tie bars, are held in place by nuts, which are on the inside of the jaws. A shoe, which can be seen in the illustration, is fastened to the right jaw. The shoe faces of all driving boxes are clamped against this shoe. When a set of boxes is to be bored, one is first laid out central with the shoe and wedge faces, then this box is clamped in the jig and the jig is set by it. All the boxes are then bored without shifting the jig. The roughing and finishing tools are, as shown in Fig. 1, both clamped in one tool holder, and the roughing

and finishing cuts taken simultaneously, one cut usually being sufficient to complete the operation.

Fig. 2 shows a jig which is used when boring driving-box brasses on a horizontal boring mill. A detail of this jig is also shown in Fig. 3. The set-screws *A* provide means for adjustment, and also help to hold the box in place. The shoe face of the box is clamped firmly to the face *B* on the jig by bolts which fit into the tee slots *D*, and by a clamp which passes across the wedge face of the box. These bolts and the clamp are shown in Fig. 2. When a narrow box is to be bored, it is set central with the face *B* on the jig by

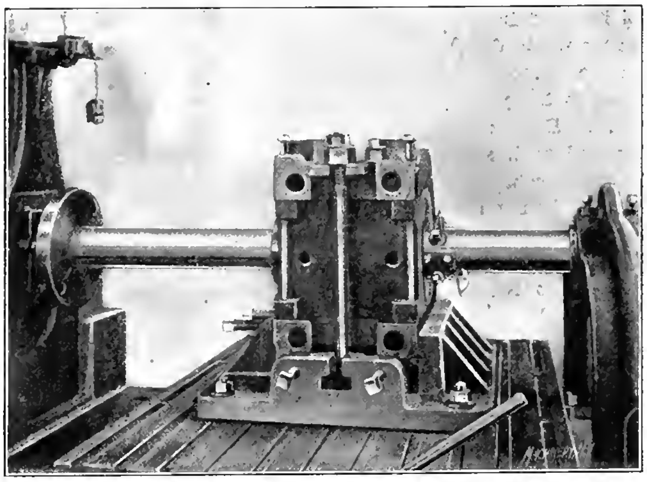

Fig. 2. Jig for Boring Boxes on a Horizontal Boring Mill.

bolting a parallel piece along the face *C*. This jig is set by practically the same method described for the vertical mill. One box is first laid out central and clamped in the jig, the jig is then set on the table, and the table set to the proper height and clamped. All the boxes are then bored without altering the position of the table. In this way, the distance from the bore to the shoe face of each box is exactly the same. Many prefer to set up each box separately, but I have found

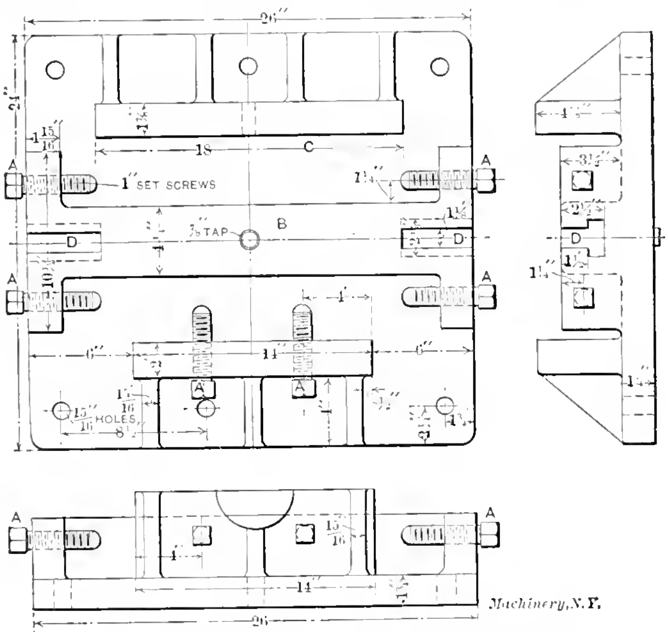

Fig. 3. Detail of Jig used on Horizontal Boring Mill.

the method described to give the best results. This boring bar also contains two tools, each tool having an adjustment which saves much time in setting the tools.

Port Huron, Mich. M. H. WESTBROOK.

THE MARVELOUS CO_2 ENGINE.

Inventive genius cannot be suppressed, not even, or particularly not, in Philadelphia. Time and again has that city seen the birth and death of the most stupendous labor-saving inventions. Though its inventors have not exactly hitched their car to a star, they have harnessed nature's forces and confined them to new and fearsome ways to do their bidding. It it not so long ago that we had Keeley with us, and not a few still lament his demise before he was able to impart the full secret of the connection between the interstellar vibrations, his fiddle, and an engine that would endlessly produce power after Keeley drew his bow.

But in the drawing of the big bow worthy successors have arisen. The confiding public is asked to subscribe to the stock of a development company, whose purpose is the creation of sub-companies, that are in turn to run engines with carbonic acid gas. The development company asks only the trifle of $10,000,000 in subscriptions. Just what is to be done with the $10,000,000 is not quite clear, unless it be presumed that the projectors consider the difficulty of inducing participation in the sub-companies such as to demand such payment. But hold! The prospectus does say: "The company has purchased from the inventor the sole ownership of the invention and all foreign and American patents pertaining to same." Possibly the company is signalizing its wide departure from nature's laws by a similar departure from the usual ones of greedy high finance, and donating a substantial portion of this $10,000,000 to the inventor as a small recognition of his genius.

One of the sub-companies to be formed is for automobile development in adapting the carbonic acid gas engine (CO_2 engine sounds more mysterious, and so spells greater possibilities) to the automobile. Who would not immediately mortgage his house, his salary, and his socks to buy a few shares at par, particularly when informed that "Last year, in the United States alone, over 160,000 automobiles were sold. If this company derived a royalty of but $100 per machine, we would earn $16,000,000." That the royalty of $100 per machine is very modest indeed must be clear, when it is realized that "an automobile will be reduced to about one-quarter of its present weight." In the automobile of to-day, the gasoline motor (so soon to be relegated into the limbo of forgotten toys), with the change gear box and radiator does take up somewhat less than three-fourths of the weight of the car. It follows that the CO_2 engine must weigh some more or less indefinite amount less than nothing. Surely a royalty of only $100 for a motor weighing less than nothing is a very modest one. Consider that a weight of less than nothing is a negative gravity, that one of our noted scientific novelists showed some years ago that a box of "negative gravity" worn on the back of its owner would set him afloat in the air, and the CO_2 company would seem to have solved the problem not only of the automobile but of aerial navigation as well, at one fell swoop. If there is any gratitude still extant in these degenerate days, the company cannot do less than immediately double its capital stock and issue half to me as a modest recognition for pointing out this unsuspected fact.

Does anybody still doubt? Hear the company: "A group of well-known, practical expert engineers in the city of Philadelphia has witnessed a demonstration of our generator and have stamped it with their approval." Are these expert engineers mere men of theory, whose investigations and opinions the world has so far been deluded into accepting as having weight? Not a bit of it! It is "the most scrutinizing inspection of practical men" that is wanted, not the preconceived notion of theoretical faddists wedded to foolish belief in accepted natural laws. "The layman can have little hesitancy" after hearing a report from one of these practical scrutinizers: "I have no doubt—not the slightest—the CO_2 generator does all that is claimed for it. I have seen the engine with the invention attached and studied it, and failed to find a single defect. Why it does it, of course, I don't know—its possibilities are limitless."

Does the company want to secure for itself all of the filthy lucre derivable from these "limitless possibilities?" No! In a noble manifestation of altruistic spirit it prefers to let the others who will form the sub-companies garner the gold. All it wants is $10,000,000 for granting this privilege to these fortunate sub-companies. Oh, proud Philadelphia, potent indeed is the spirit of brotherly love within thy borders when even the exploiter of such marvels (or shall we say marvelous exploiter) can so share with others!

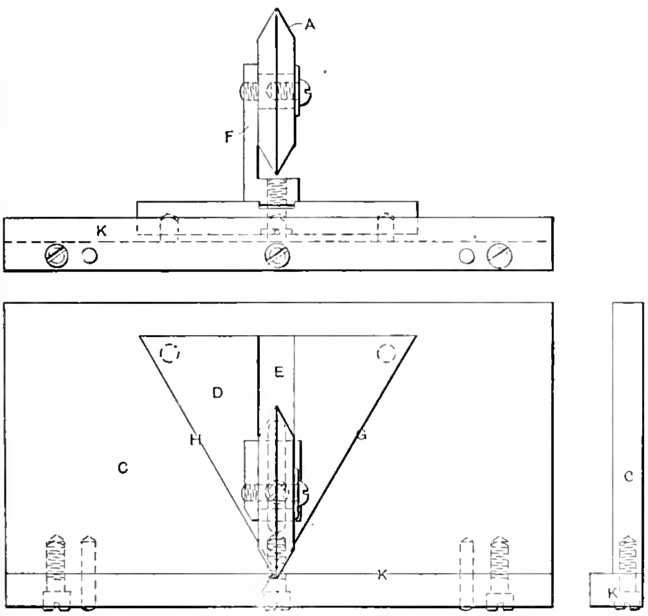
A printed pamphlet with beautiful illustrations of a CO_2 automobile, of a CO_2 100 H. P. engine, of a CO_2 railway car, and

of a residence equipped with a CO_2 system can be had on demand—not a penny, not a postage stamp even, is asked in payment. HENRY HESS.

Philadelphia, Pa.

FIXTURE FOR GRINDING ANGULAR MILLING CUTTERS.

The accompanying cut shows a little device which has proved itself very useful in grinding angular milling cutters when a perfect angle is required. The radius at the point of the angle can also be ground, radius and angle being ground at one setting. This fixture consists of a base-plate *C*, which is clamped to the grinder table so that it can be fed to and from the wheel by the feed arrangement on the grinder. On this base-plate rests a triangular plate *D*, carried on three feet. This latter plate is free to move in all directions, simply sliding on its feet on the plate *C*, and is guided only by the hands of the operator. In this triangular plate *D* there is a slot *E*, into which a tongue of the bracket *F* is fitted, this bracket then being movable back and forth on the plate *D*, and having arrangement for clamping in any position. The cutters *A* are clamped to this bracket *F* by a suitable screw and washer. For different widths of cutters, either different



Fixture for Grinding Angular Milling Cutters.

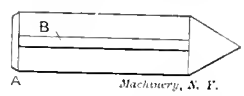
brackets must be employed or washers may be interposed between the bracket and the cutter, because it is evident that the center line of the cutter must always coincide with the center line of the triangular plate *D*. The cutter can be set to any given radius between the two angular faces by placing a gage block, having the same thickness as the radius wanted, against the point *B* of the triangular block, and placing a square against the gage, and adjusting the cutter so that the blade of the square just touches the point of the teeth of the cutter *A*. If I, for instance, have a cutter that I want to grind to a 60-degree angle, and want 1/16 inch radius at the point, I simply set my cutter central with the triangular block, and place a 1/16-inch gage block between the square and the point *B* of the block, and then adjust the cutter until it touches the blade of the square. The cutter is then clamped in place. The grinding itself is performed by sliding the plate *D* first to one side and then to the other, so that the sides *G* and *H* alternately rest up against the guide *K* on the bed-plate *C*, the side of the teeth of the cutter being meanwhile moved back and forth across the face of the grinding wheel. The turning around of the triangular block from one side to the other with the point *B* against the guide *K* evidently produces a radius at the point of the cutter between the two angular sides. The height of the cutter tooth in a horizontal direction, when setting, is determined by a gage block of such a height that the tooth face is in a horizontal plane with the center line of the cutter. The cutters are formed closely, before hardening and grinding, to the desired shape, so that there is but a few thousandths inch left to be removed when grinding. P. YORGENSEN.

Hartford, Conn.

[The manner of determining the radius to be ground is not quite correct. When a gage block 1/16 inch thick is used, as described by our correspondent, the resulting radius of the cutter is not 1/16 inch, but, for a 60-degree cutter, having a 30-degree angularity on each side of the center line, only one-half of 1/16, or 1/32. If the *exact* radius is required to be determined, the gage block should not be placed against the point of triangular block *D*, but against the side, and the blade of the square should rest against the angular face of the cutter instead of against the point. Then the resulting radius would be exactly equal to the thickness of the gage block. The method explained by our correspondent is, of course, convenient as a *relative* measurement, and is used as such where these fixtures are employed, but it does not give the real length of the resulting radius.—EDITOR.]

LATHE CENTERS WITH HIGH-SPEED STEEL POINTS.

In speed lathes and engine lathes used for turning small work at high rotative speeds, considerable trouble can be avoided by the use of dead centers that will stand considerable heat without softening. This can be accomplished by the use of machine steel centers with inserted high-speed steel points. The points are best made from about ½ inch round stock, having a cylindrical fit about 1 inch long. If the steel is cut 1¾ inch long, there will be ample stock for the tapered portion, and for truing up, and also for insuring a firm joint that will give no trouble from loosening or springing. For making centers of this description the following is suggested, and in my experience has proved to be a very satisfactory way. If a cutter grinder or grinding machine is available, mount the bar of round high-speed steel in the chuck, after first roughing out the cone point on a rough grinder, and grind it true and parallel. Then, swivel the head, and grind the cone point. Remove the bar from the chuck, nick it on a thin wheel, and break off the end to the length wanted. Then square up the end and bevel the corner *A*. This facilitates the pressing in place later. Finally grind a small flat on the side of the center at *B* to let the air escape when pressing it into place. If made in quantities, it is advisable to have the diameter a definite figure, so that the centers will fit a hole reamed with a standard reamer. FOSTER F. HILLIX.



La Fayette, Ind.

OBTAINING ANGULAR MOVEMENTS WITH THE INDEXING HEAD.

In the September, 1907, issue of MACHINERY, there appeared a criticism of the article on indexing, published in the February issue, in which the critic, Mr. John Edgar, claims to have presented a clearer explanation of the relationship existing between the movements of the crank, or worm spindle, and the angular movements of the work spindle. It may be that he has done so, but I am inclined to think that the method which I shall give is preferable. Take the number of degrees passed through by the work spindle in one revolution and divide this number by the number of teeth in the worm-wheel, or, what amounts to the same thing, the number of turns of the crank necessary to effect such a movement. The quotient will equal the number of degrees that the work spindle will move, for one revolution of the crank. In this way the relationship between the work spindle and the crank is shown as clearly as can be shown. In the criticism referred to, it was stated that a division of one degree is made by a movement of two holes in an 18-hole circle. This will be obvious from the rule which I have given, as 360 degrees divided by 40 teeth, equals 9 degrees for one turn of the crank. If the number of degrees that is to be indexed is divided by nine, the quotient will equal the number of turns that the index crank must make.

The following example is the one given by Mr. Edgar to illustrate his method of indexing: "Should it be desired to

index, say, 27 degrees, we would multiply 27 by 2 and obtain the number of holes necessary for such a movement. As 54 is a greater number than the number of holes in the circle, we would have as the movement of the index crank $54/18 = 3$ turns to make a 27 degrees division or indexing." This same result can be obtained by simply dividing 27 by 9. On the Brown & Sharpe milling machine the smallest fraction of a degree that it is possible to index exactly, by simple indexing, is 1/3 of a degree. By compound indexing, however, it it possible to index exactly 1/60 of a degree, or in other words, angles may be indexed, progressing by one minute. According to the article referred to, a division of 1/4 or 1/6 of a degree should be fine enough for even the closest jig work. Then a 1/60-degree division is evidently intended for work which must be closer than the closest jig work. But are the quarters or sixths of a degree division fine enough? Taking even the smaller fraction, the error on a 6-inch diameter is liable to be 0.0043 inch in one indexing. The error could not be more than 0.0043, as this equals the length of the arc of an angle of five minutes, the radius being 3 inches. If the work had to be indexed a few times, this error would be increased, and in that case I do not believe any one would be accused of splitting thousandths to an exaggerated degree.

Stamford, Conn. J. PRICE.

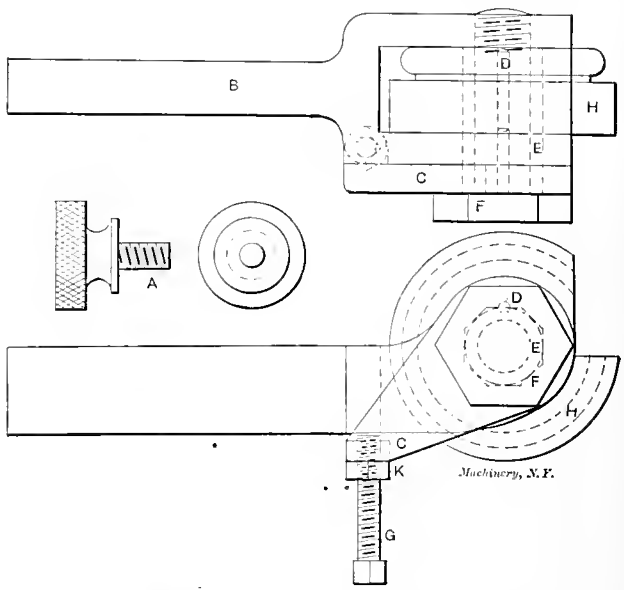
[The methods advocated by Mr. Price and Mr. Edgar are both correct, of course, and it is merely a matter of opinion which one should be preferred. To the average machinist, most likely, the fact that two holes in the 18-hole index circle represent one degree, is the one easiest to remember, and the one least likely to cause mistakes or confusion. In regard to the matter of how close angular movements may be carried on the milling machine with ordinary index heads, a certain reserve is advisable. While with compound indexing, movements of one minute are obtainable, theoretically, that does not say that with an ordinary index head such accuracy is possible when indexing, say, 30 degrees. Mr. Edgar, being a practical milling machine designer, most likely is aware of the limitations of the index head. In fact, any one who has tried to mill a side milling cutter, by using an ordinary milling machine index head, knows that when the teeth are milled on the face, and the cutter then turned so as to mill the teeth on the side, the second indexing around will not coincide exactly with the first, at least not if the indexing is not started in exactly the same relative position between cutter and index head, as when milling the teeth on the face. This indicates the practical limitations for accuracy of the index head.—EDITOR.]

IMPROVED CIRCULAR FORMED TOOL-HOLDER.

The cut herewith shows at A a formed knurled head screw, of which a large number had to be made, and a circular forming tool with its holder. Not having an automatic screw machine to take the size stock required, it was decided to make these screws on a lathe, using the circular tool and holder mentioned. The circular forming tool and forked tool-holder were made, and a bolt used to bind the prongs of the holder against the forming tool, no means being devised for adjusting, or preventing the tool from slipping.

The foreman of the tool-room, after experimenting in one way or another to stop the tool from slipping under the heavy strain of the cutter, thought it would be a good idea to drive a "maple wedge" in the space between the cutter and the holder. As the screws were made of cold rolled steel, and oil used for turning them, it is easily imagined to what extent the "maple wedge," after being soaked with oil, would stop the cutter from slipping. The tool was thrown aside as useless, and, after lying in its resting place for a week or more, the idea embodied in the cut occurred to me. I suggested it to the foreman, it was approved, the holder finished, and the job completed to the satisfaction of everybody.

In the cut, H is the formed circular tool; B, the forked tool-holder; C, a yoke with an octagon hole to fit the head of sleeve E, which has a keyway to fit the key D, the length of which is the same as the width of the inside space of the prongs of B. In the assembling of the tool, D is placed in the corresponding keyway in the hole of tool H, and tool and key placed in holder B. Then sleeve E is put into place, and yoke C is placed on the octagon head of the sleeve E. The hexagon clamping bolt F binds all together. G is the adjusting screw for setting the cutting edge of H, provided with a check nut K. The hole in the yoke C, and the head on the sleeve E being octagon, allows an adjustment of 45 degrees, before shifting the position of the yoke. Narrow cutters may



Improved Circular Formed Tool-holder.

be used in the same holder by placing washers or collars in the vacant space, or a gang of formed tools could also be used. This tool has been in practical service for five years, has never slipped, and has given entire satisfaction on every job used. FRANK G. STERLING.

Lowell, Mass.

PNEUMATIC DOLLY.

The small pneumatic dolly illustrated herewith, is used for "holding on" while riveting ball joint rings on the ends of locomotive dry pipes. This is not an entirely new device, but there are, doubtless, a number of shops not provided with this useful tool. The dolly is shown in detail in Fig. 1. It consists of a cylinder A, into which the leather-packed

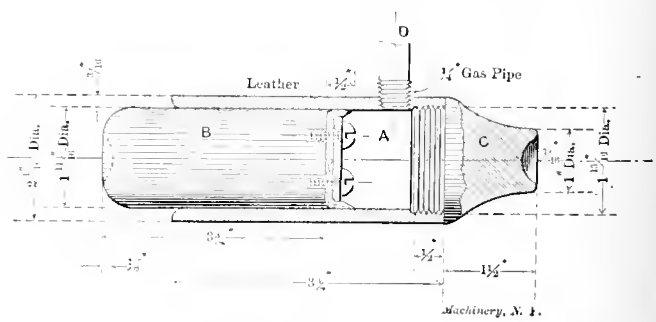


Fig. 1. Pneumatic Dolly.

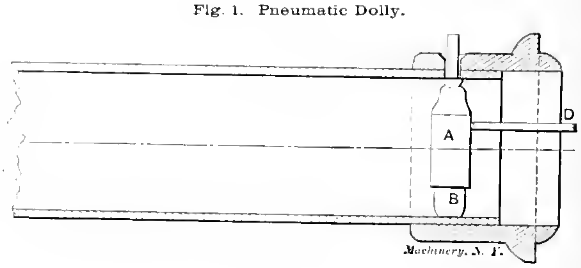

Fig. 2. The Pneumatic Dolly holding Rivet in Place.

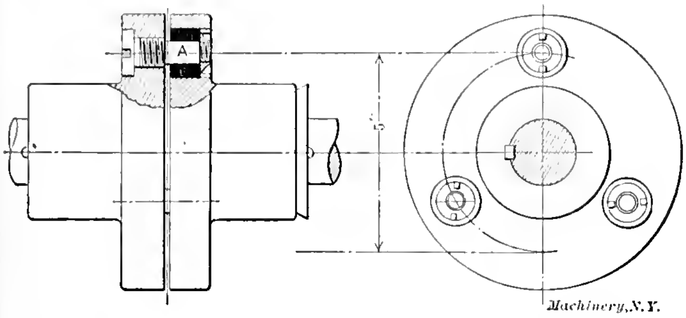
plunger B is fitted. A head C, which is cupped to fit the head of the rivet, is held against it, as illustrated in Fig. 2, and the compressed air is admitted to the cylinder A by the pipe D. The air forces the plunger B against either the wall of the pipe or the head of a rivet opposite, holding the rivet to be hammered securely in place. M. H. WESTBROOK.

Port Huron, Mich.

A SIMPLE FLEXIBLE COUPLING.

At the high speeds prevailing in steam turbine practice, it it evident that careful alignment becomes necessary on direct-connected drives. A small amount of cramping and frictional retardation, due to mal-alignment, would absorb considerable power at such high speeds. One maker of these turbines of the medium and small sizes, direct connected to pumps, fan blowers and dynamos, mounts each complete outfit on a substantial bed plate, and uses a flexible coupling of the design shown in the cut. The solid black sections indicate rubber bushings, the elasticity of which permit the necessary adjustment for alignment the drive being through the bolts *A* and the bushings. With some such coupling, any springing of bed plate or differences of shaft level, due to unequal wear in bearings of



A Flexible Coupling of Simple Design.

component parts of the outfit, will not affect the friction load appreciably. The observed example is to be found on the second motion shaft of the De Laval No. 1 B engine, rated capacity 15 H. P., running at 2,400 R. P. M., and driving a Sturtevant No. 6 Monogram fan.

Figuring back to the bolt circle, with its three yielding rubber rings, the above power and speed apportions 52½ pounds maximum pressure on each ring.

$$\frac{15 \times 33{,}000 \times 12}{5 \times \pi \times 3 \times 2{,}400} = 52.5 \text{ pounds.}$$

Apparently this pressure is below the squashing limit of the rubber, as an examination of the rubber bushings after two years' use in a warm engine room showed that they still fitted closely on the pin and in the bore of the coupling.

The groove on the hub of the coupling on the driven half, to prevent the oil from the bearing from working up and out to the flange where it might rot the rubber, should be noticed, and also the gap between the halves of the coupling for allowing adjustment of alignment, and increase of length of shafts due to temperature changes. A wedge gage or feeler tried at various places in this gap, and a straight-edge test over the edge of the flanges would quickly tell of changes in the positions of the shafts which might render a re-aligning desirable. The freedom from any projecting bolt heads seems also a good point. Other advantages may be known to the makers, but the above appear most readily to an observer.

New Britain, Conn. ROBERT S. BROWN.

[Some flexible couplings of interesting design were shown in the December, 1906, issue of MACHINERY, page 202, engineering edition, and in the June, 1907, issue, page 560, engineering edition.—EDITOR.]

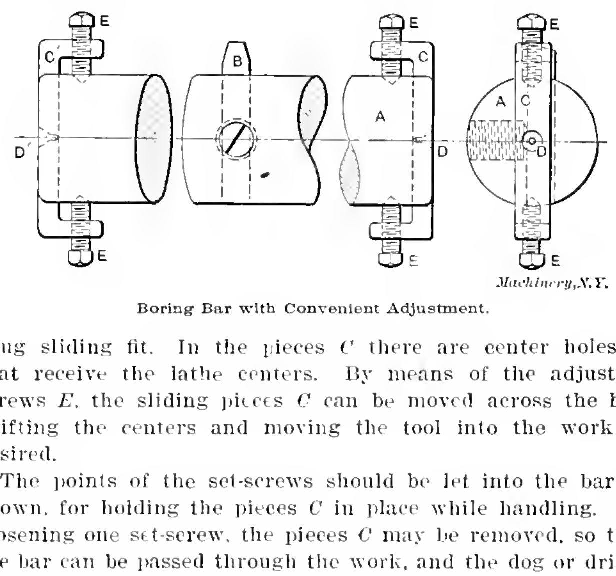
THE COLLAPSING OF HARDENED TOOLS.

In the November, 1907, issue of MACHINERY two half-tones were shown of a mandrel broken by internal stresses produced by the hardening process. An occurrence of this kind can, in most cases, be prevented, if tools are hardened in the proper manner. If we heat a piece of tool steel to a high heat, say 1,600 degrees F., and quench it in clear water until it gets entirely cold, that piece of steel is sure to become useless. Take, for instance, a mandrel or any solid tool heated and quenched in this manner. When the outside commences to cool off it shrinks, and consequently forces the mass of metal at the center together, the metal at the center still being red hot. After a while, however, the center of the piece starts to cool off also, and in cooling it will shrink. This shrinking produces tremendous strains between the outside and the center portion of the metal, because the outside portion is already cooled off, and is in a perfectly solid state, and the inside portion cannot shrink except by producing cracks in the metal. The cracks may not appear immediately, but the internal strains are in operation just the same, and will finally cause the collapse of the tool. This final collapse can be somewhat delayed by softening the mandrel on the outside, thereby relieving the strains to a certain extent, but a tool treated in this way would in most cases be too soft for the purpose for which it is intended. The proper way of hardening is, of course, to dip the heated piece of steel in cold salt water only for so long a time as to harden the outside deep enough to allow for grinding, and then place the piece in fish oil to let it cool slowly. The piece should be heated to about 1,500 degrees F. Of course we all know that if the piece is simply cooled off in water long enough to harden the outside, and then laid aside on the bench or on the floor until it cools off, it will be too soft, because the heat at the center drives the hardening from the surface. The proper method outlined, however, will insure success.

Lansing, Mich. J. F. SALLOWS.

A HANDY BORING BAR.

Although the plain boring bar with a single cutter is out of date for duplicate work, it is often useful in the tool-room, experimental room and job shop. The machinist often finds it difficult to adjust the tool of a plain boring bar to the required accuracy, and hold it rigid. The writer has found the bar which is shown in the accompanying cut, to be very useful. It consists of a straight bar *A*, of suitable diameter and length for the work at hand, in the center of which the cutting tool *B* is held in the usual manner. Each end of the bar is milled to receive the bent pieces *C*, which are made a



Boring Bar with Convenient Adjustment.

snug sliding fit. In the pieces *C* there are center holes *D* that receive the lathe centers. By means of the adjusting screws *E*, the sliding pieces *C* can be moved across the bar, shifting the centers and moving the tool into the work as desired.

The points of the set-screws should be let into the bar as shown, for holding the pieces *C* in place while handling. By loosening one set-screw, the pieces *C* may be removed, so that the bar can be passed through the work, and the dog or driver put in place. This bar will be found of special value when cutting threads into large nuts. ARTHUR NICHOLS.

Lansing, Mich.

DRIVING THREADED STUDS IN A LATHE WITHOUT MARRING THE THREADS.

Various devices are resorted to for driving a stud held between lathe centers, or for holding a bolt or other threaded piece in a vise without marring the threads. One of the simplest and most effective methods is to saw an ordinary nut of the same diameter and pitch as the stud in two parts, cutting in a plane coinciding with the center line, or exactly as the lead-screw nut of a lathe is split. If a stock of these split nuts to fit all standard threads is kept on hand, any piece of standard size can be gripped quickly, tightly, and without damage to the threads. A nut cut through one side only is also possible to use, but has to be screwed on and off—a decided waste of time, even on short threads.

SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

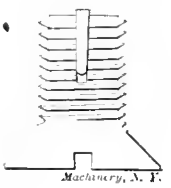
OILING CENTERS.

A very simple method for keeping the centers of a lathe properly lubricated is to tie a thoroughly oiled piece of waste around the center, so that the waste rubs against the end of the work. The pressure of the cut, of course, forces the piece of work somewhat toward one side of the center, allowing enough space to permit the oil to constantly flow into and lubricate the center hole in the work being turned. This simple method will do away with a great deal of wear on the centers, and will prevent all other unpleasant experiences which result from heated centers, not properly lubricated.

Birmingham, Ala. JOHN McLEOD.

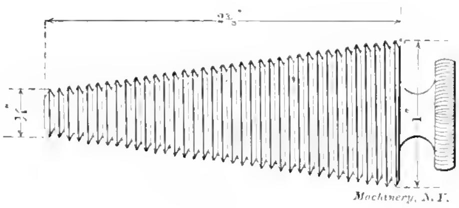
HOW TO TIGHTEN A LOOSE SCREW.

I was called upon to tighten a loose screw in a printing press. The screw was too small for the hole, and not being able to obtain one of suitable size and shape, I resorted to the following: The old screw was held between two pieces of wood in the vise, and a slot made, as shown in the sketch; the slot was opened a little, and a flat iron wedge driven in. The screw was then returned to its place, and it is now there for keeps. This method can be used also with bolts where the nut will not stay. X. Y. Z.



TOOL FOR CALIPERING TAPER TAPPED HOLES.

The tool shown in the cut is used for calipering taper tapped holes in boilers when fitting studs. It is a simple, though very useful and economical tool, and it will doubtless be appreciated by those having much work of this kind to do.

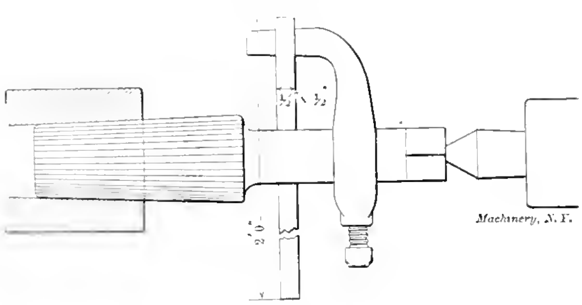


The hole in which the stud is to be fitted is calipered by filling the threads of the plug with chalk, and then screwing the plug in the hole. When the plug is removed the chalk will show exactly the largest diameter of the hole.

Brighton, Mass. F. RATTEK.

REAMING A TAPER SLEEVE.

I have seen many mechanics fuss around for hours when reaming a taper sleeve, and, finally, go to the boss for help. When doing work of this kind, the reamer is supported and guided by the dead center, and kept from turning by a lathe

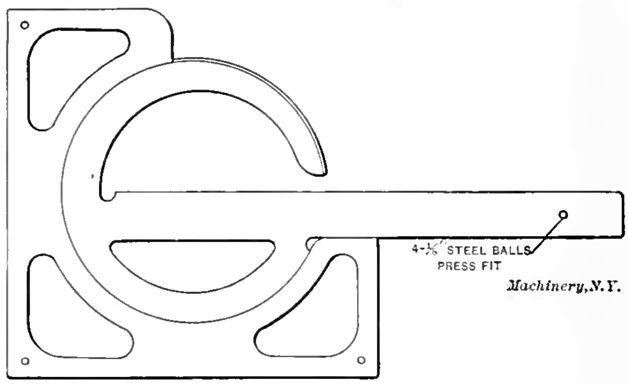


dog which is fastened to it. When held in this manner, the reamer tends to feed into the work and tear itself from the dead center. This can be prevented by the following method: After roughing the work to the desired size, prepare to ream the hole as usual. Then procure a light pine stick about ½ inch square by 2 feet long, and place this stick in the position shown in the cut. Hold the stick with the left hand, and pull slightly toward the dead center. Start the lathe slowly, and with the right hand feed the reamer into the work. This stick will enable one to feel the cutting of the reamer, and the feed can be judged accordingly. If the reamer should bind, the stick will strike the lathe and break, and the work and reamer will be free to turn. If a little care is given to the feed and speed, this method of holding a reamer will be found satisfactory. W. H. ADDIS.

Decatur, Ill.

RAISING DRAFTSMAN'S PROTRACTOR ABOVE THE SURFACE OF THE DRAWING.

Anyone who uses a Brown & Sharpe draftsman's protractor is familiar with the way it soils the drawing, when put to any extended use, in spite of the utmost care on the draftsman's part. The cut herewith shows a scheme which, I believe, is original with Mr. Geo. L. Merrill, of this city, for



raising the surface of the protractor slightly from the drawing. Four steel balls are made a press fit in the device at about the positions shown, the balls being about ⅛ inch diameter, projecting an equal amount on both sides, thus giving the same results no matter which side of the instrument is up. This addition to the instrument in no way affects its accuracy, and, as it bears only on four points, it rubs less dirt into the drawing than an ordinary triangle.

Detroit, Mich. M. R. KAVANAGH.

MULTIPLE THREAD CUTTING ON THE ENGINE LATHE.

Where there are many multiple-thread screws of *coarse* pitches and leads to be cut it is a valuable kink for a machine department foreman to know that engine lathes having lead-screws even multiples in pitch of the screws to be cut, are the most convenient to use, other things being equal. When given a multiple-thread screw to cut, most mechanics divide the change gear on the stud into as many parts as there are threads, say two for double, three for triple, and so on. This applies when the stud and spindle run at the same rate. After cutting one thread, the parallel thread or threads are located by slipping the change gear and setting for the new positions by the chalk marks on the change gear. This method takes time and is liable to cause mistakes. Quite often it happens that a change gear cannot be used having a number of teeth that is an exact multiple of the multiple thread. For example, a triple thread would require the change gear to have such number of teeth as will be exactly divisible by 3. If such gears are not available, then there is trouble.

If, instead of sending all such thread cutting to one lathe, we distribute it according to the character of the lead-screws, there will be considerable gain of time and less chance for spoiled work. Suppose, for example, that we have a quadruple-thread screw, 1 inch lead, to cut. If a lathe having a 4-threads-per-inch lead-screw can be used, the setting of the tool for each of the parallel threads will simply be a matter of opening the split nut and moving the lathe carriage one thread of the lead-screw and then closing the nut. If the screw to be cut was a triple thread of 1 inch lead, a 6-pitch lead-screw could be used, moving the carriage two threads of the lead-screw, and so on. R. H. MITCHELL.

New Castle, Ind.

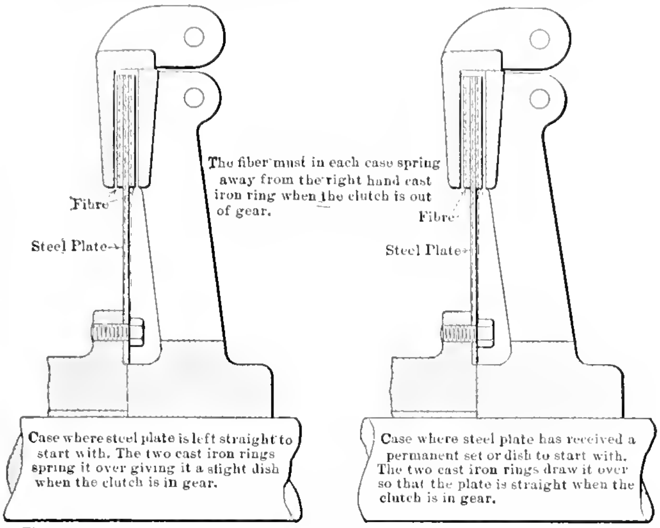
HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

DESIGN OF STEEL PLATE FRICTION CLUTCH.

D. G. M.—In the case of a steel plate friction clutch in which the steel plate with its fiber covering springs away from the cast iron face when it is out of engagement, which is the better practice: to give the plate a slight dish so that when the clutch is engaged it will straighten the plate into a perfectly flat disk, or to leave it straight and to spring it into a slightly dished shape when the clutch is engaged? The cuts Figs. 1 and 2 will illustrate the meaning clearly.



The dotted lines in each case indicate the positions of the plates with their fibre coverings when the clutch is in gear. Clutches are shown out of gear. *Machinery, N.Y.*

Figs. 1 and 2.

A.—Our preference would be to leave the plate flat and to spring it into the required shape and position by the action of closing the clutch. This will avoid the difficulty of making the plate run true after dishing it. The available clearance being small, it is essential that it run very true, and this condition is best obtained with a flat plate. The practical action otherwise should be about the same. The question is submitted to our readers for suggestion and comment.

THREADING CHASERS.

Tool-maker.—Is there any rule regarding the number of threads with which ordinary threading chasers should be provided on their face? I have seen chasers with as many as 20 threads or teeth on their face, but usually they seem to be provided with only six or seven.

A.—We infer that when speaking of threading chasers our correspondent refers to such as are held in standard threading tool holders. The chaser which is shown in connection with the accompanying table, is of the type used in the thread tool holder manufactured by the Pratt & Whitney Co. Of course, the data given herewith apply to any class of threading chaser of a similar type. There is no rule governing the number of teeth with which a chaser should be provided, but it is customary to increase the number of teeth for finer pitches as compared with the coarser ones. The accompanying table gives all dimensions necessary for these tools. The dimensions given conform to accepted practice.

DIMENSIONS OF THREADING CHASERS.

No of Threads per inch.	A	B	No. of Teeth in Chaser.	No. of Threads per inch.	A	B	No. of Teeth in Chaser.

FIGURING LATHE CHANGE GEARS.

Apprentice. Please state in a simple manner the way of figuring change gears for a lathe. I have seen some text books on the subject, but they all seem to make the subject so complicated that I do not fully understand the methods explained.

A.—While the principles and rules governing the calculation of change gears are very simple, they, of course, presuppose some fundamental knowledge of the use of common fractions. If such knowledge is at hand, the subject of figuring change gears, if once thoroughly understood, can hardly ever be forgotten. It should be impressed upon the minds of all apprentices that the subject in itself is extremely simple, and that the difficulty usually presents itself because the matter is not approached in a logical manner, and is usually grasped by the memory rather than by the intellect. Before answering the question in regard to any rules for figuring change gears, let us therefore analyze the subject. The lead-screw *B* of the lathe (see Fig. 1) must be recognized as our first factor, and the spindle as the second. If the lead-screw has six threads per inch, then, if the lead-screw makes six revolutions, the carriage travels one inch, and the thread-cutting tool travels one inch along the piece to be threaded. If the spindle makes the same number of revolutions in a given time as the lead-screw, it is clear the tool will cut six threads per inch. In such a case the gear *D* on the spindle stud *J*, and gear *E* on the lead-screw are alike. If the spindle makes twice the number of revolutions of the lead-screw, the spindle revolves twelve times while the tool moves one inch, and consequently twelve threads per inch will be cut. But in order to make the spindle revolve twice as fast as the lead-screw, it is necessary that a gear be put on the spindle stud of only half the diameter of the gear on the lead-screw, so that when the lead-screw revolves once the spindle stud gear makes two revolutions.

Simple Gearing.

Suppose we wish to cut nine threads per inch with a lead-screw of six threads per inch, as referred to above. Then the six threads of the lead-screw correspond to nine threads on the piece to be threaded, which is the same as to say that six revolutions of the lead-screw correspond to nine revolutions of the spindle; or in other words, one revolution of the lead-screw corresponds to 1½ of the spindle. From this it is evident that the gear on the lead-screw must make only one revolution while the spindle stud gear makes 1½. Thus, if the lead-screw gear has, for instance, 36 teeth, the gear on the spindle stud should have only 24; the smaller gear, of course, revolving faster than the larger. If we express what has been previously said in a formula we have:

$$\frac{\text{threads per inch of lead-screw}}{\text{threads per inch to be cut}} = \frac{\text{teeth in gear on spindle stud}}{\text{teeth in gear on lead-screw}}$$

Applying this to the case above, we have:

$$\frac{6}{9} = \frac{24}{36}$$

The values 24 and 36 are obtained by multiplying 6 and 9, respectively by 4. By multiplying both the numerator and the denominator by the same number, we do not change the proportion. As a general rule we may then say that the change gears necessary to cut a certain number of threads per inch are found by placing the number of threads in the lead-screw in the numerator, the number of threads to be cut in the denominator, and then multiply numerator as well as denominator by the *same* number, by trial, until two gears are obtained, the number of teeth of which are both to be found in the set of gears accompanying the lathe. The gear with the number of teeth designated by the new numerator is to be placed on the spindle stud (at *J*, Fig. 1), and the

gear with the number of teeth corresponding to the denominator on the lead-screw *B*.

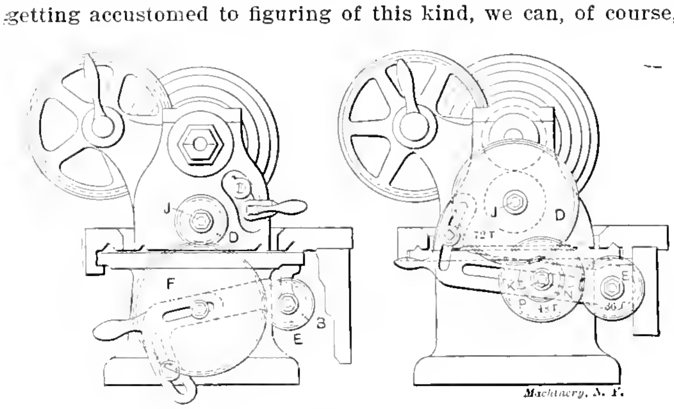
A few examples of this will more clearly define the rule. Suppose the number of teeth of the change gears of a lathe are 24, 28, 32, 36, and so forth, increasing by 4 teeth up to 100. Assume that the lead-screw is provided with 6 threads per inch, and that 10 threads per inch are to be cut. Then,

$$\frac{6}{10}=\frac{6\times 4}{10\times 4}=\frac{24}{40}$$

By multiplying both numerator and denominator by 4, we obtain two available gears with 24 and 40 teeth, respectively. The 24-tooth gear goes on the spindle stud, and the 40-tooth gear on the lead-screw. Assuming the same lathe and gears, let us find the gears for cutting $11\frac{1}{2}$ threads per inch, this being the standard number of threads for certain sizes of pipe thread. Then,

$$\frac{6}{11\frac{1}{2}}=\frac{6\times 8}{11\frac{1}{2}\times 8}=\frac{48}{92}$$

It will be found that multiplying with any other number than eight would, in this case, not have given us gears with such number of teeth as we have in our set with this lathe. Until getting accustomed to figuring of this kind, we can, of course,



Figs. 1 and 2.

only by trial find out the correct number by which to multiply numerator and denominator. The number of teeth in the *intermediate* gear *F*, Fig. 1, which meshes with both the spindle stud gear and the lead-screw gear is of no consequence.

Lathes with Reduction Gears in Head-stock.

In some lathes, however, there is a reduction gearing in the head-stock of the lathe, so that if equal gears are placed on the lead-screw and the spindle stud, the spindle does not make the same number of revolutions as the lead screw, but a greater number. Usually in such lathes the ratio of the gearing in the head-stock is 2 to 1, so that with equal gears the spindle makes two revolutions to one of the lead-screw. This is particularly common in lathes intended for cutting fine pitches or, in general, in small lathes. In figuring the gears this must, of course, be taken into consideration. As the spindle makes twice as many revolutions as the lead-screw with equal gears, if the ratio of the gears be 2 to 1, that means that if the head-stock gearing were eliminated, and the lead-screw instead had twice the number of threads per inch as it has, with equal gears the spindle would still revolve the same as before for each inch of travel along the piece to be threaded. In other words, the gearing in the head-stock may be *disregarded, if the number of threads of the lead-screw is multiplied by the ratio of this gearing.* Suppose, for instance, that in a lathe the lead-screw has eight threads per inch, that the lathe is geared in the head-stock with a ratio of 2 to 1, and that 20 threads are to be cut. Then

$$\frac{2\times 8}{20}=\frac{16}{20}=\frac{16\times 4}{20\times 4}=\frac{64}{80},$$

which two last values signify the number of teeth in the gears to use.

Sometimes the ratio of the gearing in the head-stock cannot be determined by counting the teeth in the gears because the gears are so placed that they cannot be plainly seen. In such a case, equal gears are placed on the lead-screw and the spindle stud, and a thread cut on a piece in the lathe. The number of threads per inch of this piece should be used for the numerator in our calculation instead of the actual number of threads of the lead-screw. The ratio of the gearing in the head-stock is equal to the ratio between the number of threads cut on the piece in the lathe and the actual number of threads per inch of the lead screw.

Compound Gearing.

The cases with only two gears in a train referred to are termed simple gearing. Sometimes it is not possible to obtain the correct ratio excepting by introducing two more gears in the train, which is termed compound gearing. This class of gearing is shown in Fig. 2. The rules for figuring compound gearing are exactly the same as for simple gearing excepting that we must divide both our numerator and denominator into two factors, each two of which are multiplied with the same number in order to obtain the change gears.

Suppose a lathe has a lead-screw with six threads per inch, that the number of the teeth in the gears available are 30, 35, 40 and so forth, increasing by 5 up to 100. Assume that it is desired to cut 24 threads per inch. We have then,

$$\frac{6}{24}=\text{ratio},$$

By dividing up the numerator and denominator in factors, and multiplying *each pair of factors by the same number*, we find the gears:

$$\frac{6}{24}=\frac{2\times 3}{4\times 6}=\frac{(2\times 20)\times(3\times 10)}{(4\times 20)\times(6\times 10)}=\frac{40\times 30}{80\times 60}$$

The last four numbers indicate the gears which should be used. The upper two, 40 and 30, are driving gears, the lower two, with 80 and 60 teeth, are driven gears. Driving gears are, of course, the gear *D*, Fig. 2, on the spindle stud, and the gear *P* on the intermediate stud *K*, meshing with the lead-screw gear. Driven gears are the lead-screw gear, *E*, and the gear *N* on the intermediate stud meshing with the spindle stud gear. It makes no difference which of the driving gears is placed on the spindle stud, or which of the driven is placed on the lead-screw.

Suppose, for a final example that we wish to cut $1\frac{3}{4}$ threads per inch on a lathe with a lead-screw having six threads per inch, and that the gears run from 24 and up to 100 teeth, increasing by 4. Proceeding as before, we have

$$\frac{6}{1\frac{3}{4}}=\frac{2\times 3}{1\times 1\frac{3}{4}}=\frac{(2\times 36)\times(3\times 16)}{(1\times 36)\times(1\frac{3}{4}\times 16)}=\frac{72\times 48}{36\times 28}.$$

This is the case directly illustrated in Fig. 2. The gear with 72 teeth is placed on the spindle stud *J*, the one with 48 on the intermediate stud *K*, meshing with the lead-screw gear. These two gears (72- and 48-teeth) are the *driving* gears. The gears with 36 and 28 teeth are placed on the lead-screw, and on the intermediate stud as shown, and are the *driven* gears.

* * *

Interesting experiments on the shrinkage of wood due to the loss of moisture have recently been completed by the Forest Service at its timber testing station at Yale University. These experiments show that green wood does not shrink at all in drying until the amount of moisture in it has been reduced to about one-third of the dry weight of the wood. From this point on to the absolutely dry condition, the shrinkage in the area of cross-section of the wood is directly proportional to the amount of moisture removed. The shrinkage of wood in a direction parallel to the grain is very small; so small in comparison with the shrinkage at right angles to the grain, that in computing the total shrinkage in volume, the longitudinal shrinkage may be neglected entirely. The volumetric shrinkage varies with different woods, being about 26 per cent of the dry volume for the species of eucalyptus known as blue gum, and only about 7 per cent for red cedar. For hickory, the shrinkage is about 20 per cent of the dry volume, and for long leaf pine about 15 per cent. In the usual air-dry condition, from 12 to 15 per cent of moisture still remains in the wood, so that the shrinkage from the green condition to the air-dry condition is only a trifle over half of that from the green to the absolutely dry state.

NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

CHANDLER CLUTCH-DRIVEN PLANER.

The Chandler Planer Co. of Ayer, Mass., has developed a clutch-driven planer of remarkable interest. It is shown in the accompanying half-tone. As may be seen, the driving mechanism, which is the principal feature of the improvement, has been applied to a planer of the frog and switch type, a machine which is subjected to about the hardest service that is ever imposed on a planer, thus giving a first-rate opportunity to try out the value of the new mechanism.

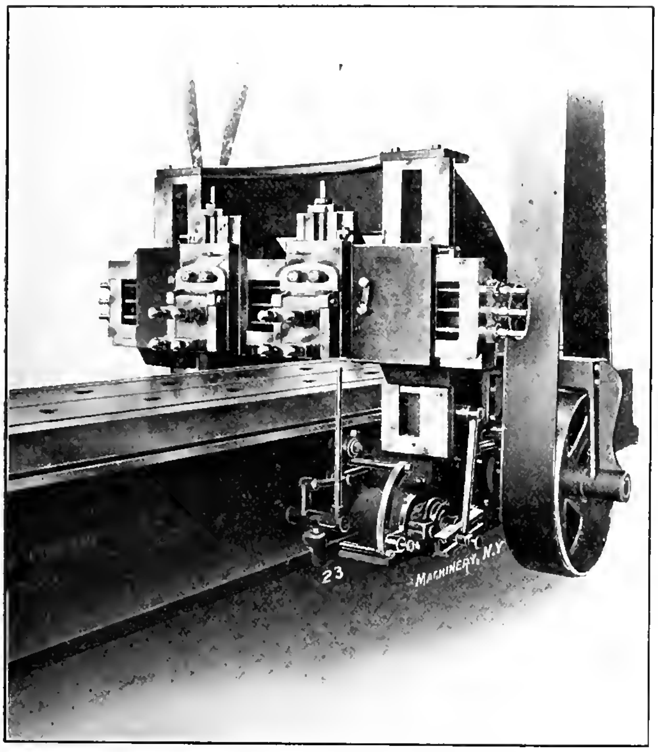


Fig. 1. The Chandler Clutch-driven Planer.

The problem of driving a planer becomes serious as the size of the machine and the severity of the duty is increased. Wide belts are required to transmit the tremendous power required for taking heavy chips at the high speeds possible with modern steels, and for reversing the table and work at these high speeds. The width of the belt can be reduced to some extent by increasing its velocity, but the fast running of the driving pulleys thus made necessary tends to defeat the object for which it was used, by increasing the momentum of the rotating parts and making the reversal much more difficult than it was before. This matter is very serious, since it has been found that the greater part of the power required for reversal (which is the greater part of the power required for driving the machine) is expended in overcoming the inertia of the rotating pulleys and gears.

There being a limit, then, to the speed at which belts can be run, and the increased power necessitating the widening of the belts, the problem of shifting them from the tight to the loose pulley and *vice versa* becomes exceedingly serious in heavy service. To obviate this difficulty, the use of clutches has been proposed for reversing in the place of shifting belts. Two forms of these clutches have been used more or less successfully—the electromagnetic and the pneumatically operated. The first has been found in practice to offer difficulties in the way of giving sufficient holding power, getting rid of residual magnetism and avoiding wear on contact faces. The pneumatic clutch has been tried on a considerably larger scale, and has been considerably used. Among its disadvantages is the fact that it requires an air-compressing plant—something which every shop does not possess, and which may have to be put in separately as an adjunct to the machine. Furthermore, it is not positive and invariable in its action, but may be changed, adjusted and regulated to suit the whim of the operator who, very likely, is better acquainted with the operation of the planer than with that of compressed-air machinery. Finally it acts with a given force which may or may not be enough to transmit the power desired. If not, the machine has to be stopped and the mechanism adjusted, this being necessary occasionally as the parts wear and conditions of lubrication, humidity of the atmosphere, etc., change.

In the machine under consideration, the clutch is operated mechanically. The problem to be solved is that of making a clutch and operating mechanism which will be strong enough to drive the heaviest cut the tools used will stand, and reverse the heaviest work at the highest speed the planer will ever be called on to work at—this to be done without shock, and without wear of the contact areas due to slipping. Of course there must be some slip to stop the planer table gently, and start it back on its return trip without violent shock. The problem is to allow just enough slip to effect this without giving so much that the contact surfaces rub on each other for a considerable period of time, thus wearing each other away.

The mechanism used in this machine effects all this in a remarkably ingenious fashion. The amount which the contact surfaces slip on each other before gripping is regulated by the design, and this amount is maintained under all conditions of lubrication and atmospheric moisture. Furthermore, it is as impossible for the clutch to slip as it is for a positive clutch. Something would have to break first. The way in which this is done may be briefly described by saying that the planer dogs do not directly operate the main clutches which connect the machine with the forward or reverse driving pulleys. The shifting of the reversing mechanism first throws a supplementary clutch into action with the driving shaft. The difference in motion between this supplementary clutch and the main driving clutch, by means of suitable mechanism, operates to engage the latter by power until the two parts are moving together. If slip occurs at any time, the

Fig. 2. An Example of Chips taken on the Clutch-driven Planer—Full Size.

slipping only serves to tighten the connection the firmer. In reversing, the throwing of the secondary clutch operates first to release the main clutch previously in operation, and then to engage the other one.

The writer witnessed a test of the frog and switch planer to which this mechanism has been applied. It was interesting to a high degree and at times really exciting. The test was intended to show that the planer had been developed to a point where it exceeded the capabilities of the steels with which it was used. In other words, in any work which it may be desired to perform on the planer, the cutting speed, and the depth and width of the cut will be limited by the tool, rather than by the machine. In demonstration of this, tools of high-speed steel of approved form and temper and unusual size were repeatedly tested to destruction. One way of doing this was by placing a 40-point carbon steel forged slab on the planer bed, and taking a series of wide and deep chips from it, one after the other, stopping each chip a little before the conclusion of the previous one. After five or six of these cuts had been made, the tool was again started in and the planer table allowed to continue its full stroke. The tool, thus catching up with one stopping point after another, took a gradually heavier and heavier chip until it finally had more than it could bear and broke short off at the shank. One of those broken measured 2½ x 3 inches at the broken section.

The chips thus produced, of which we show samples in Fig. 2, were interesting not only on account of their unusual size, but as well in showing the way in which chips are produced. This was fully explained in Mr. Taylor's paper "On the Art of Cutting Metals," the action being illustrated in Figs. 1, 2 and 3 in the February, 1907, issue of MACHINERY. As there explained, the chip is separated from the main body of the metal by alternate compressing and shearing, the different shearing planes separating the chip into sections more or less completely, depending on the heaviness of the cut taken. These separate sections are plainly shown. In many cases during the test the cuts were so heavy that these sections separated entirely, there being no continuous chip, but instead, a series of chunks of metal which flew in a stream from the tool, striking against a nearby pile of castings with a rattle like the discharge of a rapid-fire gun. The operation, in fact, seemed distinctly dangerous, and suggested the use of an armor-plate shield for the man operating the machine. Of course, these are extreme conditions, and were only undertaken to show the utmost capabilities of the machine.

During the tests the cutting speed of the table was 20 feet per minute, with a return of 4 to 1. The double cutting belt is 10 inches wide and runs at a speed of 1,860 feet per minute. The reversing belt is 5 inches wide, running at 3,900 feet per minute. The planer removed the side of the head up to the web on a pair of extra hard 70-pound relay switch points, cutting back 9 feet, in less than six minutes. At the same cutting speed it removed a chip ¾ inch deep and ¾ inch feed in a 40-point carbon steel forging. In doing this work, the tool required about 6 to 7 horse-power on the stroke and about 20 horse-power for reversing.

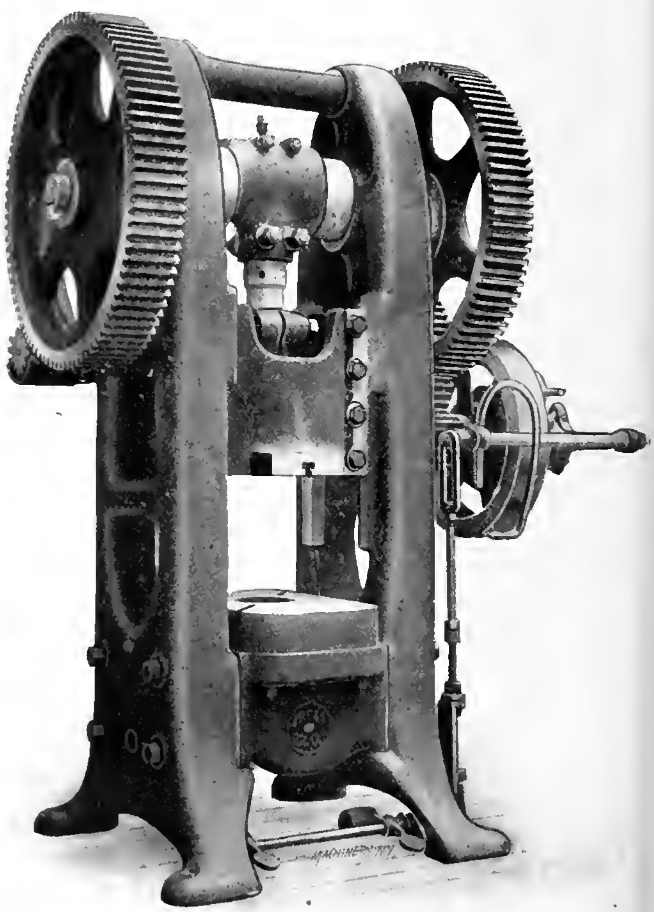
This planer has been in operation now for about three months, and has so far shown no tendency toward deterioration in the wearing parts of the clutch, which is of the multiple disk type. The disks which form its bearing surfaces are of cast iron permanently submerged in a bath of oil. After running for this length of time, the disks have been disassembled and examined, and the cast iron bearing surfaces have been found to be glazed, showing practically no signs of wear. This is, of course, the best condition for wearing in the case of cast iron surfaces in contact. It is stated that when the clutch has been disassembled while still tightly engaged under service conditions, and with the oil drained from the clutch, a layer of oil has been found between each of the separate disks, tending to show that they do not actually come in contact at all, there always being a film of lubricant between them.

The inventor of this machine is Mr. D. L. Chandler, superintendent of the firm and inventor of the three-belt planer as regularly built by this firm, and described in the July, 1904, and December, 1907, issues of MACHINERY.

FERRACUTE SINGLE-CRANK PRESS.

The accompanying illustration shows a massive single-crank press just built by the Ferracute Machine Co., of Bridgeton, N. J. In common with other machines of this kind, the press has a long stroke which adapts it for drawing cold from heavy sheet steel, deep drawn seamless shells, automobile hubs, cups for ball-bearings, and similar work. It can be built with shorter stroke for heavy blanking, trimming, shearing and embossing. A somewhat larger press of this series recently built by the Ferracute Machine Co. for the United States government is being used in the manufacture of cartridge shells for cannon.

The castings which compose the frame of this machine are exceedingly heavy, with neatly rounded corners which add considerably to the appearance of the press. Other striking features are the heavily trussed bed and the wide-faced twin gears on each side of the press. These gears are cut from the solid. Having two gears on the crank-shaft instead of one, tends to relieve the torsional stress of the shaft and affords an even pressure, besides dividing the load between



A Single-crank Press built by Ferracute Machine Co.

them. The back-shaft, with its two pinions which engage the large gears, is a single steel forging, made strong enough to obviate any torsional effect.

The main shaft is forged from high carbon steel. The clutch and fly-wheel are mounted on a stud which is rigidly attached to the frame, thereby preventing the disturbance of alignment which is apt to occur when such supports are detached and bolted to the floor. The press is equipped with a "multi-disk" friction clutch of a new and effective design. It is of the automatic stop type, but can be quickly adjusted for stopping the ram by hand at any point of its descent or ascent; or, if desired, it can be set for continuous running. Positive knockouts are provided when desired, the press being designed so they can be readily attached.

The distance between columns is 28 inches. The stroke is 3 inches, but can be made, if ordered, of any length up to 17 inches. The height from the bed to the ram when raised is 19½ inches, the adjustment of the ram being 6 inches. The fly-wheel is 35 inches in diameter with a 6-inch face;

and weighs 750 pounds. The press occupies a floor space of 8 feet 7 inches from right to left and 5 feet 5 inches front to back, and is 10 feet 7 inches high. It weighs 25,000 pounds, and exerts a pressure of 200 tons.

"LEKTRO" PORTABLE UNIVERSAL GRINDER.

This little portable tool is designed to perform, in combination with standard machine tools, all the functions of the various kinds of grinding machines in common use. It may be used on the lathe, milling machine or planer, for cylindrical, internal and surface grinding, and for sharpening of

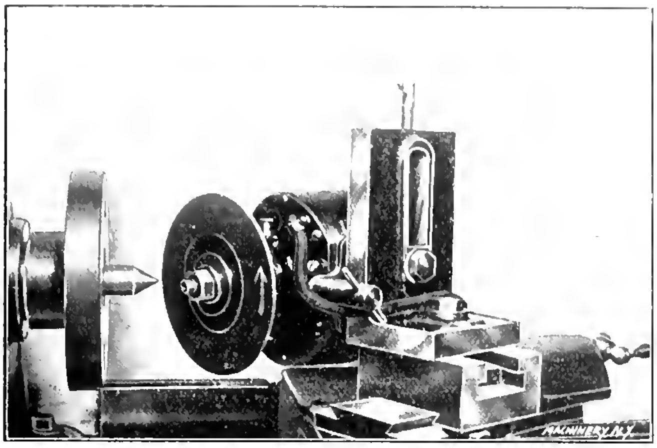


Fig. 1. The "Lektro" Portable Grinder truing up a Lathe Center.

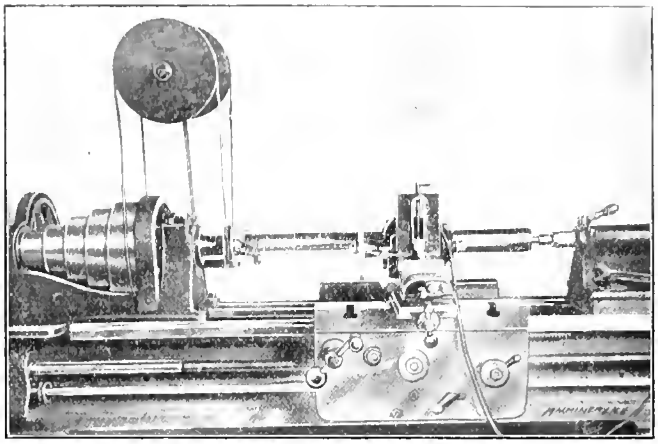

Fig. 2. Cylindrical Grinding in the Lathe.

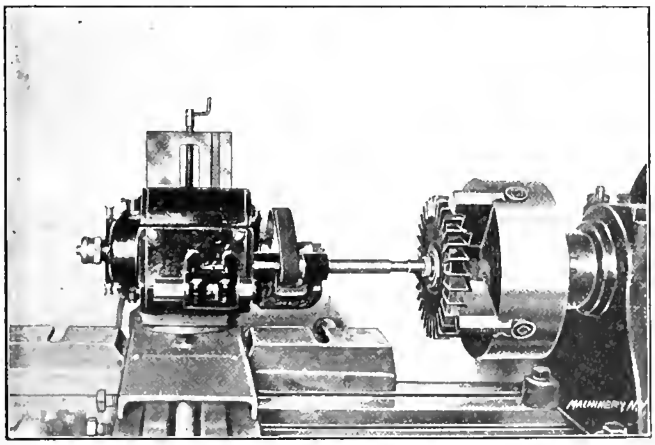

Fig. 3. Internal Grinding Attachment. The Spindle runs 14,000 R. P. M.

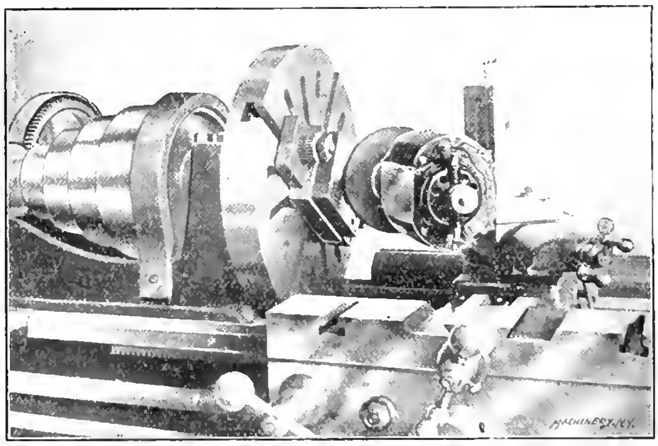

Fig. 4. Grinding a Blanking Die on the Face-plate.

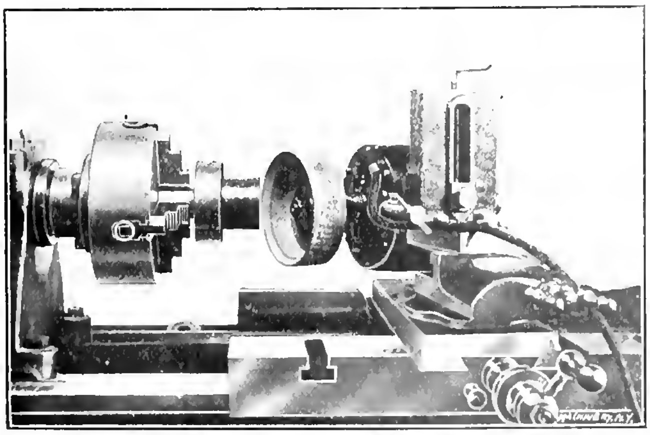

Fig. 5. Grinding a Punch with a Cup Wheel to give Shear.

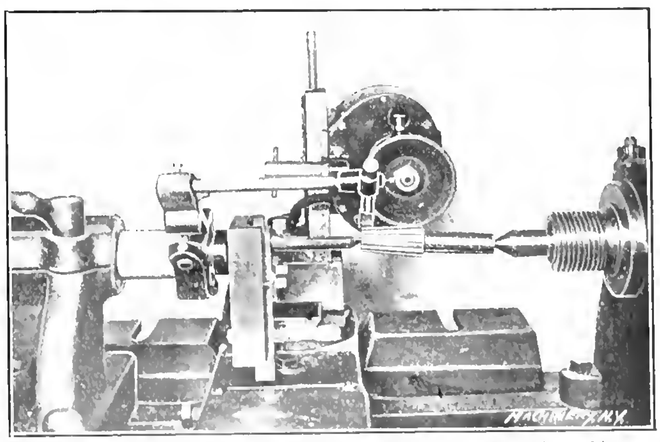

Fig. 6. Sharpening a Taper Reamer in the Lathe using Adjustable Tail Center

all sorts of tools, such as milling cutters, reamers, counterbores, circular forming tools, etc. Cutters may be ground while in place on the milling machine when so desired.

This attachment consists primarily, as may be seen in Fig. 1, of an electric motor mounted on an angle plate or knee, on which it may be raised or lowered by means of the elevating screw shown. The motor is especially designed for this work, the end motion of the spindle being prevented by an accurately made thrust bearing. The motor shaft is of tool steel, hardened, ground and lapped to size. The armature disks are ground on separate arbors before being assembled on the finished armature shaft, and are balanced after winding to insure smooth running. The commutator is balanced separately, and the whole armature tested for balance when assembled. The bearings are in phosphor bronze bushings, tapered and split, and adjusted by threaded collars. Oil cups are provided on both sides of this bearing, so as to allow the motor to run in an inverted position. The field magnet of the motor is so compactly arranged as to allow work to be brought within 1 9/16 inch of the axis of the shaft on the front or working side of the tool. The whole motor can be swung on the knee which carries it to any desired angle, and can be completely turned around in the opposite direction if desired.

The half-tone engravings shown herewith are nearly self-explanatory, and serve to illustrate a few of the varied uses to which the tool can be adapted. In Fig. 1 the live center of a lathe is being trued up, the compound rest being set at the proper angle for that purpose. In Fig. 2 is shown an example of cylindrical grinding on the lathe, this being done on dead centers, a special drive being arranged for the purpose. The spindle cone is disconnected from the spindle, and a bushing is clamped to the live center, carrying a pulley

loosely revolving on it. This is belted over the quarter turn counter-shaft shown, to the large step of the spindle cone. A spring-supported dead center is provided similar to that used in grinding machine practice.

In Fig. 3 the tool is being used with an internal attachment which is supplied with it. This attachment consists of a bracket fastened to the front face of the motor, and carrying a holder having bearings for the small internal spindle, which is driven by a short belt from a pulley mounted on the motor shaft in place of the usual emery wheel. In this operation, the hole in a hardened cutter is being ground to size.

Figs. 4 and 5 show examples of the grinding of press tools. Fig. 4 is practically a surface grinding operation. The die which is being sharpened is clamped to the face-plate, and a facing cut taken over it by the grinding wheel. Fig. 5 shows a cup wheel being used for grinding a round punch. The angle at which it is set makes it possible to grind the cutting edge with any desired amount of shear.

clearance desired for the cutting edge of the face. The cut is taken by working the longitudinal feed of the slide. A hook stop is used, and the belt is preferably run off from the cone pulley, which is operated by hand to index the work against the stop. In Fig. 9 the outside cutting edges are being sharpened. In this case the stop is mounted on the table, and the cross-feed of the saddle is used for the grinding operation. Fig. 10 is unusually interesting in showing the ability of the device to perform grinding operations of a delicate character. Here we have an end mill of very small diameter, having the teeth on its end sharpened. The operation is essentially the same as that of Fig. 8, the added difficulties being due to the small size of the work.

Of course these ten figures merely give an idea of a few of the operations for which the device may be used. Its use as a surface grinder in connection with the planer will be readily suggested, while its application to internal and external grinding of all kinds, and the sharpening of cutters, reamers, taps, mills, etc., is well nigh universal. This machine is manufactured by the "Lektro" Mfg. Co., 44 Walnut St., Cincinnati, O.

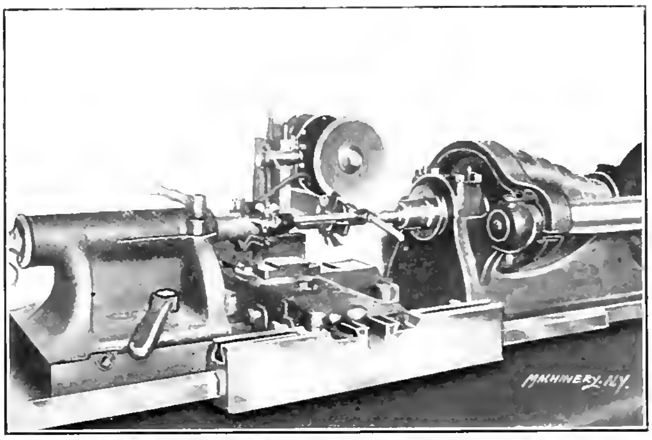

Fig. 7. Sharpening a Gear Cutter in the Lathe with Tooth Rest clamped to the Tail-stock Spindle.

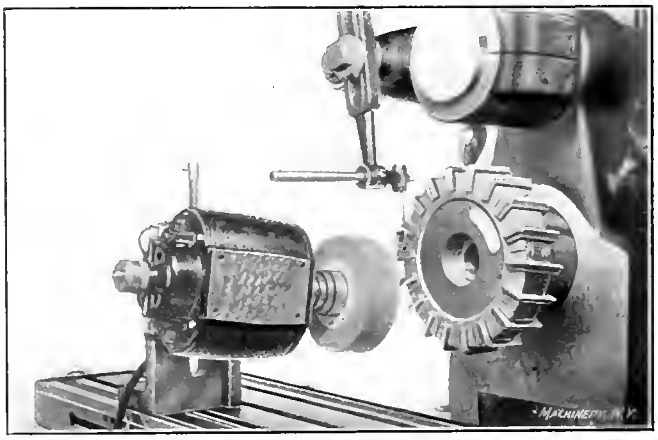

Fig. 8. Sharpening the Face of a Heavy Face Mill in place on the Milling Machine.

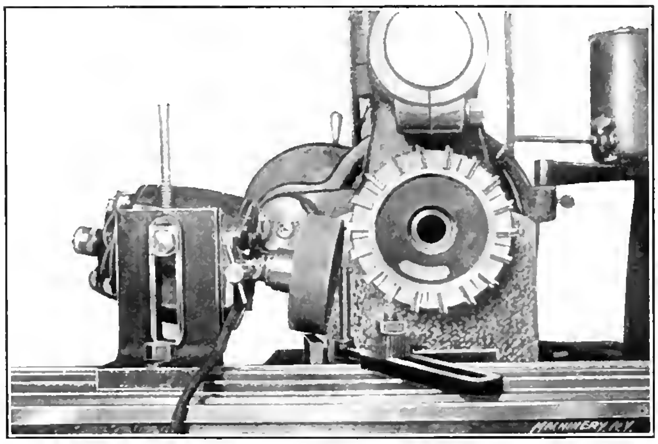

Fig. 9. Sharpening the Periphery of a Face Mill, the Blades of which are set at a Slight Angle.

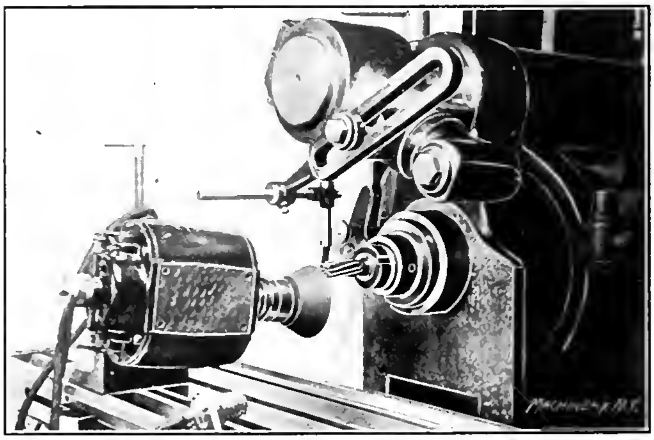

Fig. 10. Sharpening the End Teeth of a Small End Mill in place in the Milling Machine Spindle.

The next two figures show the machine used for sharpening small tools in the lathe in combination with attachments provided for the purpose. In Fig. 6 an adjustable center is used in place of the regular solid center. It may be raised or lowered to suit the taper it is desired to grind. A taper reamer is shown in place between the centers. A tooth-rest or stop is provided, held by clamping straps to the tail-stock spindle. This may be adjusted in various ways to suit different kinds of cutter and reamer work. In Fig. 7 a formed gear cutter is being ground, in this case on an arbor between the regular centers. The tooth-rest is again shown in operation. These cuts are, of course, taken by actuating the carriage by the usual hand-wheel.

Figs. 8, 9 and 10 show another class of cutter grinding for which this tool is particularly adapted—namely, the sharpening of cutters in place on the milling machine, under such circumstances as to insure their running true, with every tooth doing its duty. In this case the tooth-rest is supported in any convenient way to suit the case in question. In Fig. 8 it is supported from the overhanging arm. The large face mill is being sharpened in this case. A cup wheel is used on the grinder, which is set at the proper angle to give the

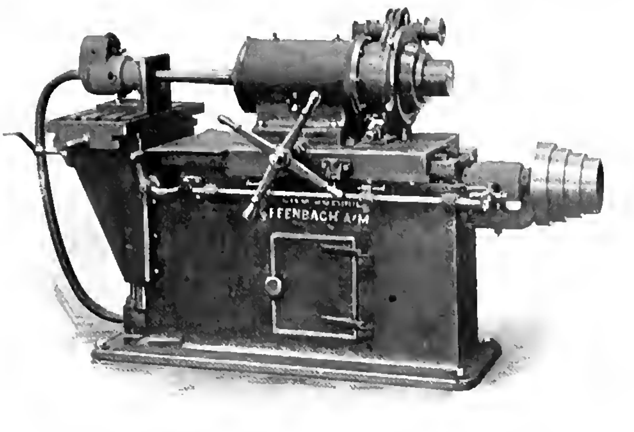
AUTOMATIC CYLINDER GRINDER.

The illustration shows an automatic cylinder grinding machine, manufactured by Mayer & Schmidt, Offenbach-on-Main, Germany, which was exhibited at the Olympia Exposition, London. The photograph was received too late to permit it to be included in Mr. James Vose's notes on the exposition, published last month.

This machine is designed to work completely automatically in all its movements, and an attainable accuracy within 0.00025 inch is claimed. The grinding head, which, judging from the cut is unusually rigid, is mounted on a carriage which moves back and forth during the grinding operation. The cylinder to be ground is mounted on a table which has adjustment both sideways and in a vertical direction, which provision makes it easy to get the axis of the cylinder in line with the axis of the grinding head. During the grinding operation, however, the cylinder is stationary.

The wheel-carrying arbor or spindle of the grinding head

has, besides its rotary motion, also a motion around the axis of the grinding head, the grinding spindle being eccentric in relation to this. The amount of this eccentricity is easily adjustable. The machine is also provided with a scale by means of which an automatic stop can be engaged when the desired diameter in the cylinder has been reached, at which time a bell rings, and the grinding spindle recedes automatically from the work. All feeds are automatic, and a cone feed pulley is provided so that a great variation of the forward and



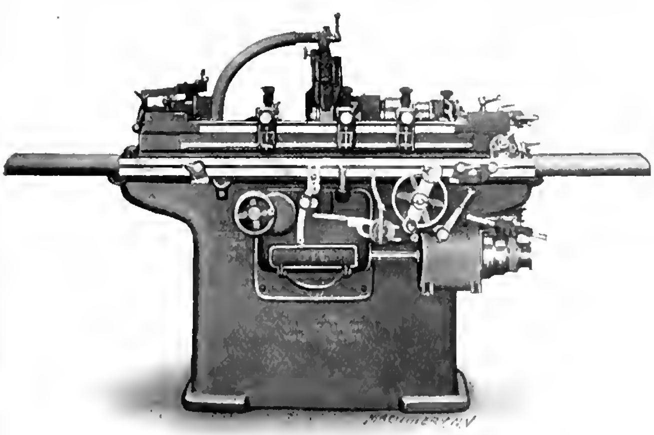
Automatic Cylinder Grinder.

reverse carriage feeds is obtainable. The grinding spindle is driven through a movable counter-shaft which follows the eccentric motion of the spindle. With the exception of the grinding spindle itself, which, of course, must be long enough to reach through the work, over-hanging parts have been avoided so far as possible, and this, together with the perfect rest during the operation of the cylinder which is to be ground, makes a high degree of accuracy possible. These machines are built in sizes to grind from 4 inches to 12 inches inside diameter, by 8 inches up to 44 inches in length.

SMALL NORTON GRINDING MACHINE.

We show herewith a new size of the well-known line of grinding machines made by the Norton Grinding Co. of Worcester, Mass. This machine is the smallest of the line, as built at the present time. It is made to swing the work up to 6 inches in diameter and 32 inches long, though its ordinary working range is for work from ½ to 2½ inches in diameter, the steady-rests being of suitable design for shafts of this character.

The well-known Norton system of universal steady-rests is used. Three of these appliances are furnished with the



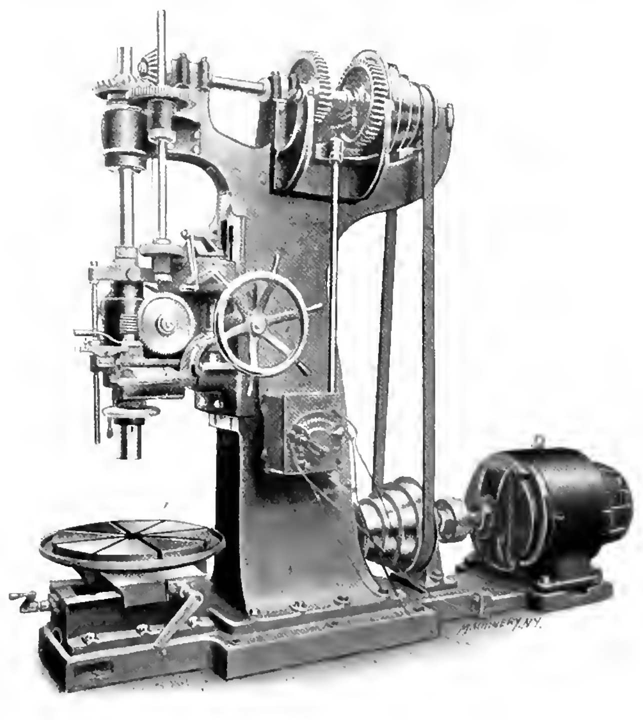
A New Addition to the Line of Norton Grinders.

machine, supplied with a set of work shoes for one diameter of work. Other sizes can be made from blue-prints furnished with the machine. These shoes are designed with a view to quick change from one size work to another. They all furnish a good rigid support for long work, within the range of sizes given. Provision is made for grinding tapers up to 2 inches per foot. A center grinding attachment is furnished with this machine, arranged to grind center points round, true, and to an accurate 60-degree angle. If a different angle is required, a special attachment can be made.

The over-head works furnished with the machine is of improved design, with shafts made of the best material, ground on centers. The hangers have large, self-oiling bearings. The weight of the machine with the over-head works, is about 3,600 pounds. The tool is arranged for belt drive only.

AN ENGLISH HIGH-SPEED DRILL PRESS.

The half-tone illustrates a drilling and boring machine built by J. Butler & Co., Halifax, England. This style of machine is built in two sizes, taking 30 inches and 36 inches diameter, respectively. Among the points included in the construction may be mentioned a fixed and rigid work table with adjustments in each direction by quick pitch screws, and through which the weight is taken solidly on the base plate; a strong drill head-stock fitted to the vertical column and balanced for quick and easy adjustment to the height of the work; and a very substantial spindle, which is supported in a steel sleeve with gun metal lining and ball thrust bearings at top and bottom. The sleeve has a slow hand traverse and a quick hand adjustment, each instantly disengaged or engaged, and governed by an automatic trip motion. The positive feed is



An English High-speed Drill Press.

driven by spur gears from the spindle, and is variable either by a three-speed feed box, or quadrant plate with change gears as desired. Further points are the powerful drive by a pair of steel bevel gears—the one on the spindle having a long sleeve in the upper bearing, and driving by two long keys. The driving shaft has capped bearings with gun metal bushings, and is driven by the speed cones directly, or through the double gear. As will be seen, the machine is self-contained, the counter-shaft being fixed on the base of the machine with starting lever close at hand, the illustration showing the machine driven by electric motor, direct. In the case of belt driving from the main shaft, the motor is replaced by fast and loose pulleys with belt shifting device. The machines may be made to drive by speed cones only, or with the double gear arrangement, enabling heavy boring to be done. In this case the speeds are arranged to give as gradual a progression as possible. Some details of the machines are appended.

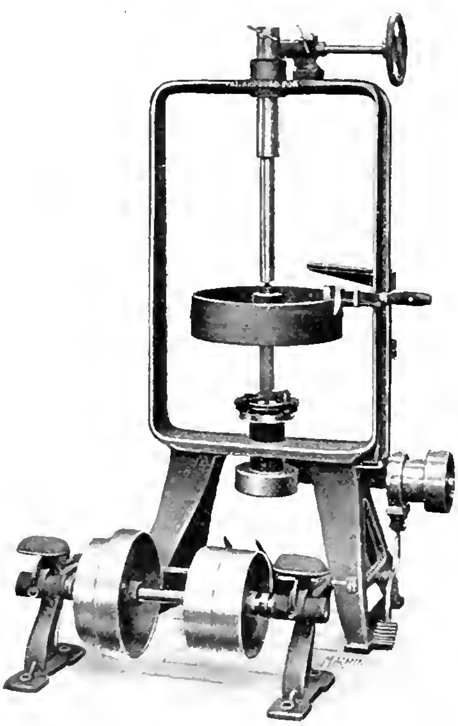
The 30-inch machine admits from spindle end to top of table 24 inches, and to base plate 42 inches. The 36-inch machine admits 28 inches and 46 inches. The diameters of the spindles at the driving end are 2 and 2¾ inches respectively; the diameters in the sleeves 2¼ and 3 inches, and the diameters of the sleeves 4½ and 6 inches, the bores of the

spindles being Nos. 4 and 5 Morse taper. The travels of the spindles are 12 and 16 inches, and the vertical range of the drill head on face of uprights 12 inches. The table diameters are 24 and 30 inches. In the 30-inch machine, the number of speeds on the cone is three, and in the 36-inch machine, four, the widths being 3 and 3½ inches, and the largest diameters 18 and 20 inches. The ungeared 30-inch machine will drill from ½ to 1½ inch holes at 600 to 270 revolutions per minute, and the 36-inch size will drill from ¾ to 3 inch holes at 600 to 183 revolutions per minute. When geared, 3 and 6 inch holes represent the duty recommended, the speeds varying from 600 to 83 revolutions in one machine, and from 600 to 39 in the other. The machines weigh 7,280 and 9,850 pounds respectively. Though the duty given is that which high-class high-speed drills will perform, the machines themselves are powerful and speedy enough to ruin any twist drill within their capacity. One of the machines was used for demonstrating the capacity of high-speed drills at the Olympia Exhibition, and in one test a ¾-inch drill was fed at the rate of 25 inches per minute, and a 2½-inch drill at 2½ inches per minute. J. V.

CURRIER REAMING MACHINE.

The machine illustrated in the accompanying half-tone is of an entirely new design, and is intended for performing reaming operations by mechanical means, at a great saving of time and with greater accuracy than is possible to be had when reaming by hand. The obstacles to be overcome in a reaming machine are mainly the difficulty of starting the reamer in the hole without roughing the end of the hole, which also includes the difficulty of starting the reamer straight, and the troubles met with from the digging in of the teeth of the reamer, which cannot as easily be provided for in a reaming machine as in hand reaming. Both of these difficulties have, however, been taken care of in the present machine, the work being guided until the reamer has fully entered the hole, and an equalizing drive, referred to later, provided to insure uniformity and ease of cutting action.

In the upper and lower ends of the frame 2½-inch holes are bored in perfect alignment. The lower end is fitted with a spindle, which is driven by a worm-gear drive. This spindle



A Machine for Reaming by Power.

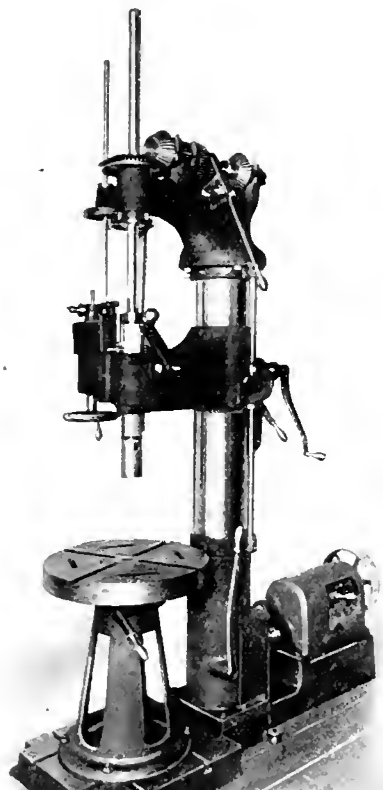
is in turn fitted with a center and an equalizing carrier for driving the reamer. At the upper end of the frame a sleeve is fitted, which is operated vertically by a rack and pinion. In this sleeve a bar is held, upon which the work to be reamed is placed until the reamer is put on the centers, one end of this bar containing what we might call the tail center. A brake attached to the lower side of the right-hand leg makes it possible to stop the machine instantly by foot power.

The work to be reamed is first chucked in the usual manner and reamed, leaving from 0.004 to 0.005 inch. The work is then placed on the guide bar, and a swinging arm, shown on the right-hand upright, brought forward to prevent the work from dropping while the reamer is placed on the centers. When the reamer is in place, the machine is started, the swinging arm is thrown to one side, and the gravity of the work feeds it slowly down over the reamer. To prevent the work from turning, it may be held by a wrench, as shown in the cut, or by any similar suitable device. It will be noticed also that the reamer is fluted through the shank; this provision is made in order to permit the chips to fall through easily. The simplicity of the machine permits it to be run by a great deal cheaper help than could be employed for hand reaming.

The machine will take in work up to 24 inches diameter. It is built by J. E. Snyder & Son, Worcester, Mass., and is furnished with counter-shaft, six carrier wrenches, and one guide bar of any size from 1 inch to 2½ inches. The speed of the counter-shaft is 400 R. P. M., and the weight of the machine is 430 pounds.

DRILL PRESS OF NOVEL DESIGN.

The cut herewith shows a 24-inch upright drill press, built by the National Machine Tool Co., Cincinnati, Ohio, termed by the makers their 1907 design. As will be noticed, it is



The National Machine Tool Co.'s 24-inch Drill Press.

designed differently from the ordinary type of upright drills, being without back support or top braces. But none the less, for a machine of its size, this drill is particularly rigid.

The head of the drill rotates with the sleeve about the column, an arrangement which will be found advantageous for heavy work. The vertical adjustment for the head is by means of a crank, bevel gearing and screw, as plainly shown in the cut. Twelve changes of speed, arranged for drills from ½ inch to 2½ inches, are provided for. One-half of these speeds are obtainable by the speed box, which provides for six changes of speed, it being possible to make changes while the machine is running. This number of speeds is multi-

plied by two through the back gears. The latter are also designed to be thrown in while the machine is running.

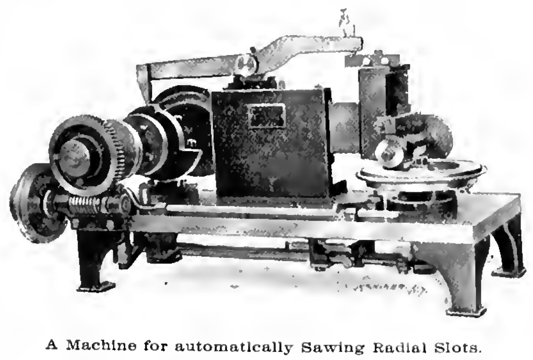
There are four feed changes, the feed change mechanism being located directly on the front of the head. The quick return and approach lever also engages and disengages the feed, so that but one hand needs to be used for these operations. The tapping attachment is placed in the base of the column, behind the back gears, which insures greater power. The starting, stopping, and reversing lever is right under the hand of the operator, as shown in front of the column in the cut. The style of table used insures alignment at all times. It is rigid and stiff, and has a revolving top. The table, as is seen from the cut, is easily removable, and drilling on the base can be performed without much trouble experienced in first removing the table.

The general dimensions of the machine are as follows: Total height of drill, 7 feet 5 inches; diameter of column, 8 inches; Morse taper in spindle, No. 4; maximum distance between the spindle and base, 48 inches; between spindle and table, 23 inches; diameter of table, 22 inches; working surface on base, 22 x 22½ inches; spindle speeds, from 36 to 267 R. P. M.; feeds per revolution of spindle, 0.008, 0.012, 0.016 and 0.020 inch; speed of driving pulley, 360 R. P. M. The floor space required is 22½ x 55 inches, and the total weight of the drill is 2,100 pounds.

AUTOMATIC SLOTTING MACHINE.

The machine shown in the accompanying engraving is a modification of the automatic pinion cutter built by the Standard Manufacturing Co. of Bridgeport, Conn. It is shown engaged in the operation of sawing slots in the base and edge of a ring, which is part of a knitting machine. The mechanism is cam-operated throughout.

In this particular case, the cut taken is a peculiar one. In the figure, the cutter is set in a position to start a cut. It travels toward the outer edge of the ring, then travels down past the edge of the saw, making a perfect right-angle cut in the work. The slide carrying the cutter is forced down by a mechanism which, in the standard pinion cutting machine, is used for withdrawing the cutter on the return stroke during the indexing, and bringing it down again to cutting depth.



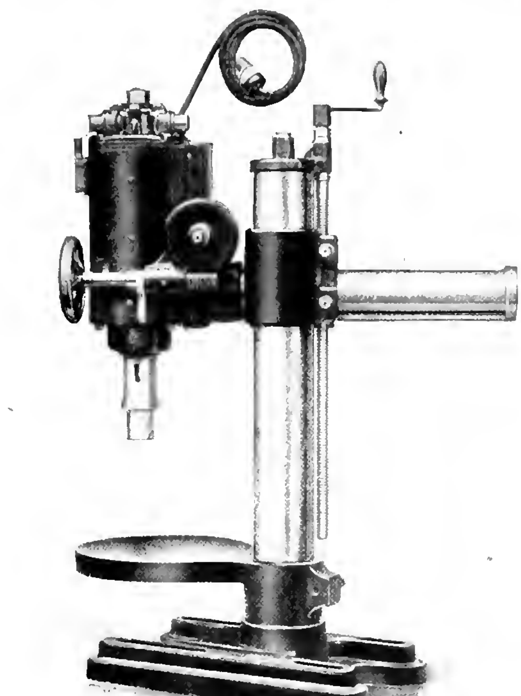
A Machine for automatically Sawing Radial Slots.

The index mechanism is so arranged as to be adjustable to the desired number of cuts, by altering the number of teeth that the ratchet will take. A positive lock is provided, which holds the index disk firmly while the saw is doing its work. Provision is also made for holding this disk while the work is being removed from the table or tightened down upon it. This is done in such a way that no strain is thrown on the indexing mechanism, so that all possibility of throwing the machine out of alignment is avoided. This machine is also sold arranged for slotting screw heads of all sizes and styles, a hopper feed being used in conjunction with it.

PORTABLE ELECTRIC RADIAL DRILL.

In the accompanying cut a new portable tool made by the Hisey-Wolf Machine Co., Cincinnati, O., is illustrated. This tool is termed by its makers the Hisey portable electric Scotch radial drill, of 2-inch capacity. These drills are also made in two smaller sizes of ⅞-inch and 1¼-inch capacity, respectively. These drills are self-contained, and are portable in the full sense of the word, being of a comparatively small size. The range of work that can be done on these machines is, within their capacity, as complete as that of the large size types of stationary radial drills, but on account of their small weight, the machines can be taken to any part of the shop, or outside of the works, without trouble, one man being able to easily handle a machine of this size. These drills are electrically driven, and are made for either direct or alternating current. The motor has two speeds, controlled by a thumb lever at the lower end. The driving power is obtained from an ordinary lamp socket. This permits the drill to be used anywhere within the machine shop.

The 2-inch capacity drill, which is the one illustrated, has a 12-inch feed through the hand-wheel shown at the left, and



A Small Portable Drill of the Radial Type.

is arranged for quick return by hand. It can drill at a radius of 24 inches, at any place in the horizontal plane, and at any angle. The hand-wheel and the worm box are provided with a swivel adjustment so that the tool may be used in corners and where space is limited. The horizontal column, as well as the vertical arm, is made of hollow steel tubing, and the column is fitted with a screw to raise and lower the motor and drill head, as shown. The bracket on the horizontal column is also fitted with a pinion meshing with a rack on the vertical arm, which provides the radial adjustment. These attachments permit the operator to adjust the drill to his work very quickly. The table is adjustable and detachable. As may be judged from the illustration and description, the machine is thus provided with possibilities for quick adjustments in all respects, and will therefore, undoubtedly, be found a very useful tool wherever a small portable drill is required.

POWER HACK-SAW GIVING RELIEF ON THE RETURN STROKE.

The Racine Gas Engine Co. of Racine, Wis., is building a power hack-saw which has mechanism designed to raise the blade of the saw on the return stroke. This operates without interfering with the feeding mechanism. The builders state that it gives surprising results in the way of length of life of the blades, rapidity of cutting, and accuracy of the cut. Fig. 1 shows the general appearance of the machine; the line cut, Fig. 2, will serve to explain the action quite clearly.

A is the guide on which the saw frame travels, while *B* is a weight adjustable on the bar on which it is mounted for the degree of feed desired. The saw frame is reciprocated by a crank in the usual fashion. The crank is mounted directly on the driving pulley shaft, the pulley being large enough in diameter so that no gearing is required. Fastened to guide *A*,

which is pivoted around the driving shaft, is a sector *C*, curved to the arc of a circle with the same center as the guide, and having ratchet teeth on its concave surface. On the driving shaft is a cam *D*, half of the periphery of which has a somewhat greater diameter than the other half. This operates a roll on lever *E* in such a way that the latter is raised at the beginning of the return stroke and lowered at the beginning of the cutting stroke. The outer end of lever *E* carries a dog *F*, engaging the teeth in sector *C*. When this lever with the dog is raised as the cutting stroke is completed, the sector is raised with it, and the saw returns free

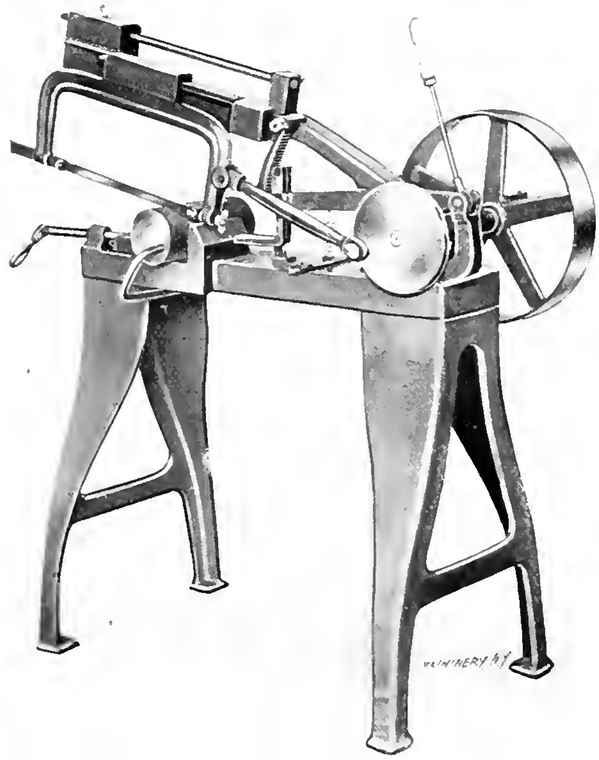


Fig. 1. Racine Automatic Relieving Power Hack-saw.

of the work, not dragging as is the usual case. At the end of the backward stroke, as the saw is about to return, cam *D* allows lever *E* to drop again, and the saw is again lowered in contact with the work. The long bent tail of the dog *F*, when it is lowered, rests on the head of screw *G*, and is by it thrown out of contact with sector *C*, leaving the saw thus entirely free to be acted on by the feeding weight *B*.

Lever *H*, operating a clutch, is connected with the slide in which screw *G* is held in such a way that the latter is

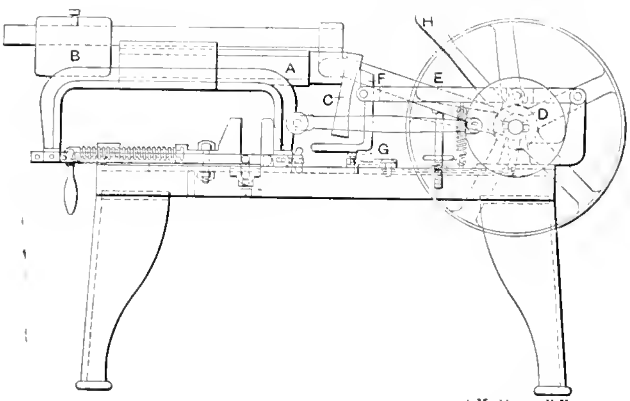

Fig. 2. The Mechanism of the Racine Power Hack-saw.

moved out of contact with the tail of the dog when the machine is stopped. This allows the saw to be raised and held in any position when it is not in operation, making it convenient for inserting work or taking measurements, etc. A stop is provided for depth of cut in cases where it is not desired to cut clear through the piece. The clutch is connected with an automatic stop arrangement which throws out the power connection when the work has been cut through. Provision is made for using either 10-inch or 14-inch blades, depending on the size of the work, thus allowing the full length of the blade to be used in any case.

This machine was the result of the necessities of its builders, who had large quantities of crucible machinery steel to saw. They experienced great difficulty in doing this, owing to the fact that the saw would become so dull before the cut was completed that it would run out of true from ¼ to ½ inch, and sometimes would not go clear through without breaking the blade, thus wasting time and material, besides the extra facing required in the lathe. After the lifting device

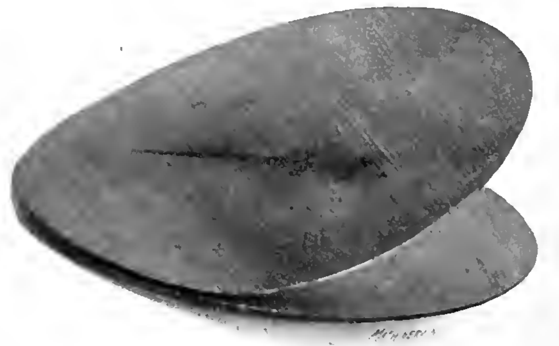

Fig. 3. A Sample of the Fine Work of which the Machine is Capable.

was applied, there was no trouble on the same work in taking six cuts with one blade, these being so nearly square that the stock was cut to within 1/16 inch of finished length. As an example of the excellent work of which the saw is capable, we show in Fig. 3 a reproduction of a photograph of a section of crucible steel in which a cut has been taken separating a piece of only about 0.040 inch thickness, there being a variation of less than 0.010 inch over the whole area of the cut.

SHEPARD ELECTRIC HOIST.

The electric hoist shown in two forms in the two accompanying half-tones has been designed after careful reference to operative requirements of such mechanisms, and it is believed by its builder (the General Pneumatic Tool Co., Montour Falls, N. Y.) to fill these requirements very nearly. Perhaps the appliance can best be described by taking up these requirements in turn, and explaining how the design, in each case, has been made to conform to them.

One of the features of this hoist, plainly in evidence in Fig. 1, is its compactness. This has not been considered as a primary virtue, and nothing in the way of accessibility and strength has been sacrificed to obtain it. It will be seen, however, that the mechanism has been enclosed in an unusually small casing or framework. The ruggedness of construction necessary for a machine to be used largely by unskilled workmen has been carefully looked out for, also, all its load sustaining parts being of unusual strength. With the simple design chosen, this has been found possible without exceeding the dimensions or weight of other hoists of equal rated capacity.

Interchangeability has been carefully provided for. Not only is the hoist built on a plan which makes it possible to replace repair parts without fitting, but parts made for these hoists will interchange with corresponding parts in traveling cranes built by the same makers as well. This plan results in greater economy of manufacture also, and makes it possible to furnish at current prices a much better hoist than would otherwise be possible. The hoists themselves may be considered as interchangeable parts to be applied indiscriminately as simple hoists, or as parts of electric cranes and other apparatus of a similar nature. As all these machines of the same capacity will interchange perfectly, very few spare parts will suffice for a large and varied equipment. This interchangeability extends to the pneumatic form of the hoist as well, which is identical with the electric form in many of the mechanical features of its design, and so may be interchanged with it in any given case.

Careful attention has been given to the matter of accessibility, no other feature of the design having been allowed to interfere with this prime requirement. This has been carried out to the extent that every important group of parts

is accessible without disturbing unrelated mechanism. For instance, the armature can be removed without disturbing any part of the electrical connections except the armature leads, and requiring the removal of no part of the mechanism except the front housing of the motor. The monkey wrench and screw driver are the only tools needed to take the machine apart or reassemble it.

In the design of this tool the severe use to which it is likely to be put, and the lack of skill in the workmen who are expected to use it have required that adjustments be entirely done away with. All wearing surfaces are made to take permanently their proper position, and are designed with sufficient bearing area so that any disturbances due to natural wear will not affect their perfect operation. Any attendant of average ability or less will have no difficulty in removing or replacing parts successfully and safely, since no delicate adjustments are involved.

Constant and thorough lubrication is necessary in any machine of this kind, no matter how well designed and made it may be. Provision is taken in these hoists to insure the access of oil to all running parts, even when proper attention to this important matter is not given by the operator or attendant. Every part of the hoist will be properly oiled when three conspicuous oil reservoirs are filled. The supply of lubricant contained in each of these three reservoirs is sufficient to protect the machine from harm, even if it is not replenished for a long period.

An important improvement consists in providing the motor with a variable speed electric control. It has been usually considered that this is not necessary with series-wound motors of small size, but experience has led the builders to believe that the sudden turning on of full current strength into a

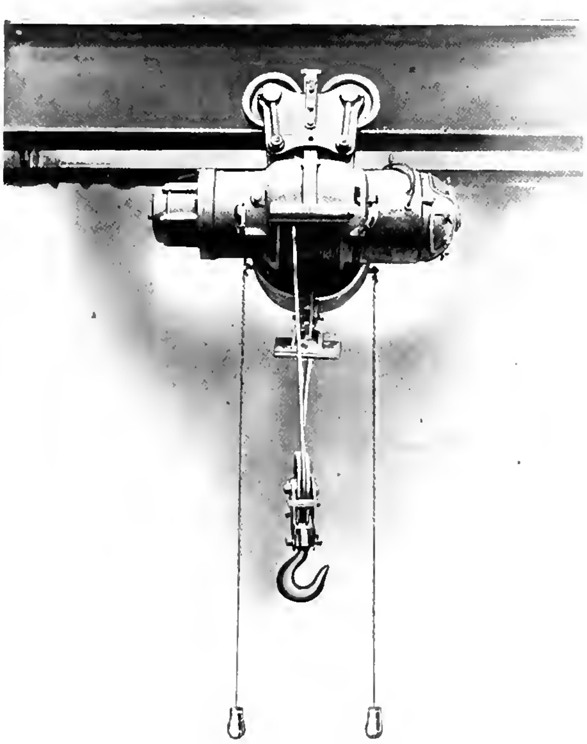

Fig. 1. The Shepard Electric Hoist

hoist motor results in unnecessary strain on the shafts, gears and hoisting rope, and when long continued, results in serious deterioration in the motor as well. On opening the circuit under full voltage and current strength, there is also the serious damage to the controller contacts to reckon with. The controller used with these hoists provides an unusual number of contact steps—14 on the smallest size, and 18 in those of larger capacity. It is proven in practice that this improvement results in a great decrease in the amount of care necessary to maintain the electrical features of the hoist in good condition.

As intimated in the paragraph devoted to the matter of interchangeability, these devices may be applied in a number of different ways, using the proper structure or holding mechanism for the work in hand. In Fig. 1 is shown the simplest form of the hoist, arranged to be supported by a single I-beam, and to be traversed by hand. The controller in this case is mounted on the farther side of the hoisting drum, and is operated from the floor by pull ropes. An automatic stop is provided to prevent over-winding. In Fig. 2

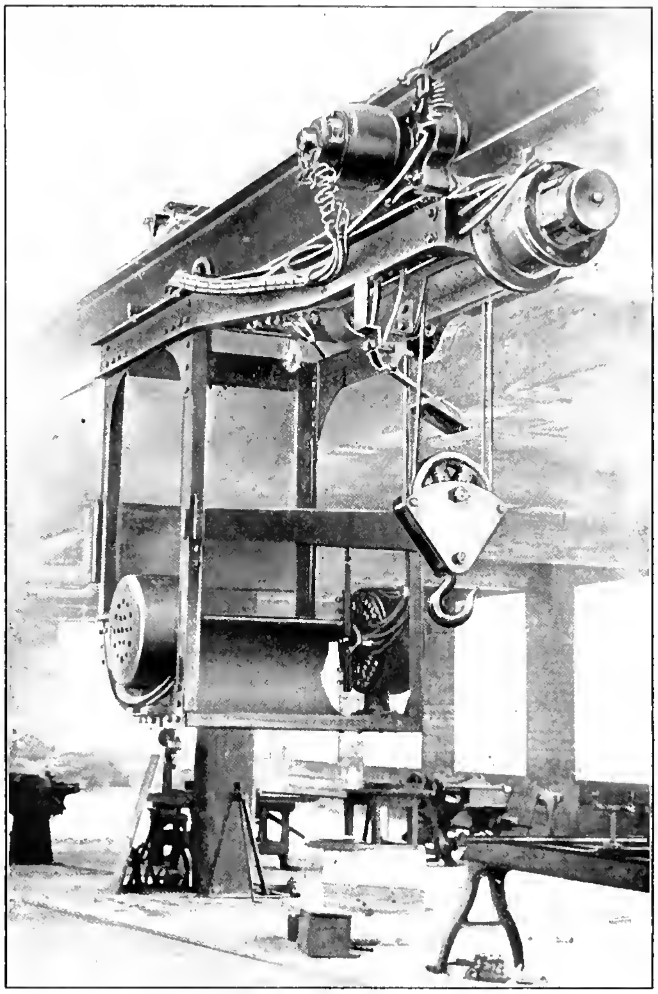

Fig. 2. The Shepard Hoist arranged with Self-traversing Trolley and Operator's Cab.

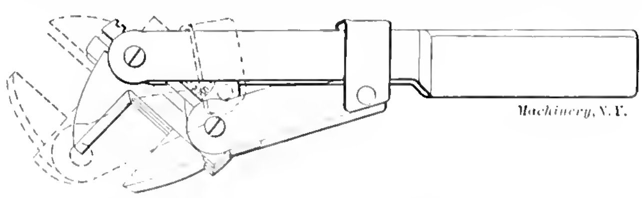
the device is shown applied to a trolley suspended from an I-beam as before, but with a second motor for power traverse, and a suspended operator's cab carrying the controllers, operated in this case directly by hand levers. The equipment shown in the latter figure is in use in the works of the American La France Fire Engine Co. Of course this hoist may be used in many other ways besides in the two applications shown.

RATCHET MONKEY-WRENCH.

The engraving shows a wrench of new and unusual construction which combines the handiness and quick adjustment of the monkey-wrench with the ability of the ratchet wrench to work in confined quarters. The jaws are adjusted to the size of the nut or screw head by a knurled thumb nut as in



An Adjustable Ratchet Wrench.

the monkey-wrench. As may be seen, the head containing these jaws is pivoted at one end to the handle, and at the other to a link connecting with a stirrup sliding on the handle. It may be used as a monkey-wrench with the jaws in the position shown if there is room for the turning movement re

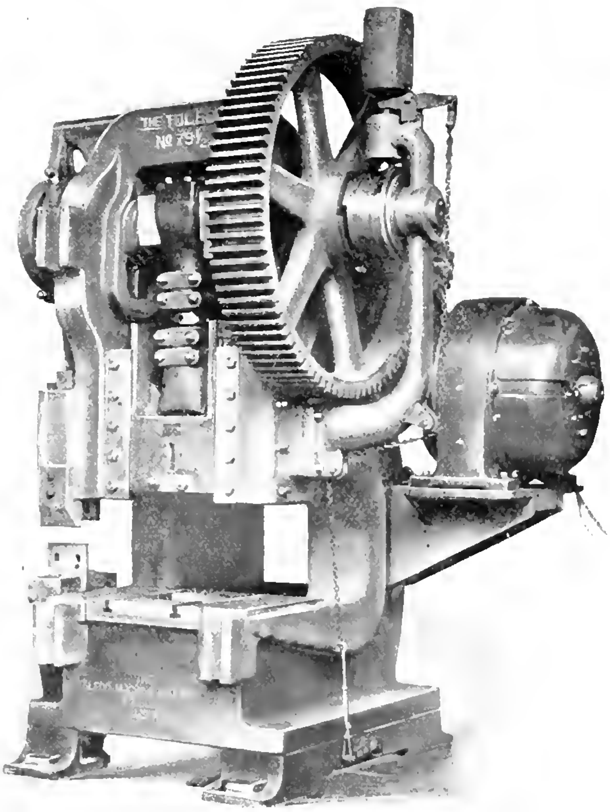
quired. When there is not room for this, the nut or bolt head may still be turned by successive short angular movements of the handle. The stirrup in this case acts as a ratchet, pushing the jaws around farther and farther with each movement. The head of the wrench can also be turned in the same way at any convenient angle, to get it into odd corners where an S-wrench would otherwise be necessary.

This tool is made by the Simplex Mfg. Co., 90 West Street, New York City.

LARGE OPEN-BACK SINGLE PITMAN GAP POWER PRESS.

The machine shown herewith was designed and built by the Toledo Machine & Tool Co. of Toledo, Ohio, for use in one of the United States Navy Yards for trimming hot or cold forgings. It is also intended for heavy blanking and shearing, thus making a tool of considerable range of usefulness.

As shown, the frame is of the over-hanging or gap pattern, with provisions for using the rods at the front for unusually heavy work which does not require the use of the gap. It is powerfully geared, and has an unusually long stroke for the main ram (7 inches), adapting it to the trimming of forgings



Press for Heavy Trimming, Blanking and Shearing.

of irregular or special shapes. An outer or shearing slide is provided on the left-hand housing. This has a stroke of 3 inches, and is capable of shearing, hot, 3-inch square bars.

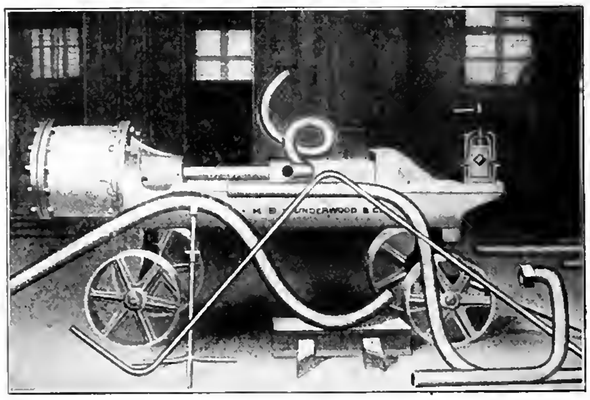
The clutch gear of this machine is 62 inches in diameter by 10 inches face, and the balance wheel, which weighs 1,600 pounds, is 50 inches in diameter. The distance between the uprights is 27 inches, the distance from the bed to the slide is 20 inches, and the area of the bed is 41 inches from right to left, and 28 inches from front to back. The distance from the center of the slide to the back is 16½ inches. The net shipping weight of the machine is 35,000 pounds. This press is the largest of a line of fifteen sizes designed and built by the makers.

RIGHT-ANGLE DRIVE FOR DILL SLOTTER.

The T. C. Dill Machine Co., Kensington, Philadelphia, Pa., has recently built a number of slotters with a drive at right angles to the axis of the base. This arrangement, which is believed to be new in slotter construction, has been found to be of marked advantage in allowing the tool to be placed in the proper relation with the line-shaft and the apparatus for placing and removing the work. This is especially true in the case of shops of the usual construction for heavy work, having a central bay served by a traveling crane, with side bays provided with line shafting, running lengthwise of the shop. Under these conditions, the slotter can be placed with the table projecting out from under the gallery into the space served by the crane, in which case its driving shaft will be parallel with the line-shaft from which it receives its power.

UNDERWOOD PNEUMATIC PIPE BENDING MACHINE.

H. B. Underwood & Co., 1024 Hamilton St., Philadelphia, Pa., have recently added to their list of tools a pneumatic pipe-bending machine, covering the range required in the ordinary work of the locomotive or air brake repair shop. It is

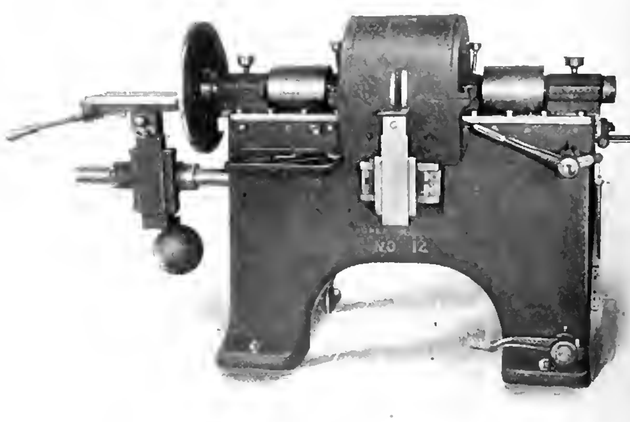


A Pneumatic Machine for Bending Pipe.

pneumatically operated, and will bend pipes to the desired radius without the filling and heating required for hand-operated machines. It will make a right-angle bend in a 2-inch pipe in two minutes, without flattening or injuring the work in any way. It will handle pipe from ½ inch up to 2 inches in diameter, in any standard radius required for locomotive work. Special dies for special radii or shapes are made to order.

COMBINATION SINGLE AND DOUBLE DISK GRINDER.

The machine shown herewith is a combination single and double disk grinder built by the Gardner Machine Co. of Beloit, Wis. It consists of a rigid box frame provided with ways on the top for two spindle heads, of which the one at the right is a sliding head operated by hand or foot lever, while that at the left is adjustable through a range of 8 inches.



Gardner Disk Grinder arranged for Single and Double Surfacing.

The latter head also carries a disk at each end of the spindle, the outer one being adapted for the full range of ordinary disk grinder work. For this work a table of any style desired may be furnished, the one shown being what the makers call their "universal lever feed table," adapted for a large variety of manufacturing operations. The feeds of this table are provided with micrometer stop screws on all movements.

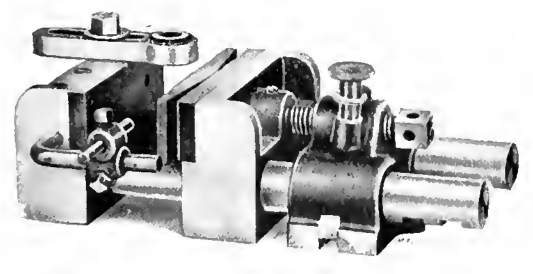
The double head grinder is adapted for machining rough pieces having equal opposite parallel faces, such as washers,

nuts, bolt heads, etc. The wheels are covered by a cast iron hood provided with a sheet steel shield, in which an opening of any desired size may be cut to suit the work being operated on. When an exhauster is used, this hood so encloses the machine that the operation is as dustless as that of turning or milling. As may be seen, the work is supported by a narrow table, adjustable on ways at the front of the machine for height and lateral position. This table projects between the two disks and supports the work when the disks are pressed against it. Micrometer stop screws are provided for limiting the movement of the heads toward each other, so that the work may be finished accurately to size. In work which requires both the hands of the operator for holding it, the feeding pressure is applied by the foot lever shown, a retracting spring being provided for withdrawing the movable head when pressure is removed, while a back stop limits its retracting movement.

The spindles of this machine are very large, and are driven by 8-inch belts. The end thrust is taken on large hardened steel collars bearing on composite babbitt and cast iron thrust surfaces. Double disks of any size up to 20 inches, and an outside disk up to 23 inches in diameter, may be used if desired. Chucks for carrying ring emery wheels are provided by the builder if the purchaser desired to use these on certain classes of work. A full assortment of tools and e.uipment, such as setting up press, cement, wrenches, etc., are provided with the machine.

THE BOWN DRILL PRESS VISE.

The drill press vise, shown in the accompanying cut, has been designed with the object of overcoming the inconvenience of hunting for straps, clamping bolts, nuts, etc., every time a piece of work has to be clamped to the drill press table. A great deal of time is spent unprofitably, because of lack of proper provisions for holding work on the tables of machines; and, although it is difficult to say to what extent the breakage of drills is due to improper means of holding work, it is probable that the expense incurred in this respect cannot be lightly considered. With a drill press vise, such as is shown in the cut, the work can be clamped instantly. As will be seen from the illustration, the vise is also provided with an adjustable strap, containing a drill bushing,



A Drill Press Vise with Locating and Jig Bushing Attachments.

and with adjustable stops, so that interchangeable work can be drilled in the vise accurately. The saving resulting from this use of the vise is apparent, as the expense of drill jigs for many ordinary jobs becomes unnecessary. In cases where a drill jig would not be made, then a great deal of time would have to be spent in laying out each piece of the work for drilling; this also becomes unnecessary for simple duplicate drilling when the vise is used. When work with many holes is to be drilled, a jig plate can be placed between the jaws, and this jig plate, covering the work, can contain any number of holes desired. In order to hold taper or irregular work rigidly, one jaw is made to swivel. Jaws are also made provided with vertical grooves, for holding round pieces in a perpendicular position for centering or drilling. The vise may, of course, also be used on other machines, such as planers, shapers, or milling machines.

The movable jaw is instantly adjusted to any desired opening, by pressing down a knob, which is connected with the tool steel locking bar. By giving the knob a slight turn, the bar is held down until the jaw is moved to the right position. Turning the knob back again, allows the locking bar to spring back into the square notches milled on the lower side of the rods; these notches are plainly shown in the cut. The jaws are made of tool steel and hardened, and the rods are also made of tool steel and ground.

The width of the jaws is 5½ inches, and the full depth to the bottom, 3½ inches. The depth to the rods is 1¾ inch. The regular vise can be opened up to 8 inches between the jaws, but longer rods are made to order so that openings of any width can be obtained. The weight of the vise is 33 pounds. It is made by the Bown Machine Co., Ltd., Battle Creek, Mich.

CORRECTION TO DESCRIPTION OF PLANER CLAMP.

An error was made in our description of the J. H. Williams & Co.'s planer clamp, which was illustrated in the December issue. The clamp is not case-hardened as was stated therein, but is given a special heat treatment which toughens and strengthens the forging, making it better suited to stand the rough usage that such machine tool accessories commonly get.

* * *

Some experiments regarding the strength of cast iron beams have recently been carried out at the Worcester Polytechnic Institute, and the data obtained during these investigations are given in the November issue of the *Journal of the Worcester Polytechnic Institute.* The experiments were carried out by Messrs. E. A. Adams, C. S. Frary, and E. H. Fish, of the Polytechnic Institute. The conclusions arrived at are very interesting, more particularly so as they do not fully agree with the commonly accepted ideas that a much higher stress should be permitted in cast iron beams on the compression side than on the tension side. It will be recollected that in our November issue we published an abstract from a paper on physical characteristics of cast iron, in which this question was referred to in connection with the design of shear or punch frames of the open jaw or gap type, in which it was stated that the breakages on the tension side were often caused by comparatively too little metal being deposited on the compression side. While the report of the tests at the Worcester Polytechnic Institute concludes with the statement that it is difficult to arrive at a definite conclusion of the tests made, it is added that it appears to be correct to design beams on the assumption that the strength of the material is the same in tension as in compression. A design made in this way would seem to be wasteful of material on the compression side, but it is said if the indications from these experiments are correct, then a smaller factor of safety might be used than has previously been the custom. The investigators sum up this conclusion, however, with the statement that what has been found from the present experiments can be taken only as an indication, and that tests on a still wider range of cross sections and sizes would be necessary before they would consider that this statement could be accepted as an actual fact. It will be understood, of course, that, while in designing a beam to carry a load the design would be based on the same strength of material for tension as for compression, that should not be construed to mean that cast iron when subjected simply to stress or simply to compression has got the same strength in both cases. Of course the well-known relation between cast iron's tensile and compressive strength, each considered by itself, which was thoroughly investigated over a century ago, is as true to-day as ever.

* * *

An item in the *Daily Telegraph*, London, mentions that lately about 0.1 ounce of radium was produced at the University laboratory at Vienna. Small as this quantity is, it is claimed to be the greatest yet produced, and to obtain it, ten tons of uranium pitchblende had to be used. The process of obtaining this amount of radium cost $10,000. Important experiments will now be begun at Vienna to ascertain whether the theory of Sir William Ramsay, that radium can be converted into other elements, especially into helium and lithium, be correct or not. It is also mentioned that the Vienna Academy of Science, in recognition of the great services rendered by the English scientist in connection with radium discoveries, will lend him a fraction of this one-tenth of an ounce for the purpose of experiments.

INDUSTRIAL NOTES FROM EUROPE.

BRITISH TRADE TOPICS.

Though the aggregate of British trade keeps up wonderfully, signs are not wanting that considerable caution will, in many instances, be needed as regards future productive policies. German producers of iron and steel in various forms are not so well engaged as for some time past, and doubt as to the future action of the Continental and American syndicates tends to restrict British trade movements. The high bank rate, largely due to the drain of gold on account of American financial troubles, also considerably hinders current enterprise.

Trade Disputes and Labor Questions.

The threatened railway trouble has been obviated, largely through the tact and administrative ability displayed by Mr. Lloyd George, president of the Board of Trade. The agreement reached holds good for at least six years. Committees of various grades of railway men will confer with the local railway companies' officials with respect to any grievances. If the matter is not settled to the satisfaction of the men, the directors of the companies may be negotiated with. Failing a settlement, the matter is to be placed before a Conciliation Board composed of equal numbers of representatives of the companies and the men, the men's trades union officials being eligible as members of the board; and an arbitrator appointed by the Speaker of the House of Commons or the Master of the Rolls, or both, will give the final decision, which will be binding on both parties. Though deprecated by extreme trade unionists, the settlement arrived at is generally approved as admitting the principle of trades union recognition, with a minimum of interference with the internal discipline of the railways.

Ship Building and Naval Topics.

Shipbuilding returns show a continued decline, both on the northeast coast and on the Clyde, new orders comparing very unfavorably with the corresponding period of last year. The rapid completion and fine trial records of the *Mauretania* are naturally very gratifying to the Northeastern district, its constructional facilities being thus proved second to none. In naval circles current matters of interest include the launch of the *Cyclops*, now being fitted at Portsmouth. The vessel will be the most powerful and completely equipped repair ship afloat. The lifting shears fitted on board will be capable of lifting a torpedo boat completely out of the water. The naval dockyard extensions at Devonport are of an important character. The new crane will lift 160 tons at a radius of 95 feet, 80 tons at 115 feet, and 30 tons at 128 feet, and is understood to be the largest of its class yet installed. Satisfactory progress is being made with the piecing up of the *Suevic*, and it would appear, as a consequence of precautions taken, that the vessel will be more seaworthy than when new.

General Progress of British Industries.

During the last few years British manufacturers have, in the face of international competition, done so well generally, in consequence of adoption of meritorious foreign methods or machinery, that there is some little danger of a return of the self-satisfied condition which preceded the temporary setback experienced in some branches about ten years ago. Mr. Joseph Adamson, president of the Manchester Association of Engineers, in his presidential address, drew attention to the importance of the Manchester district retaining, or regaining, its previous reputation as a center of industrial research and pioneer work. It is only necessary to mention such names as Crompton, Arkwright, Roberts, Nasmyth, Whitworth, Bodmer, Fairbarn, Daniel Adamson, Joule, Dalton, etc., to indicate the type of men who initiated the characteristic productions and influence of Manchester engineering, and the task which awaits their industrial successors. Mr. Adamson was of the opinion that standardization of designs, products, and methods, had gone far enough for a while, and that more attention should be paid to original work than has been the case for some time. Curiously enough, similar advice has recently been proffered to American manufacturers and engineers.

The utilization of what has often been considered waste heat or gases from blast furnaces, etc., is being much more systematically carried out than formerly. The latest proposition, likely to be carried into effect, is to employ the waste heat from coke ovens for the production of electric current, the plant being run by special power companies, who will purchase the gases from the coke oven proprietors and sell the current. In some instances the same procedure will be followed in the case of blast furnace gases.

Touching on South America and neighboring machinery business, it is of interest to note the obtaining by Mirrlees, Watson & Co., of Glasgow, of a large contract for the machinery of a sugar factory at Porto Rico, the order, which amounts to about $350,000, being obtained against considerable international competition.

Automobile Industry.

The outstanding feature at the motor car exhibition at Olympia is the strong position of British makers, who appear to have quite made up the considerable leeway which divided them from their Continental competitors a few years back. The greatest successes of the Continentals have been represented by the cars constructed practically regardless of expense, but in consequence of the bad summer and overproduction, the firms building these cars are not so well placed as the British builders mostly are, who, while offering the expensive styles, have also planned to easily change, if necessary, to the manufacture of moderate, or even comparatively low-priced, cars, and in fact the latter are now being made a leading line by several makers. While special tools for manufacturing the parts of motor-car mechanism have been designed and largely sold, the needs of repairers and small makers are receiving a fair share of attention. As was the case a few years ago in the cycle trade, small makers can often produce a small or medium priced car of a quality to compare favorably with the product of the large concerns, and at a distinctly lower price.

Machine Tools.

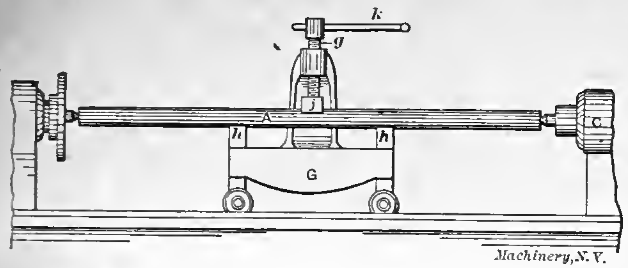
A lathe of 9-inch swing, adapted for repair and amateur workshops, is being built by King & Co., Armley, Leeds. In addition to turning and boring work, it is easily adaptable for many milling jobs. The main variations from ordinary lathe design are in the saddle and tail-stock. The saddle slides on a pair of Vs, cast on the front face of a strong bed, and carries a vertical pocket, the bore of which corresponds to the bore of the tail-stock barrel. Cast onto the under side of the compound slide-rest is a shank which is turned to fit both the saddle pocket and the tail-stock barrel, a nut in the end of the shank being made to engage with the screw in both barrels and saddle pocket. The change from a lathe to a milling machine is easily effected by taking out the spindle from the tail-stock, and then taking the compound rest out of the saddle pocket and putting it into the tail-stock barrel. The top slide of the compound rest consists of a table 8 x 5 inches, provided with two T-slots on which to secure tools and jigs when used as a lathe, and jigs and work when used as a milling machine. The table has a traverse of 10 inches, and a cross traverse of 5 inches. Within the limits of these traverses objects can be milled with practically the same facility as on an ordinary milling machine. Spur wheels up to 10 inches diameter by 1½ inch face can be cut, or greater widths up to 7 inches diameter. Attachments are in preparation for converting the lathe into a shaping and boring machine. Though, as a rule, machine tools of too comprehensive a range are not desirable, a tool as described can be profitably used in many cases. We may add that the machine, as described, is listed at $150 when arranged on a 4-foot bed. At one time the small upright and sensitive drill presses were almost an impregnable line with certain American makers. Though a good many of the best makes from the States are still sold, several makers over here find that they can make them with profit. In fact, one firm—Jones, Pollard & Shipman—almost confine themselves to upright and sensitive drills, and, finding their works accommodation altogether too cramped, are now building a large new works at Leicester, adjoining their old premises. With the additional equipment to be installed, the firm will be placed in an exceptionally good position for profitable manufacture and rapid output. JAMES VOSE.

Manchester, England, Dec. 5, 1907.

PUNCH PUNCH

SHOP OPERATION SHEET NO. 52.

H. K. Griggs. MACHINERY, February, 1908.



To Straighten a Rough Bar for Making a Shaft.

1. Take the rough bar *A* to the centering machine, and drill and ream center holes in each end.

2. Place the shaft straightener *G* on the lathe bed with its supporting wheels between the inside and outside vees.

3. Fasten a lathe dog to one end of the bar *A*, and place the bar between the lathe centers.

4. Start the lathe at a moderate speed, the slowest speed with the gears out being about right, and hold a piece of chalk close to the bar. If the bar runs out of true, the chalk will make a mark on the high side. In this way test the bar at various points until the greatest bend has been located.

NOTE.—When straightening a small bar, it may be rotated by drawing the hand rapidly across it. This will cause the bar to revolve on the centers, and then the chalk may be held against it as described. When rotating a bar in this way, the dog is, of course, not needed.

5. Turn the bar *A* until the chalk marks are up, and then move the straightener *G* to the most pronounced bend in the bar, as indicated by the chalk marks. Bring the pressure-screw *g* directly over this bend, and place the blocks *h* under the bar as shown. Slack up on the lathe centers to avoid springing them. Bring down the pressure-screw block *j* upon the bar *A*, and with the lever *k* turn the screw *g* sufficiently to bend the bar, not only straight, but to produce a slightly reversed curve to compensate for the tendency to spring back. If there is a reverse bend in the bar, the bar running out in opposite directions, first straighten one of the bends. The bar will then run out in one direction only, and this bend can then be straightened.

NOTE.—In case of short bends, the blocks *h* may be placed nearer each other. If very short bends occur near the ends, the center hole may run out of true and should be reamed again. Very large shafts, or those of high carbon steel, having short bends, should be heated before being straightened.

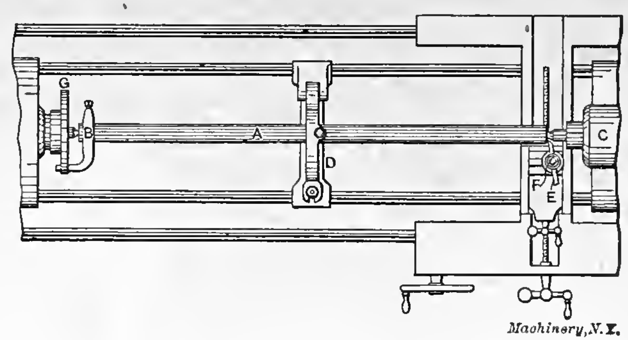
6. Set up the tail-center, and again test the bar with the chalk. If the bar still runs out, again move the straightener to the most pronounced bend and straighten as before. Continue in this manner until the bar is practically straight.

NOTE.—The surface of a shaft is sometimes under a tension due to the rolling process. Because of this it is at times difficult to turn a long shaft and have it perfectly straight when finished, as this tension is removed in turning the shaft, which causes it to spring and run out of true when the center-rest is removed. For this reason it is often necessary to straighten the finished shaft.

PUNCH PUNCH

SHOP OPERATION SHEET NO. 53.

H. K. Griggs. MACHINERY, February, 1908.



To Face the Ends of a Rough Bar for Making a Shaft.

NOTE.—In the regular production of shafting, special appliances are in use by which the standard sizes are rapidly turned out. It is, however, often necessary to make shafts when these facilities are not available. In the present instance the shaft is supposed to be of such a length that a center support is necessary to prevent sagging. It is also assumed that center holes have been drilled and reamed in the ends of the rough bar.

1. Set the tail-stock *C* so that the lathe will take the bar *A* between the centers, and clamp it.

2. Fasten the lathe-dog *B* to one end of the bar *A*, and place the bar between the centers of the lathe, the dog engaging with the slot in the face-plate *G*. Oil the tail-center and set it up in place.

3. True up a spot, which is to be used as a bearing for the center-rest, near the middle of the bar *A*. This spot should not be midway between the ends of the bar, but about six inches nearer the head-stock end. When turning this spot, use a sharp pointed tool, and take light cuts, using a fine feed.

4. Clamp a center-rest *D* to the lathe bed, placing the center-rest so that its jaws are opposite to the spot just turned. Adjust the jaws to the work and oil their inner ends.

NOTE.—If a bar is quite long, it may be impossible to turn a spot near the middle of the bar because of its extreme flexibility; in such a case, a spot is turned on the bar as far from the dead center as possible and the center-rest jaws are adjusted to this spot. Then a second spot is turned farther along the bar, and, if necessary, the operation repeated. When it is not desirable to turn a spot for the center-rest, a "cat head" is sometimes used. This consists of a collar, about six inches long, which has four set-screws in each end. This collar fits loosely over the bar, and it is adjusted by the set-screws until it runs true. The jaws of the center-rest are then adjusted to the cylindrical surface of the cat head between the heads of the set-screws.

5. Place the facing tool *E* in the tool-post *F*, and clamp it.

6. Face the end of the bar *A*, feeding from the center out, by hand.

7. Take the bar out of the lathe, turn it end for end, and change the dog to the opposite end. Then face the second end as described in steps 5 and 6.

PUNCH PUNCH

SHOP OPERATION SHEET NO. 54.

H. K. Griggs. MACHINERY, February, 1908.

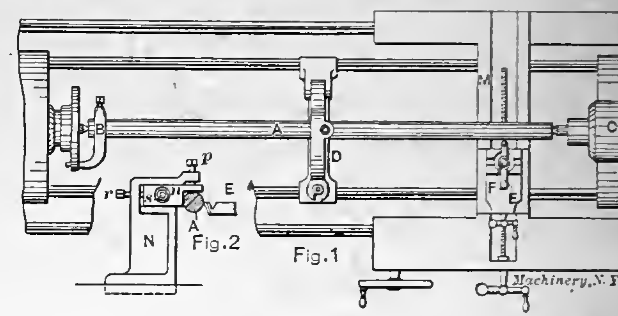


Fig. 2 Fig. 1

To Rough Turn and Finish a Shaft from the Rough Bar.

NOTE.—The bar *A* is supposed to have been center-drilled and reamed; to have been straightened; to have had the ends faced and a spot turned near the middle for a center-rest bearing.

1. Adjust the jaws of the center-rest *D* to the turned spot on the bar *A*. Care should be taken to have the jaws bear evenly on the bar to avoid springing it, and when the jaws are adjusted, the bar should rotate easily. Oil the inner ends of the jaws.

2. In the tool-post *F*, clamp a diamond point roughing tool *E* and turn 3 or 4 inches of the end of the bar to within 1/32 inch of the finish diameter.

3. Upon the rear of the carriage *M*, fix the follow-rest *N* (Fig. 2) with its jaw *n* in close contact with the turned portion. Adjust the jaw *n* by the set-screws *p* and *r*, and clamp it by the bolt *s*. This follow-rest steadies the bar when it is being turned, and the roughing cut may now be continued until the carriage is prevented from going farther by the center-rest *D*.

4. Turn the bar *A* end for end, and change the dog *B* to the opposite end. Rough turn this half of the bar as described in steps 2 and 3.

NOTE.—When rough turning a shaft, it will become more or less heated which will cause elongation. Because of this it is necessary to slacken the tail-center at times, especially when turning long shafts, to avoid springing them.

5. After taking the roughing cut, unscrew the center-rest jaws, speed up the lathe and see if the rough-turned shaft runs true. If it does not run true, again turn a spot for the center-rest jaws.

6. Again adjust the jaws of the center-rest to the work, and replace the roughing tool *E* with a finishing tool having a straight cutting edge and slightly rounded corners. Set the tool to the exact finish diameter, and take the finishing cuts in the manner described for the roughing cuts in steps 3 and 4. When taking this cut the tool should be lubricated with soda water, or some soapy mixture. A lubricant of this kind can also be used to advantage when taking the roughing cuts.

NOTE.—Regular shafting lathes are sometimes arranged so that a shaft can be driven from either end. This is desirable when turning a long shaft, as otherwise the torsional stress at the beginning of the cut would be considerable.

This data sheet is made up so as to be readily bound. It may be cut into four sections, 6x9 inches in size, and bound into note-book form for convenient reference, by means of staples inserted into holes punched at points indicated.

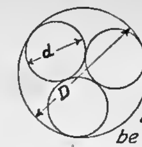
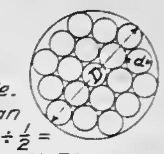
TABLE OF INSCRIBED TANGENT CIRCLES.



Approximate Formulas:

$N = 0.907\left(\frac{D}{d} - 0.94\right)^2 + 3.7. \qquad R = 0.94 + \sqrt{\frac{N-3.7}{0.907}}.$



N = Number of inscribed circles.
R = Diameter of large circle ÷ diameter of small circle.
Example:- How many wires $\frac{1}{2}$ inch in diameter can be placed inside a 5 inch pipe? The value of R is $5 \div \frac{1}{2} =$ 10, and looking for this number in table, find by interpolation N = 76.

N	R	N	R	N	R	N	R	N	R

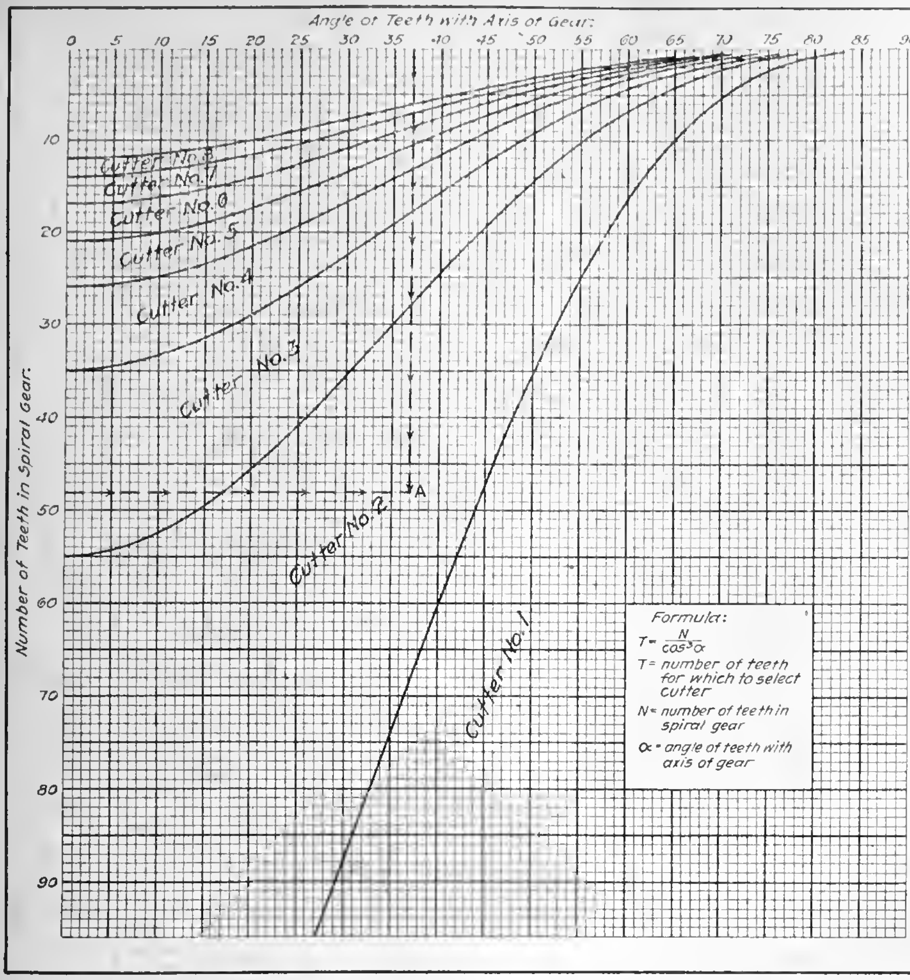
DIAGRAM FOR FINDING SPIRAL GEAR CUTTER NUMBERS.



The cutter used in milling spiral gears is a standard spur gear cutter; the only difference being that the number of the cutter used to cut a spiral gear is not necessarily the same as that used to cut a spur gear of the same number of teeth. The angle of the teeth of a spiral gear with its axis affects the tooth form, and therefore, the number of the cutter.

The selection of the cutter is fixed by the formula given in the lower right-hand corner of the diagram. The delimiting curves thereon were plotted by the formula, the area between the curves being the field of intersection of the combinations of angles and numbers of teeth covered by each designated cutter number.

For example, suppose the angle of the teeth of a gear is 37 degrees with its axis, and the number of teeth is 48. The point A, at which the horizontal line (representing the tooth number), and the vertical line (representing the angle) intersect, falls within the area marked "Cutter No. 2" Therefore, a No. 2 cutter is required to cut a 48-tooth spiral gear having the teeth at an angle of 37 degrees with its axis.

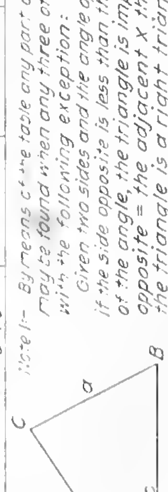

Fig. 1

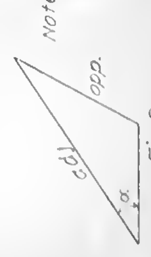

Fig. 2.

Note 1:— By means of the table any part of an oblique triangle may be found when any three other parts are given, with the following exception:

Given two sides and the angle opposite one of them; then, if the side opposite is less than the adjacent × the sine of the angle, the triangle is impossible; or if the side opposite = the adjacent × the sine of the angle, the triangle is a right triangle; or if the side opposite is less than the adjacent but does not come under the above, the triangle is capable of two solutions and can be drawn as in Fig. 2 as well as in Fig. 1.

Note 2:— In some cases two steps are necessary to solve, as for example, having given sides a and b and angle A, to find c: The formula reads $c=\frac{a\sin C}{\sin A}$ but angle C must first be derived from $C=180°-(A+B)$, and the same applies to other angles in certain cases as is apparent above.

MACHINERY.

MONEY AND MONEY-MAKING MACHINERY.

CLAUDE E. HOLGATE.*

C. E. Holgate.

IT has been said that one of the most important functions of the government is the creation of money and its distribution. Money itself is the most important instrument of civilization in contributing to human comfort and enjoyment. With pieces of paper bearing the seal of the Treasury of the United States, the holder can procure for his use any article of necessity or luxury produced in the world. Without this contrivance called money, he would be compelled to live within very narrow limitations, and his conveniences and comforts would be but little better than those of a savage. It is not the province of this paper to discuss the money question, nor to volunteer individual opinions as to the prospective future policy of the United States with reference to its money, but it is proper to say that the tendency of modern thought and civilization is to regard the issue of all kinds of money as distinctly a national function, to be exercised only by that sovereign power whose mandates and prerogatives constitute the supreme law of the land. Therefore, a word or two in these times of financial stringency, concerning the machinery and the manner of producing our national currency, may prove of interest.

Fig. 1. Bureau of Engraving and Printing, where the Paper Money is made—and afterwards destroyed.

In a general way, most every one knows that our so-called paper money is made at the Bureau of Engraving and Printing, at Washington, but it is safe to say that very few outside of those directly connected with the industry, know that practically all of the important machines used in bank-note engraving, not only in the United States, but all over the civilized world, are supplied by less than half a dozen concerns in Newark, N. J.

The office of the Bureau of Engraving and Printing is to design, engrave, and print all the obligations of the government of the United States, including the interest-bearing bonds, the treasury notes, the national bank-notes, and the gold and silver certificates; also to design, engrave and print the customs and internal revenue stamps, postage stamps, and checks and drafts used in the different departments of the government.

Until recent years, the postage stamps were printed by private bank-note companies, who were the lowest bidders in competition with the Bureau of Engraving and Printing. The Secretary of the Treasury selects the subjects which appear on the face of the government money and securities. The portraits only of departed citizens who have won distinction are used. Living subjects are not reproduced in the design. The designs are made under the supervision of the Chief of the Engravers' Division of the Bureau, and all are subject to the approval of the Secretary of the Treasury.

The designs on the government money are engraved on steel dies. The complete design for the engraving having been selected, a corps of engravers begins work on the different parts of the design. One engraver may work upon the portrait, one upon the lettering, and others upon the ornate work. The engraving of an entire design is never entrusted to a single person, and the whole design is never made upon a single plate, but in sections. When the engraving on the different sections is completed, the dies are hardened and tempered. Sectional rolls, of soft steel, are then passed over the hardened dies by pressure, and the design is transferred in relief to the roll. Each sectional roll bears a part of the complete design. The whole design is then transferred to one piece of steel called the bed-piece, from which a complete roll is made. The finished roll is then tempered and hardened, and four notes are transferred to each plate. This plate is also hardened, and is then ready for the printer. When the complete roll and the printing plates are worn out, recurrence is had to the original rolls, and when these rolls are unfit for further use, the original dies are brought into requisition for the production of new rolls and plates. Rolls and plates are hardened by the cyanide of potash process.

The paper money of the United States, when it is new and fresh from the press, is the finest in the world, and its production is the most expensive. The paper used is made by the Crane Mills, at Dalton, Mass., expressly for the Bureau of Engraving and Printing, and directly under its supervision. It is composed of fine linen and silk, and a collection of silk fibers run lengthwise through the sheets. The process of its manufacture is known only to the manufacturers and the officers of the Bureau. Heavy penalties are imposed merely for the act of having the unprinted paper in possession. The commercial bank-note companies have the government's sanction to use a security paper, also made by the Crane Mills, in which planchettes or small pieces of silken fiber are interwoven in the texture of the paper during manufacture, but they are not permitted to use the kind employed by the government in the making of money.

All of the engraving on the plates used is hand work, with the exception of the fine scroll or lace work, which is done by a triumph of mechanical ingenuity known as the geometric lathe, and a cycloid ruling machine for the straight work. Most of the engraving on the back of the different denominations of paper money is the work of the geometric lathe. As these machines cost over $5,000, and as it requires an expert mathematician to operate them, it will readily be seen that the work of the counterfeiter is much embarrassed by its operation.

* Address: 464 Washington St., Newark, N. J.

Origin of the Geometric Lathe.

The first geometric lathe was invented by Charles W. Dickinson, who died in 1900, and whose business is now carried on by his son, C. W. Dickinson, Jr., at Belleville, a suburb of Newark. Mr. Dickinson, the senior, was employed as a watch-case maker, and became interested in fine machinery. "Engine turned" watch cases began to be the style, and he made his first lathe for the purpose of decorating a watch case. This was a success, and a jeweler asked him to make a machine to cut a die which could be used to decorate an oval silver salver. The salver was thirty-four inches long, and the pattern was to follow its general form in one continuous figure or set of interlaced lines. This necessitated new motions being added to the machine, the one he then had being arranged for circles only. Mr. Dickinson made the machine and it was a great success. Later a man wanted a machine to make the curved combinations on bank-notes. A thousand dollars was deposited as a guarantee, and the machine was made. Notice was sent to the individual ordering it when it was completed. Nothing was heard from him, however, and the lathe was sold to someone else. Three years afterward this man was one of a gang arrested for counterfeiting. This gave Mr. Dickinson an idea of one great use for his lathe, and the present geometric lathe, to which improvements have been added from time to time, is the result. The first one was used upon bank-note plates in 1862. Mr. Dickinson went to Washington to run the lathe he had built for the government, and stayed there a year and a half, cutting new combinations for the currency then in use, until he had succeeded in instructing someone in the intricacies of running the lathe. The geometric lathe complete is one of the finest pieces of machinery in existence. It is constructed of a number of superimposed flat plates, accurately hand scraped to surface-plates, which are actuated by cams and gearing, and these are as near perfection as it is possible for human endeavor to get them. It requires four men, about five months, to build one of these lathes, and as infinitesimal accuracy is required in laying out the work and fitting the various movements together, only the most skilled mechanics, who have had years of experience in building this class of

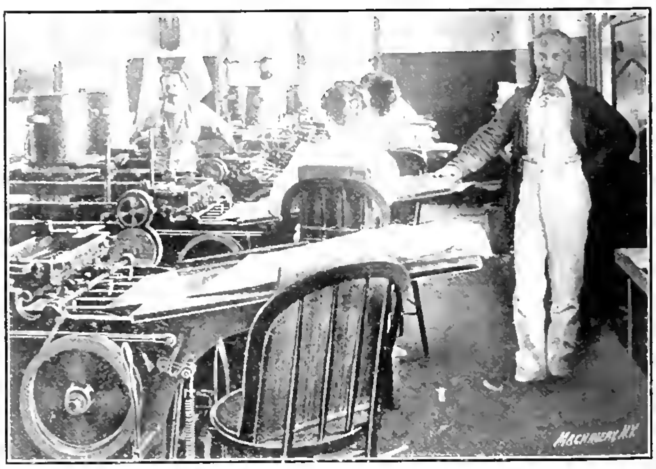

Fig 6. Machines for Gumming Postage Stamps.

machinery, are employed in the work. The accuracy required will be appreciated when it is known that this machine will produce lines so close together that they can only be counted with the aid of a microscope. In the finer engraving, it is possible to work within a twelfth of one-thousandth of an inch. The lathe produces an almost endless combination of geometric figures, by means of combinations of gears, cams and eccentrics. Over twenty million different patterns have already been counted off, and the end is not yet reached. In fact, with his latest improved lathe, Fig. 7, Mr. Dickinson claims to be able to get almost any movement desired.

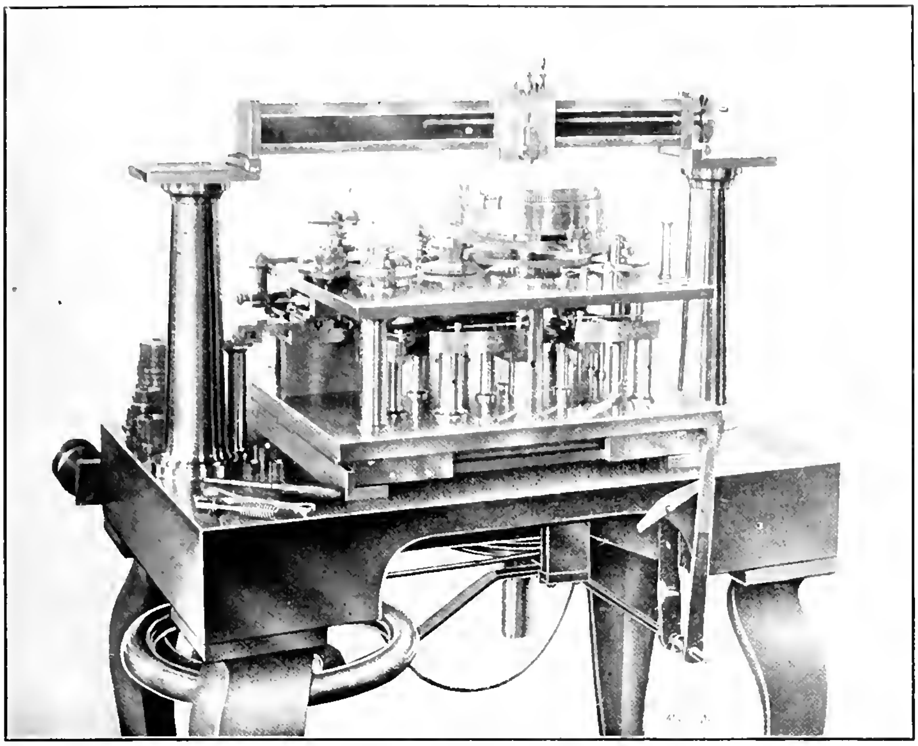

Fig. 7. Improved Dickinson Geometric Lathe.

At the corner of a treasury note, the figure denoting its denomination rests upon an ornate design in the shape of a heart, trefoil, a hexagon, an oval or some other design composed of wave lines finer than hairs. Down in the corners you will find the words "five," "two," or the letter "V" or figure "2" printed upon the same little lacy figure made up of the finest lines. Turn the bill over and you will find the lacy figures repeated in groups or borders, almost entirely covering the back. Look at the little green band around a box of cigars or a bag of tobacco, and somewhere upon it appears similar combinations of circles and wave lines. Every treasury note, every revenue stamp, postage stamp, bank bill or bond carries these fine lined creations, and each of a different combination so as to make it difficult to counterfeit. In fact the design in each corner of the face of every bill is different, thus multiplying the difficulty. The die to be engraved is clamped to the top platen or chuck of the lathe. The hardened steel cutting tool—sometimes pointed with a diamond—is fastened in a stationary position on the cross-beam shown at the top of the lathe. The working of the lathe is like fairy fingers. There is no noise only a slow movement or series of movements of the platen holding the die. The die follows the directions necessary to produce the pattern. Each pattern is calculated mathematically from the degree of a circle. Sometimes it will take two months to make a shell or die of the most intricate patterns. Ordinarily it takes four or five days to complete one of the small designs in the corner of a bill. Not only is the distance from each line measured, but the depth to which the tool is to go. The cutting tool is adjustable vertically, and after a given series of movements is completed, the tool is adjusted and a deeper cut taken. The average number of cuts on each movement is about twenty. Having had one row or thread of the figure cut upon it, a shadow of change in the adjustment of the lathe is made, and now the movement may perhaps be from the center to the rim of the design, in and out, over and over again. There are only about twenty of these lathes in existence, and they are owned by the United States and foreign governments, or by the bank-note companies, and it is safe to say that they are the product of either the Dickinson shops, or those of the W. H. Chapman Co., which are also located at Newark. It is unnecessary to add that the U. S. Secret Service keeps a close watch on where new lathes go, as well as the plates that are turned out on them.

While the operator of the geometric lathe has been turning out his lacy designs, the hand engravers have been busy with the portrait work and lettering, and when all the separate dies are completed they are then ready for the transferrer, whose methods of operation are described in the fore part of this article.

The Transfer Press.

The transfer press, which is used for transferring the separate designs from the dies to the soft steel rolls, and thence back to the flat plates as a completed design, is an important machine in this work. It not only is an aid to the government in its policy of having each part of a treasury note engraved by a separate person, but on bonds and other work of this character, it effects a wonderful saving in time, as it enables several engravers to work on various parts of a design at one time; these are then assembled by means of the transfer press into a complete design. It would take a great many months to complete a design if the original engraving were all done on one plate, and each engraver would be required to wait for the other to finish before he could start on his part of the work.

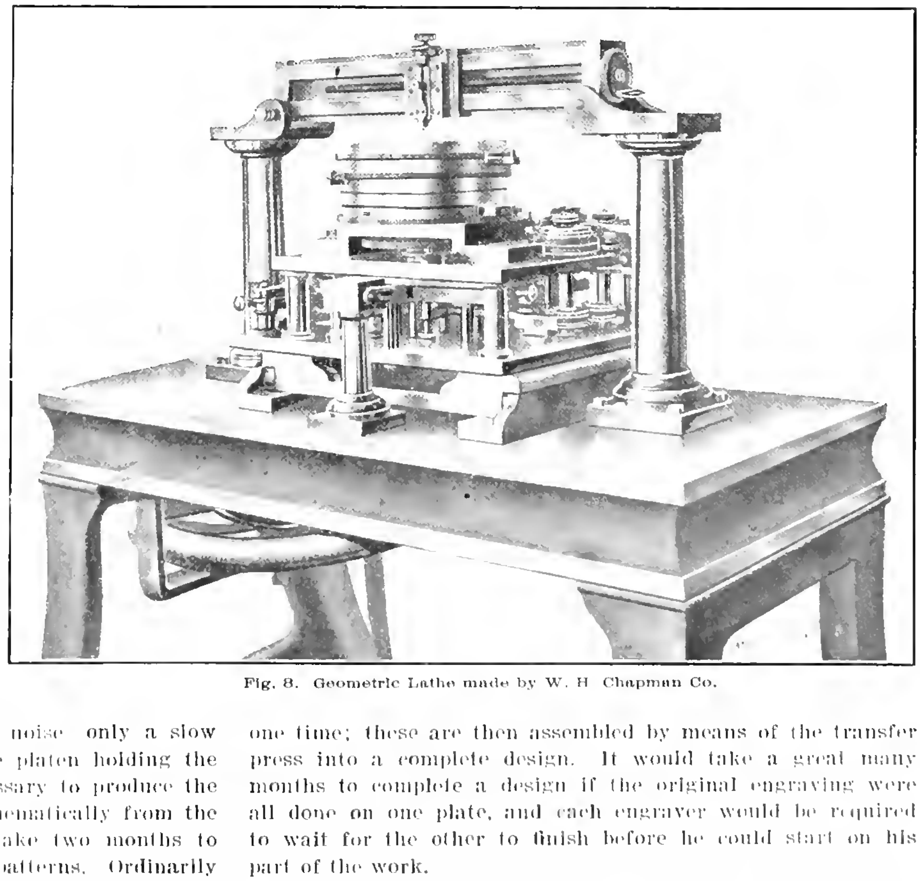

Fig. 8. Geometric Lathe made by W. H. Chapman Co.

The transfer press is designed on the compound lever prin-

ciple, as will be noted on referring to the illustration. The engraved die, and the roll which is to receive the impression, are set square with each other by means of a very delicate and accurate gage seen at the front end of the large beam at the top of machine. Then the foot-lever which extends under the bed of the press is depressed and the operator, or transferrer as he is called, racks the die back and forth across the surface of the roll through the medium of the large hand-wheel on the side of the press. The shaft on which this hand-wheel is keyed, carries a spur pinion on its inner end which meshes with a rack in the bed of the press. With this style of press and its system of compound levers, great pressure can be produced, the ratio between the end of the foot-lever, where the

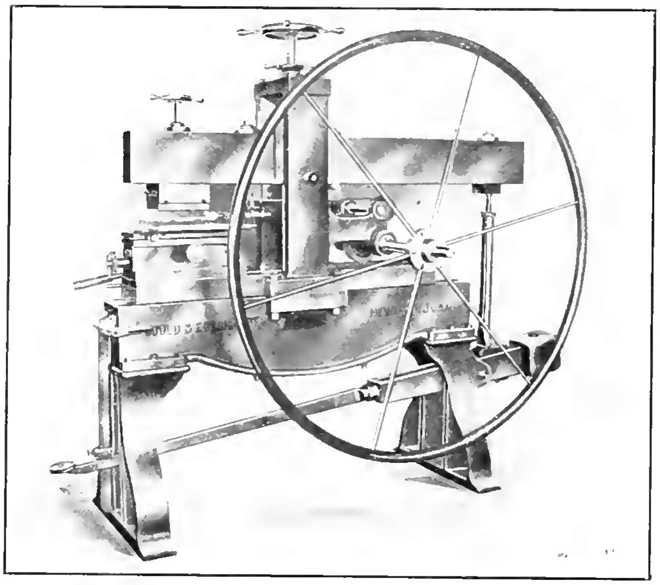

Fig. 9. Gould & Eberhardt's Improved Transfer Press.

initial pressure is applied, and the end of the beam where the roll is placed being about thirty-five to one.

At one time the government manufactured its own presses. Castings were made under the directions of the Bureau, and put together by machinists in their employ. This policy, however, was abandoned several years ago, and the government now purchases new presses when needed. Some of the first transfer presses were made by Poole & Hunt, of Baltimore, but in later years nearly all of the presses used by the bureau and the bank-note companies have been manufactured by either W. H. Chapman Co., or Gould & Eberhardt, of Newark. The latter concern has made a number of valuable improvements in the press, some of which have been patented. The original design of the press has been made more stable in construction, and more convenient for the operator, and their type of transfer press is used by the government in issuing its specifications for new machines.

The Printing Presses.

Two styles of presses are commonly employed by the plate printers for their flat work, one known as the D-roller hand press, and the other as the steam power plate press. A new press, however, has recently been designed, by which it is possible to bend up the engraved plates in circular form and print from them on this press very much like the ordinary cylinder presses. While the commercial bank-note companies find occasion to use a great many of the steam presses for their bond work, lithographing, etc., and while the government also uses them for some of its work, for the finer work, the government prefers the hand press, of which there are several hundred in use. It was long contended by expert engravers and printers that the fine effects attained by hand work could not be obtained by the steam presses, however ingenious.

This contention, however, has been disputed, and a test by inspection, was made several years ago, of work done on the two styles of presses. As a result of this, the government still continues to use the power presses. The law governing the printing of the United States money requires that it be done "in the highest state of the art," and it is safe to say that hand-operated presses will still continue to be an important factor in turning out the higher grades of work.

The steam presses are used almost exclusively at the Bureau for printing the backs of treasury and bank-notes, and for revenue and postage stamps. The first printing of any money is on the back. The printing of the face of the note (which is done on the hand presses) then follows. Then follows the numbering consecutively by automatic numbering machines. The final process is the imprint at the treasury of the seal of the Treasury Department, which makes the money valid. The signatures of the Treasurer and Register of the Treasury are printed in fac-simile, and not signed as many suppose. The national bank-notes, however, are signed in ink by the president and cashier of each bank.

The special paper used comes from the Treasury Department dry. It is then counted and prepared in the damping room for the presses. Women in the damping room receive so much paper each morning, count the sheets and give receipts for them. Layers of sheets are laid between layers of wet cloths, twenty sheets to a cloth, and then subjected to a strong pressure. When the sheets are turned over to the printer, his woman assistant counts them and certifies to the number, which certificate is witnessed by the printer, who thus in turn becomes responsible. Lock-boxes, attached to each press, register automatically every sheet printed. During the process of printing, before the plate is inked, it is warmed over a gas stove which is attached to the press. The plate is then inked thoroughly, so that the ink fills all of the engraved depressions. The surplus of ink is next rubbed off with a cloth, and it is finally rubbed off with the hand and polished with a whiting substance. The assistant lays on the sheet, and the final impression is made. This seems a slow process, and yet each hand printer and his assistant average from 800 to 1,000 impressions a day, each sheet containing four bills.

The functions of the steam power plate press are practically the same as those of the hand press, with the exception that the different operations are nearly all performed automatically by the press itself. The steam press consists of a large, square table, with four "planks" on which the engraved plates are carried. Sometimes only one plate is used at a time, and at

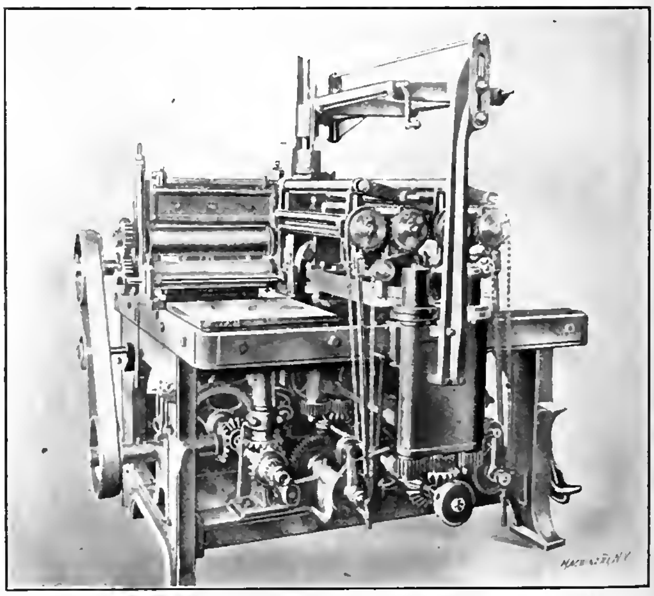

Fig. 10. Gould & Eberhardt's Steam Power Plate Printing Press.

others any number up to the capacity of the press, which is four plates. These plates are automatically and continuously carried around each side of the press by means of an endless chain, bringing them successively under the inking and printing rolls. One man and three women assistants are required to operate it. After the plate is inked by the machine, an automatic wiper removes the surplus ink, leaving but very little hand polishing to be done. One of the assistants then lays the sheet on the plate, which passes under the printing roll, after which the sheet is removed by another assistant, and the plate continues on to complete another cycle. The speed with which the plate is carried around the press varies with the work to be done, and can be regulated to suit. The number of impressions, however, average from eight to ten a

minute. After printing, the sheets are put in lock-boxes, and are taken by messengers in lots of 200 to the Examining Division, where they are counted and certified. If the count is correct, they are put in perforated racks and wheeled into the drying room where they are dried by artificial heat.

Just before the last stage of the work, and after printing, the sheets are placed between heavy sheets of cardboard, and subjected to hydraulic pressure. The pressure is 5,000 pounds to the square inch on money, checks and postage stamps, and 4,500 pounds on the revenue stamps. The next step is to take the sheets to the numbering room, where they are trimmed and numbered. Finally they are put up in packages of 1,000 sheets and placed in the receiving vault of the Bureau, where they are kept until transferred to the Treasury Department. Each sheet has been counted more than fifty times, and it takes about one month to complete the printing.

HIGH-PRESSURE TURBO-COMPRESSORS.

ALFRED GRADENWITZ.*

Centrifugal ventilators, until a short time ago, were used for compressing air only in the case of pressures inferior to 1 m. (40 inches) water. The introduction of steam turbines and high-speed electric motors reaching very high speeds of rotation, however, made possible the use of turbo-compressors even in the case of rather considerable pressures. The first successful turbo-compressors of this kind were designed

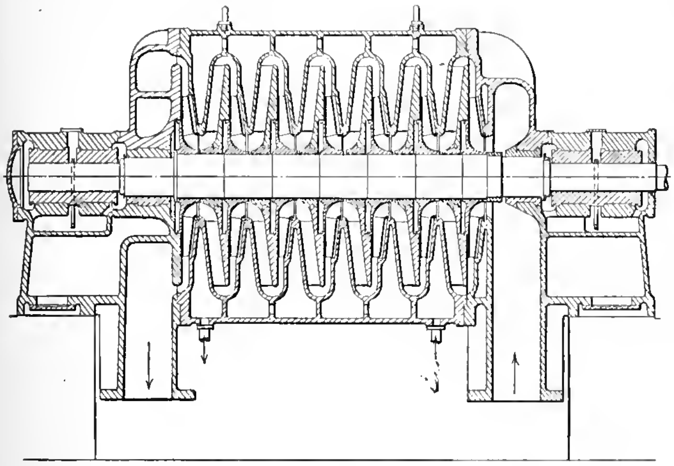

Fig. 1. Longitudinal Section of Rateau Turbo-compressor, showing Cooling Chambers.

by Prof. A. Rateau of Paris, and are exactly analogous to the centrifugal pumps constructed by the same engineer.

In Fig. 1 is shown a longitudinal section of a multiple-rim compressor unit cooled by water injected between the various cells. The rotating rims are made of steel. Especially remarkable is the construction of the diffusers, the cross-sections of which are U-shaped channels surrounding the partitions. Fixed vanes are placed in the section of the channel, conveying the fluid toward the center, and sometimes also in the centrifugal section. These U-shaped diffusers are largely the cause for the high efficiency of this type of centrifugal apparatus. In order to avoid any leakage, the outside bearing is made entirely enclosed.

The cooling of the air to be compressed is a very important question in the case of pressures of compression exceeding, say, twice the initial pressure. Whereas, in the first compressors constructed by Prof. Rateau, a system of cooling analogous to surface condensing plants between each two successive compressor units was employed, a less expensive solution has been suggested by M. René Armengaud, *viz.*, simply to cool the compressor housing. This arrangement is represented in Fig. 1.

In the compressors recently constructed, a further advance has been made in this connection, fresh water being introduced into the partitions (which to this effect are hollowed out) and even into the diffuser vanes. The cooling surface is thus augmented considerably, and the heating of the air is reduced in proportion, so as to bring the working of the machine even closer to an isothermal cycle than that of reciprocating compressors.

From the numerous efficiency tests made by Prof. Rateau on turbo-compressors of recent construction, it is inferred that very high pressures can be obtained with efficiencies approaching 60 per cent, which is a figure quite comparable to those applying in the case of good reciprocating compressors. When cooling the compression by a water circulation round the compressor housings, even higher figures can be obtained, the working cycle coming very close to that of isothermal compression, though at a temperature far superior to that of the sucked-in air. The efficiency in this case reaches figures as high as 63 per cent.

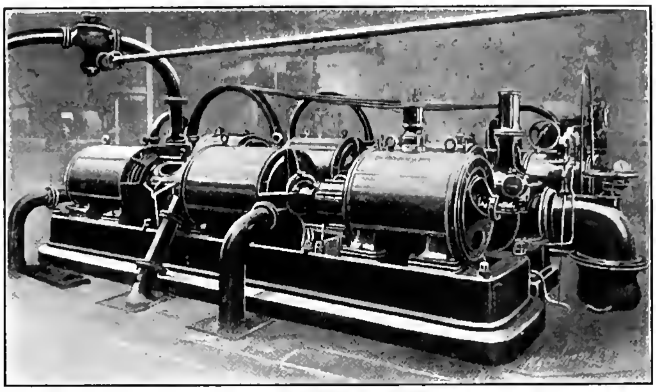

Fig. 2. Rateau Turbo-compressor for the Bethune Mines.

While the efficiency of turbo-compressors and reciprocating compressors thus is about equivalent, the former type of compressor possesses a number of advantages over the latter. The dimensions of the new type of compressor are obviously far smaller than those of ordinary compressors. A very striking instance is quoted by Rateau, *viz.*: the turbo-ventilator of Commentra, which takes up a total area of 75 square feet, whereas the blowing machine for which it was substituted took up an area more than twenty times greater, or 1,760 square feet. The centrifugal apparatus also is of far smaller weight, and as its vibrations are quite immaterial, it obviously requires far less substantial foundations.

A further advantage is the extraordinary simplicity of construction and relative cheapness of centrifugal compressors. Again, there are no working expenses worth speaking of, due to the consumption of lubricating oil, the only parts subject to friction being the bearings of the shaft. As no oil enters the interior of the apparatus the compressed

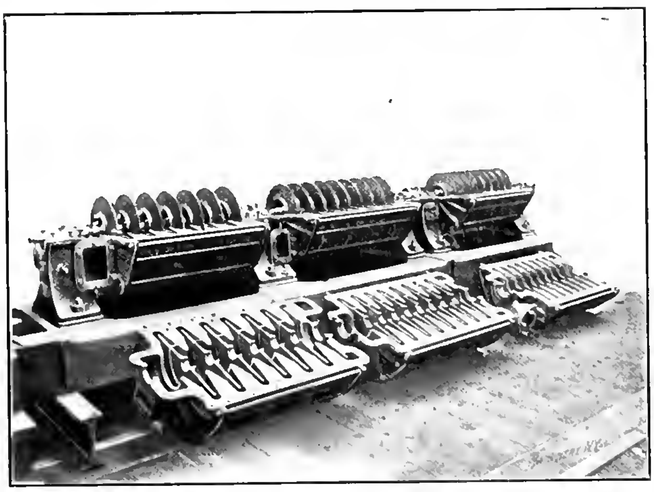

Fig. 3. Rateau Turbo-compressor built by Brown, Boveri & Co., to be driven by Gas Turbine.

gas does not contain any, which in some cases may be important.

The perfect regularity of the air current yielded by turbo-compressors is another good point as compared with the pulsations produced by reciprocating compressors which necessitate the installation of compensating reservoirs.

The output of a centrifugal compressor is obviously regulated readily within wide limits, by slightly varying the speed, or by opening and closing a gate in the suction or compression conduits, whereas, in the case of reciprocating compressors, a similar result could be obtained only by controlling the speed of the motor.

* Address: Berlin W. 50, 3 Regensburgerstrasse, Germany.

No accident need be feared in case one of the conduits becomes obstructed, as the compressor continues to turn freely with the consumption of energy reduced in proportion. The safety valves, which are quite indispensable in the case of reciprocating compressors, are, therefore, superfluous. In spite of the elasticity of output, the turbo-compressor allows a constant output as well as a constant pressure to be insured. The regularity of the motor is, in fact, controlled without difficulty by a special apparatus which acts on it in the case of any variation of the output or pressure. The regulators constructed to this effect by Rateau are of remarkable simplicity and are absolutely reliable in operation.

The possibility of coupling turbo-compressors directly to electric motors or to steam turbines without any intermediary gearing, is another advantage of centrifugal compressors, resulting in a diminution of friction losses. The

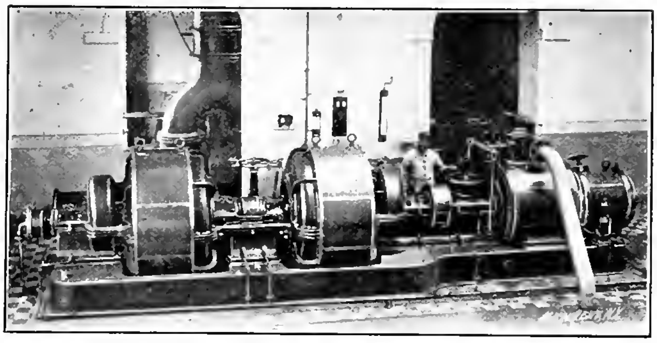

Fig. 4. Rateau Turbo-compressor at the Chasse Blast Furnaces.

exhaust steam from other engines, operating low-pressure steam turbines of the Rateau system, can thus be utilized for the production of compressed air, by combining a steam accumulator with a turbo-compressor driven by low-pressure steam. Compressed air can, for instance, be produced in mining plants and in metallurgical works exclusively by the aid of the exhaust steam from the winding engines or rolling mills, respectively. A striking instance of this economical scheme is found in the Béthune mines, and will be described in the following, and many other plants of the same kind are in course of construction. In this special field the old type of compressor will obviously be quite unable to compete with the newcomer, which may be called an ideal machine for a satisfactory utilization of exhaust steam. On the other hand, it should be borne in mind that turbo-compressors would be less satisfactory in the case of small outputs and low speeds of rotation. A few typical instances of plants constructed by Prof. Rateau and his licensees will be described in the following.

The turbo-compressor installed at the Béthune mines, which has just been referred to, serves to compress air to 6 and even to 7 atmospheres (88 to 103 pounds per square inch) by utilizing the exhaust steam from the winding engine. This machine (Fig. 2), which has been in regular operation since May, 1906, is made up of four multi-cellular units, traversed by the air, in series. These units are arranged in groups of two each on two parallel shafts, each of which is actuated by a low-pressure turbine. A high-pressure turbine fitted to one of the shafts does not do any work under normal conditions, and is used only as reserve in the case of interruption in the supply of exhaust steam, when an automatic apparatus will open the entrance conduit of the boiler steam to the high-pressure turbine, the exhaust of which is conveyed toward the low-pressure turbine. Another automatic apparatus is intended for uniformly distributing the charge between the two shafts. Between each two consecutive compressor units are inserted cooling devices, traversed by the cold water which is supplied by a small centrifugal pump mounted on the same shaft.

This plant, at a speed of 5,000 turns per minute, has been found to yield 32 cubic feet of air per second, the pressure of compression being 100 pounds per square inch above the atmospheric pressure. This is the highest figure so far obtained with centrifugal compressors.

The efficiency of the first three compressor units is especially remarkable, being as high as 70 per cent, while in the case of future applications it is hoped to raise the efficiency of the last unit to the same figure.

A compressor of even greater size, Fig. 3, has been constructed in 1906 by Brown, Boveri & Co. This is intended for operation by the aid of an Armengaud petrol turbine, and consists of three units mounted on the same shaft, the cooling of the air being effected during compression by a water circulation surrounding the compressor units. This compressor has been designed for drawing in 39 cubic feet of air per second in order to compress this to an absolute pressure of 71 pounds per square inch at a speed of 4,000 revolutions per minute.

Another turbo-compressor, Fig. 4, which was constructed by Sautter Harlé & Co., has been in operation at the Chasse blast furnaces since the month of March, 1907. This is calculated for yielding 255 cubic feet per second (this volume being reduced to atmospheric pressure) at a pressure of 11¾ inches mercury. The same plant is capable, in the case of any irregularity in the working of the blast furnace, of yielding 141 cubic feet per second at a pressure of 23½ inches mercury. To this effect the compressor has been divided into two identical units, which can be coupled up either in quantity or in series. The speed of rotation is 3,000 revolutions per minute. This machine is provided with an apparatus for recording its output, so as to ensure a perfect regularity.

As regards the numerous turbo-compressors in course of construction, the centrifugal blowers constructed by the Gutehoffnungshütte should be mentioned in the first place. These are intended for being operated by electric motors of up to 2,000 H. P. Brown, Boveri & Co., on the other hand, have received orders for about 10 turbo-compressors, one of which (of 1,500 H. P.) will be used for the compression of air to 120 pounds per square inch absolute. Some of the compressors planned for the blowing-in of Bessemer converters will have a capacity of even more than 4,000 H. P.

* * *

POWER TRANSMISSION BY FRICTION DRIVE.*

A friction drive, as the term is employed in the following, consists of a fibrous or somewhat yielding driving wheel, working in rolling contact with a metallic driven wheel. The drive may consist of a pair of plain, cylindrical wheels mounted on parallel shafts, or of a pair of beveled wheels, mounted on shafts at right angles. In the following, the results of tests with such drives are summarized.

Wheels Tested.

Wheels of the following materials have been tested in the experiments referred to: Straw fiber; straw fiber with belt dressing; leather fiber; leather; leather-faced iron; sulphite fiber; and tarred fiber.

The straw fiber wheels were worked out of blocks, built up of square sheets of straw-board, laid upon one another, with a suitable cementing material between them, and compacted under heavy hydraulic pressure. In the finished wheel the sheets appear as disks, the edges of which form the face of the wheel. The wheel of straw fiber, with belt dressing, was similar to the one described, excepting that the individual sheets of straw-board were treated with belt dressing before being converted into a block.

The leather fiber wheel was made of cemented layers of board, consisting of ground sole leather cuttings, imported flax, and a small percentage of wood pulp. The leather wheel was composed of layers or disks of sole leather. The leather-faced iron wheel consisted of an iron pulley, having a leather strip cemented to its face. After less than 300 revolutions, the bond holding the leather face failed, and the leather separated itself from the metal of the pulley. The wheel proved incapable of transmitting power, and no tests were recorded. The wheel of sulphite fiber was made up of sheets of board, composed of wood pulp. The tarred fiber wheel was made up of board, composed principally of tarred rope stock, imported French flax, and a small percentage of ground sole leather cuttings.

* Abstract of paper by W. F. M. Goss, read before the American Society of Mechanical Engineers, December meeting, 1907.

Each of the wheels was tested in combination with driven wheels of iron, aluminum, and type metal. All the wheels tested, both driving and driven, were 16 inches diameter, the face of the driving wheels being 1¾ inch, while that of the driven was ½ inch. The purpose of the experiments was to secure information for formulating rules regarding the power which may be transmitted by friction between fibrous and metallic wheels. To accomplish this, it was necessary to determine for each combination the coefficient of friction under varying conditions, and the maximum pressures of contact which could be withstood by the fibrous wheels.

Results of Tests.

The results of the experiments involving the straw fiber driver and the iron driven wheel, show that although the ranging from 100 to 400 pounds, the coefficient of friction is practically constant, when the rato of slip is constant. With a type metal driven wheel, the coefficient was 0.310.

Wheels of straw fiber, treated with belt dressing, and of iron, worked together with a pressure of 150 pounds per inch width of wheel and with a slip of 2 per cent with a coefficient of friction of 0.12, the friction remaining practically constant up to a pressure of 400 pounds per inch width of wheel.

The coefficient for 150 pounds pressure per inch width of wheel between leather fiber and iron, and a slip of 2 per cent equals 0.515. The same material with aluminum shows a friction coefficient of 0.495, and with type metal, 0.305.

The coefficient of friction between an iron wheel and one of tarred fiber, with a slip of 2 per cent, and a pressure of 150 pounds per inch width of wheel, equals 0.220, and for a

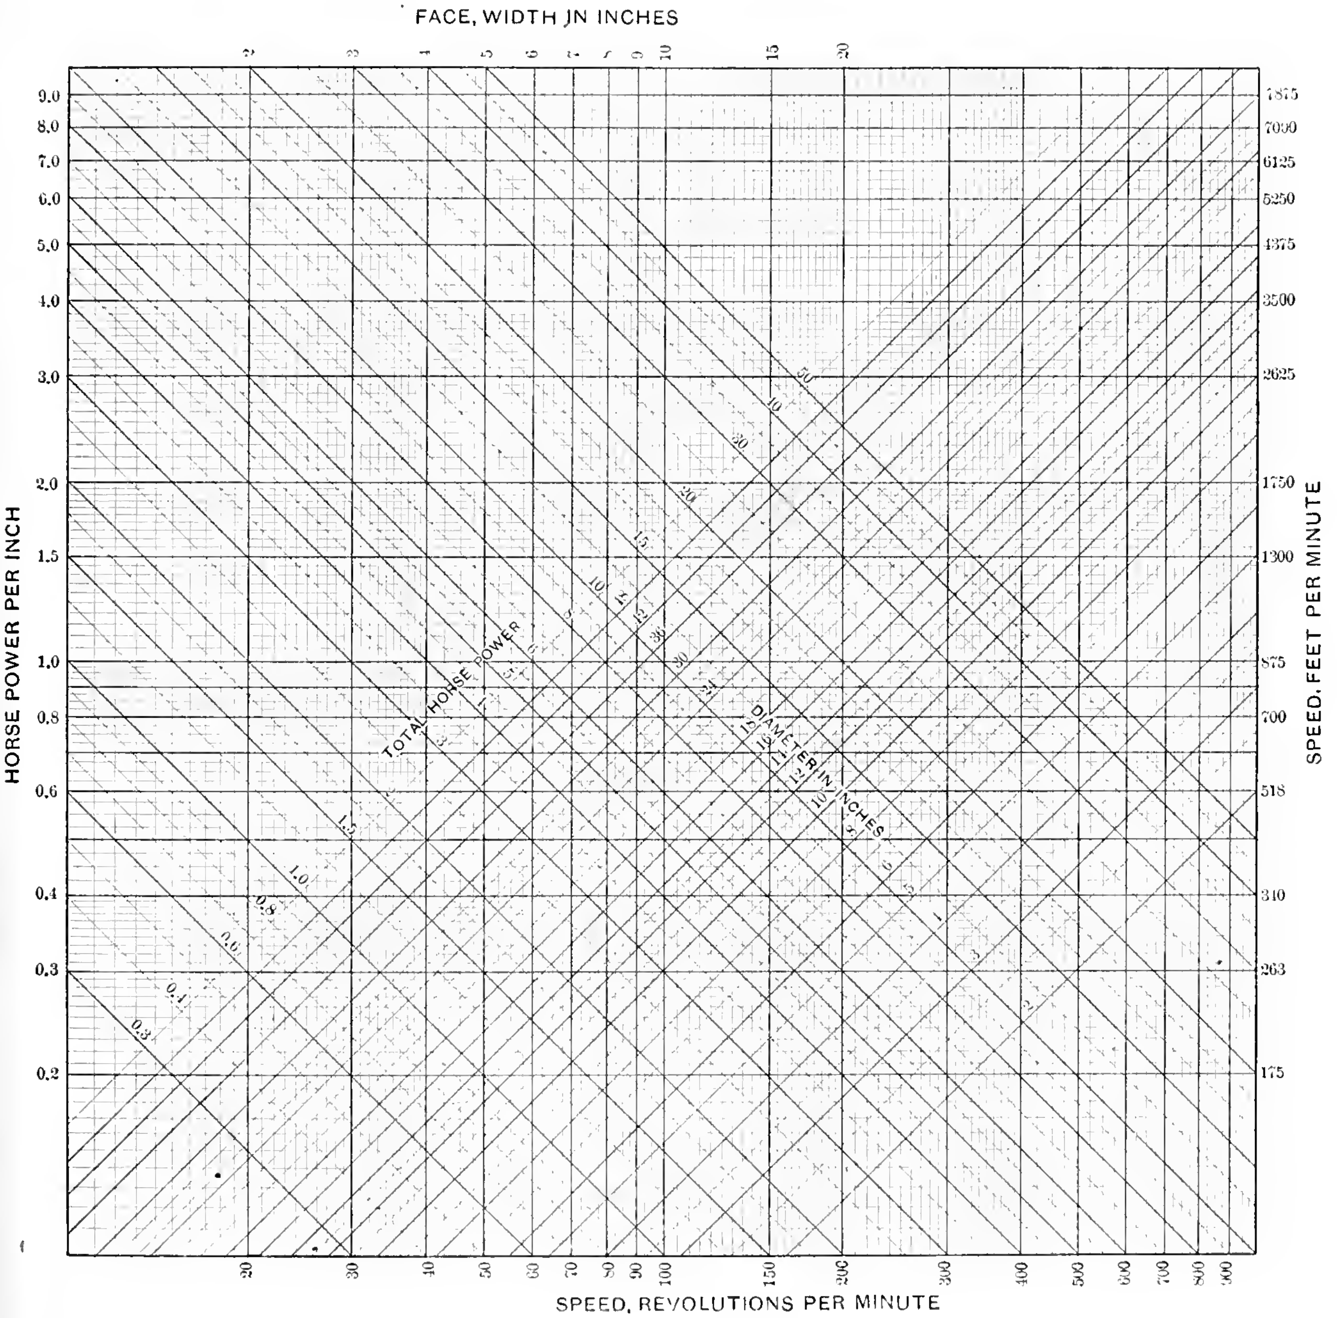

Chart for Determining the Horse-power Transmitted by Straw-fiber Friction Wheels working against Iron Wheels.

values of the coefficient of friction for 400 pounds pressure per inch width of wheel were slightly lower than those for 150 pounds pressure, the results were sufficiently similar to establish the fact that the law governing the change in the coefficient of friction, with slip, is independent of the pressure of contact. With a 2 per cent slippage the coefficient of friction for the pressures mentioned varied between 0.410 and 0.425.

Experiments with the straw fiber driver and aluminum-driven wheel show that the coefficient of friction with a working pressure of 150 pounds per inch width of wheel, and a slippage of 2 per cent is 0.455, and that for all pressures pressure of 400 pounds per inch, 0.250. Aluminum and tarred fiber show a coefficient of friction of 0.305 for a pressure of 150 pounds, and a coefficient of 0.295 with a pressure of 400 pounds per inch width of wheel. With type metal the coefficients for 150 and 400 pounds are 0.275 and 0.270, respectively.

The coefficient of friction between leather and iron with a slip of 2 per cent and a pressure of 150 pounds per inch width of wheel equals 0.225, and for a pressure of 400 pounds, 0.215. A leather driver may be successfully operated up to a pressure of 750 pounds per inch width of wheel. With aluminum, the coefficient of friction proved to be 0.260 and 0.295 for 150 and

300 pounds pressure, respectively. Running with type metal, the leather showed a coefficient of friction of 0.410, with a pressure of 150 pounds per inch width of wheel.

Sulphite fiber proved to have a coefficient of friction of 0.550 for a pressure of 150 pounds, and was successfully operated up to a pressure of 700 pounds per inch width of face. The coefficient of friction for this material running with aluminum was 0.410, with a pressure of 150 pounds; and when running with type metal, the coefficient of friction was 0.515 for the same pressure.

Tests were also undertaken to demonstrate the maximum pressure per inch width of face, which each wheel could stand. These experiments showed that hardly any of the wheels would decrease in diameter under a pressure of 200 pounds per inch width of face, but when the load was increased, a decrease in diameter followed. For straw fiber wheels and a pressure of 750 pounds, the decrease in diameter was 1/8 inch. Leather fiber proved to stand pressures to a far greater extent. A pressure of 800 pounds per inch width of face compressed the diameter of the wheel less than 1/16 inch, and it took 1,100 pounds pressure to compress it as much as 1/8 inch. Tarred fiber wheels decreased in diameter more than 1/8 inch when the pressure reached 800 pounds, and the leather wheels, when the pressure reached 550 pounds. Sulphite fiber decreased nearly 1/16 inch in diameter with a pressure of 400 pounds, and more than 1/8 inch with a pressure of 600 pounds.

General Conclusions.

The relative value of the metal drive wheels is not the same when operated in combination with different fibrous driving wheels. Driving wheels which are more dense, work more effectively with an iron follower than with either aluminum or type metal followers, but the softer and less dense driving wheels work better with aluminum and type metal than with iron.

The relative value of the different fibrous wheels, when employed as drivers of a friction drive, show that the addition of belt dressing to the composition of the straw fiber wheel is fatal to its frictional qualities. The highest frictional qualities are possessed by the sulphite fiber wheel, but, on the other hand, it is the weakest of all the wheels tested. The leather fiber and tarred fiber wheels are the strongest, and the former possesses also frictional qualities of a superior order. The plain straw fiber, which in a commercial sense is the most available of all materials, possesses frictional qualities which are far superior to leather, and strength which is second only to the leather fiber and the tarred fiber.

As safe working pressures of contact, the following figures may be given:

Material.	Pounds per inch of Width of Face.
Straw fiber	150
Leather fiber	240
Tarred fiber	240
Sulphite fiber	140
Leather	150

For *working values* of the coefficient of friction, the following figures may be considered correct:

Type of Drive.	Coefficient of Friction Working Value.
Straw fiber and iron	0.255
Straw fiber and aluminum	0.273
Straw fiber and type metal	0.186
Leather fiber and iron	0.309
Leather fiber and aluminum	0.297
Leather fiber and type metal	0.183
Tarred fiber and iron	0.150
Tarred fiber and aluminum	0.183
Tarred fiber and type metal	0.165
Sulphite fiber and iron	0.330
Sulphite fiber and aluminum	0.318
Sulphite fiber and type metal	0.309
Leather and iron	0.135
Leather and aluminum	0.216
Leather and type metal	0.246

Horse-power Transmitted.

Having now determined the safe working pressure of contact, and a representative value for the coefficient of friction, it is possible to formulate equations expressing the horse-power which may be transmitted by each combination of wheels tested. In these equations let

d = diameter of friction wheel in inches,
W = width of face of friction wheel in inches,
N = number of revolutions of friction wheel per minute,
H.P. = number of horse-power transmitted.

The formula would then be:

$$\text{H.P.} = k\,d\,W\,N$$

in which equation k is a coefficient which for the various materials is as follows:

Type of Friction Drive.	Coefficient.
Straw fiber and iron	0.00030
Straw fiber and aluminum	0.00033
Straw fiber and type metal	0.00022
Leather fiber and iron	0.00059
Leather fiber and aluminum	0.00057
Leather fiber and type metal	0.00035
Tarred fiber and iron	0.00029
Tarred fiber and aluminum	0.00035
Tarred fiber and type metal	0.00031
Sulphite fiber and iron	0.00037
Sulphite fiber and aluminum	0.00035
Sulphite fiber and type metal	0.00034
Leather and iron	0.00016
Leather and aluminum	0.00026
Leather and type metal	0.00029

A convenient means for finding the horse-power transmitted is supplied in the chart shown. This chart, in fact, gives a diagram for determining the value of *any one* of the variable factors in the formula H. P. = $0.0003\,d\,W\,N$ for the straw fiber friction wheel working in combination with an iron follower, the remaining factors being known or assumed. To transform values thus found to corresponding ones for the other possible combinations of wheels, it is only necessary to multiply by the proper factor chosen from the table of multipliers given above. The use of the chart may be illustrated as follows:

TABLE OF MULTIPLIERS FOR FINDING HORSE-POWER OF FRICTION DRIVES.

Type of Friction Drive.	Multiplier.
Straw fiber with iron	1
Straw fiber and aluminum	1.10
Straw fiber and type metal	0.73
Leather fiber and iron	1.97
Leather fiber and aluminum	1.90
Leather fiber and type metal	1.17
Tarred fiber and iron	0.97
Tarred fiber and aluminum	1.17
Tarred fiber and type metal	1.03
Sulphite fiber and iron	1.23
Sulphite fiber and aluminum	1.17
Sulphite fiber and type metal	1.13
Leather and iron	0.53
Leather and aluminum	0.87
Leather and type metal	0.97

a. To find surface speed, locate the intersection of the vertical line representing the given speed in revolutions per minute with the diagonal one representing the given diameter. The horizontal line passing through this point will give the surface speed in feet per minute on the vertical scale to the right of the diagram.

b. To find the horse-power for a given wheel, locate the intersection of the vertical line representing the given speed in revolutions per minute with the diagonal line representing the given diameter. Follow the horizontal line passing through this point to the right or left until the intersection between it and the vertical line representing the given width, as shown on the scale at the top of the diagram, is reached. The diagonal line passing through this point marked "Total horse-power" will represent the required horse-power.

c To find the face width of a given wheel, necessary to transmit a given horse-power, the speed being known, locate the intersection of the vertical line representing the given speed in revolutions per minute with the diagonal line representing the given diameter. Follow the horizontal line passing through this point to the right or left until the intersection between it and the diagonal line representing the required horse-power is reached. The vertical line passing through this point will give the width of face in inches on the scale at the top of the diagram.

* * *

It is stated that, at the present time, there are in the United States 700 steam turbines in use, representing 1,500,000 horse-power.

GEAR-CUTTING MACHINERY.—2.

RALPH E. FLANDERS.*

This installment continues the description of the formed milling cutter type of machine for cutting spur gears, the automatic gear-cutter of orthodox design being under consideration.

Another well-known tool in this field is that shown in Fig. 24. It is built by Gould & Eberhardt, Newark, N. J. In this machine, as in the Flather machine, the column is double and

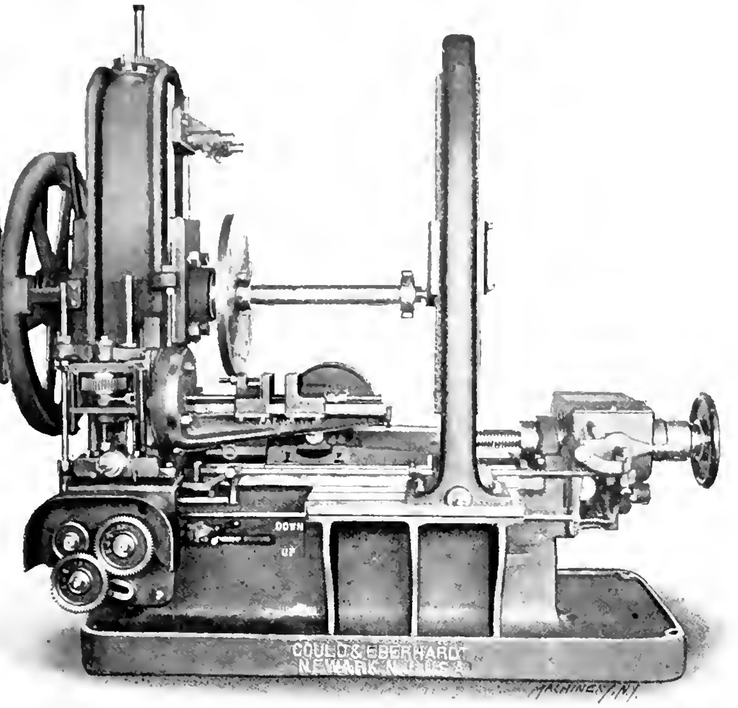

Fig. 24. Gould & Eberhardt Spur Gear Machine, with Special Automatic Rim Clamping Device Attached.

the work carrying head passes through it. This machine is of larger capacity than any of the others shown so far, and in common with most large capacity machines, is provided with a mechanism for raising and lowering the work spindle head by power. Another point of interest in this machine is the automatic clamping feature with which it is provided, used for firmly holding the rim of the blank being cut while the cut is in progress. This is in addition to the usual positive back stop against which the blank rests. This clamp consists of a pair of jaws, carried by slides on the adjustable arm shown at the front of the machine. This arm is set to bring the jaws in position to clasp the rim of the gear being cut. The jaws are operated by a screw connected with the mechanism of the machine in such a way as to hold the work firmly while the cut is in progress, releasing it while the indexing takes place, and again clamping it for a new cut. It is especially useful for comparatively slender work.

The general features of this line of machines can be best seen by referring to Fig. 25, which shows another member of this line, specially constructed for the severe service of cutting steel motor gears. The cutter and feed screw are in line with each other, so that a direct central thrust is imparted to the slide. The machine is driven through a single pulley, from which the movement is transmitted through gearing and keyed shafts to the different parts of the machine. This insures a large and constant area of belt contact at all speeds. The cutter spindle is driven by worm and worm-wheel through change gearing. The index wheel is of the split rim type with hobbed teeth, the final finishing of which is done with the dividing wheel in position on the machine. Means are provided for compensating for all wear and lost motion which may take place in this mechanism. A slight tension is constantly maintained between the stop cam and the worm in the direction of rotation, which prevents all danger from back lash and rebound. The rigid construction of the outer support of the work arbor will be noticed. Its base is mounted on a bracket cast on the side of the main frame. In removing a finished gear from the machine, it can be moved back out of the way without disturbing the height adjustment of the outboard bearing.

An automatic gear-cutter of continental design and manufacture is shown in Fig. 26. This tool is built by Ludwig Loewe & Co., of Berlin, Germany. Its most striking feature, so far as appearance is concerned, is the provision made for supporting the outer end of the work arbor. Two uprights are used, one at the front and the other at the rear of the bed, supporting a bearing for the work arbor. This bearing is counterweighted, so as to be easily adjustable for vertical position. The uprights can be moved back when it is desired to insert the work, by operating the hand-wheel shown at the base of the front one. The spindle of this machine is driven by a worm-gear. It has a dividing wheel of large diameter for the range of work it is intended for, it having a diameter of 57 inches, and being made in two parts, by the method which generates each wheel anew, rather than making it a copy of a previously made master wheel. Eight changes of feed are provided, varying from .010 to 0.42 inch per revolution of the cutter. This machine is also built in two smaller sizes; the size shown will cut gears up to 78 inches in diameter.

The machine shown in Fig. 27 is built by J. Parkinson & Son, Shipley, England. This machine cuts gears up to 48 inches in diameter by 10 inches face. The cutter spindle is driven by a worm and worm-gear, and has four changes of speed obtained by a sliding quick change gear arrangement, instead of by the usual removable gears. The dividing mechanism is driven by friction, and has a device which starts and stops it gradually to avoid shock. The gradual starting and stopping is done by the interposition of a pair of elliptical gears which gradually increase the rapidity of the indexing movement when it is started, and retard it in the same way as it is being completed. Provision is made also for preventing the feeding of the cutter into the work if a wrong division takes place. By means of suitably arranged connections, provision is made for multiple indexing, which is often resorted to, to avoid local heating. In cutting a gear having 47 teeth, for instance, every fourth tooth may be cut continuously, until the gear is completed. In this way, the heat due to cutting

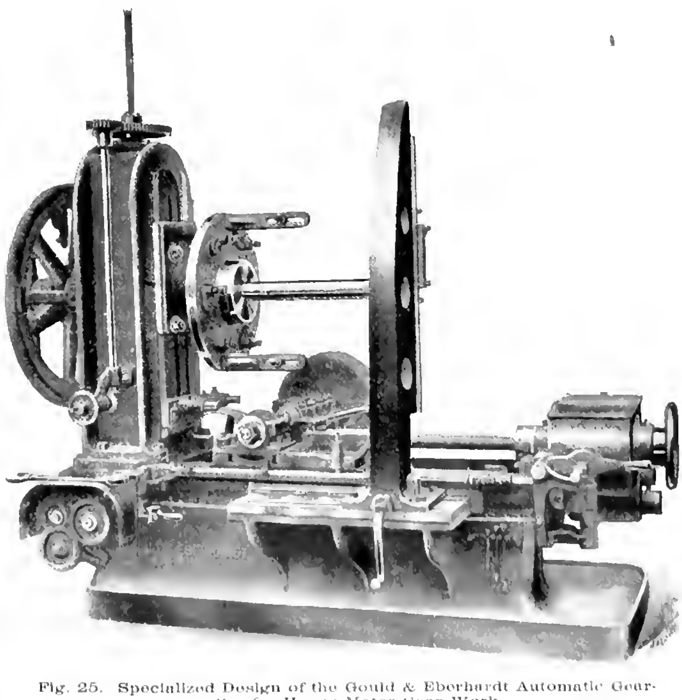

Fig. 25. Specialized Design of the Gould & Eberhardt Automatic Gear-cutter for Heavy Motor Gear Work.

* Associate Editor of MACHINERY.

is distributed more uniformly around the rim, avoiding the distortion due to local heating, which is liable to occur when teeth are cut in regular order. This multiple indexing is obtained without requiring the change gears to be specially calculated for it.

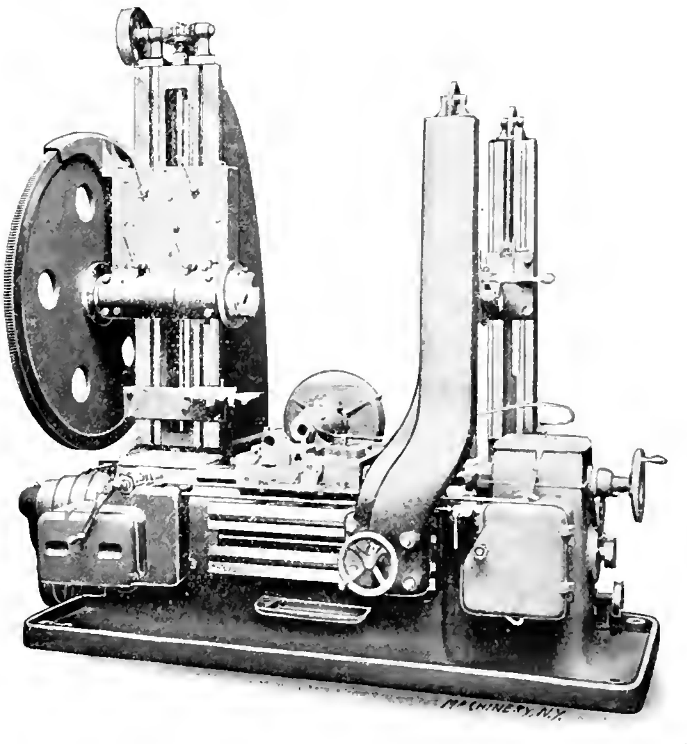

Fig. 26. The Largest Size of the Line built by Ludwig Loewe & Co.

A gear-cutter made by J. E. Reinecker, of Chemnitz-Gablenz, Germany, is shown in Fig. 28. The index wheel of this machine is of large diameter, about 7/10 of that of the largest gear that can be cut. The mechanism controlling the movements of the machine is so arranged that the forward feed does not commence until the indexing has been completed, the cutter slide being retained in its rearward position until that

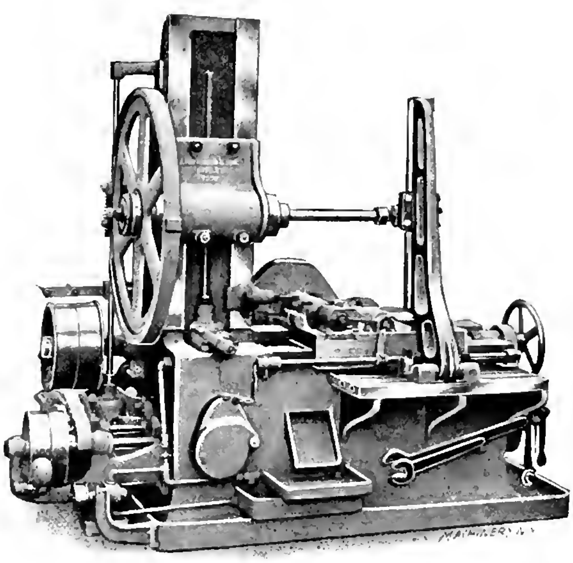

Fig. 27. An Example of English Design, built by J. Parkinson & Son.

time, thus avoiding the possibility of damage to the machine or work from failure of the mechanism to operate properly. An unusual feature of the machine, seen in the view shown, is the spindle drive gearing. The spindle is driven by a worm. This is not of the ordinary type, with a hole through its center, splined to be driven by the longitudinal driving shaft on which it slides as the table is fed forward or back; instead, a long worm is used, fixed longitudinally, and threaded for a sufficient length to accommodate the worm-wheel throughout the full travel of the slide. It will also be observed that the outboard support for the work arbor is hinged to facilitate the insertion and removal of the work.

A gear-cutter built by Messrs. G. Wilkinson & Son, of Keighley, England, is shown in Fig. 29. This is essentially the same in principle as the previous machines described, but it has an entirely different appearance, due to the fact that the bed is set on legs, instead of extending down to a solid bearing on the floor. The controlling mechanism is also somewhat differently arranged, although the movements required are the same. It will be seen that it is intended for comparatively small work. It takes wheels up to 18 inches in diameter and 6 diametral pitch. The cutter spindle is driven by a spur gear of large diameter.

Conventional Type of Automatic Formed Cutter Machine for Heavy Work.

The machines we have just been describing are representative of the standard form of automatic machine for small and

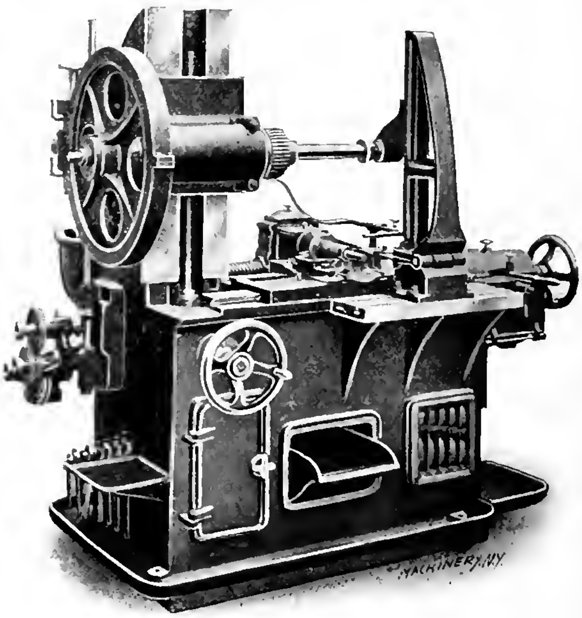

Fig. 28. The Reinecker Automatic Spur Gear Cutting Machine.

medium work. Considerations of ease of handling the work and convenience in arranging the mechanism, have evolved a somewhat different form of machine for the largest and heaviest work. The change made may best be described by saying that the previous type of machine is laid down on the back of its column, with the bed extending vertically upward into

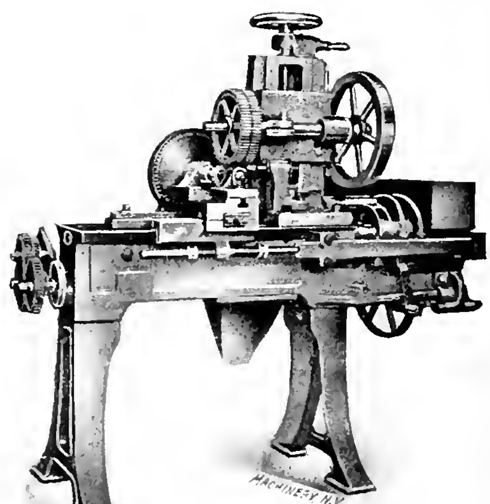

Fig. 29. The Wilkinson Automatic Machine for Small Gears.

the air. In other words, the change is simply a change of base. The bed becomes the column, and the column becomes the bed. This explanation will be easily understood by comparing the machines shown in Figs. 33 to 36 with those in Figs. 21 to 28. The principal advantage due to the change

of base in this machine is the better support given to heavy work, the weight of which is carried directly by the bearing of the slide on the bed, instead of being taken by the elevating screw in the column, as in the design previously discussed.

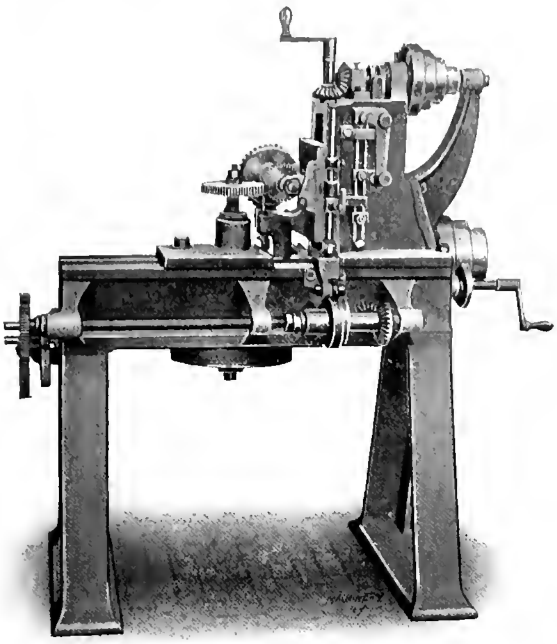

Fig. 30. A Small Armstrong Whitworth Automatic Machine.

Although it was stated that this design was especially adapted for heavy work, the first three machines here shown of this kind are comparatively small. That shown in Fig. 30 is built by Sir W. G. Armstrong Whitworth & Co., Manchester, England. The machine is very simple in design and ruggedly

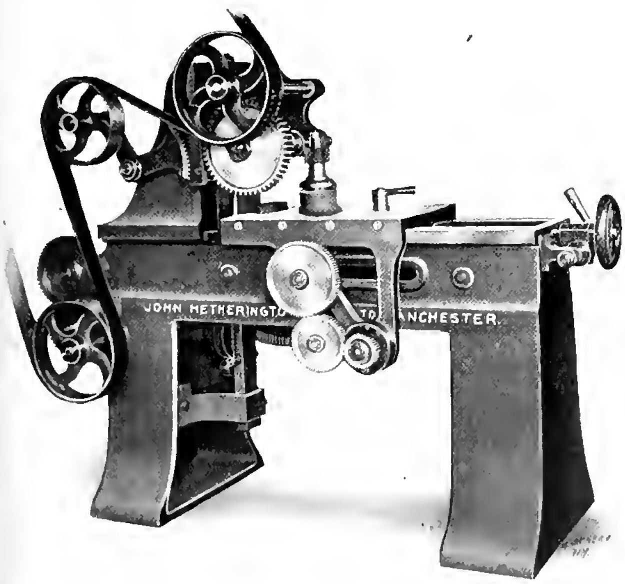

Fig. 31. A Simple Machine with Cam-operated Feed, built by John Hetherington & Sons.

built. The slow downward feed and quick return is obtained by epicyclic gearing in the feed cone at the top of the column. The clutches controlling this mechanism are operated by stops on the side of the column operated by the slide. The indexing mechanism is of the frictional type set by change gears for the required number of cuts.

The gear-cutting machine shown in Fig. 31 is built by John Hetherington & Sons, Ltd., of Manchester, England. A number of interesting points are evident from the cut. For instance, as may be seen, the vertical feed of the cutter slide on the face of the column is effected by a cam under the base, at the end of the horizontal bearing in the rear leg. This cam, and the roller and slide which it operates, are plainly visible beneath the machine. The slide is counterweighted to keep the roll always pressed up against the cam. Another ingenious detail of the mechanism is the belt tightener provided, which compensates for the change in position of the cutter slide. The belt is passed over an idler fastened to one end of a bell crank, whose other arm has teeth engaging a rack on the cutter slide. As the slide descends, requiring more belt, the idler moves toward the right, furnishing the required amount. The same belt drives both the spindle mechanism and the feed mechanism. The index worm and wheel are beneath the table. A quick withdrawing motion operated by an eccentric lever is provided for bringing the spindle back from the cutter when it is desired to remove or replace work on the arbor; this can be operated without disturbing the setting for depth of cut. This machine will cut gears up to 30 inches in diameter, 4 inches face and 4 diametral pitch. The proper change gears for varying the feed and indexing are furnished with the machine.

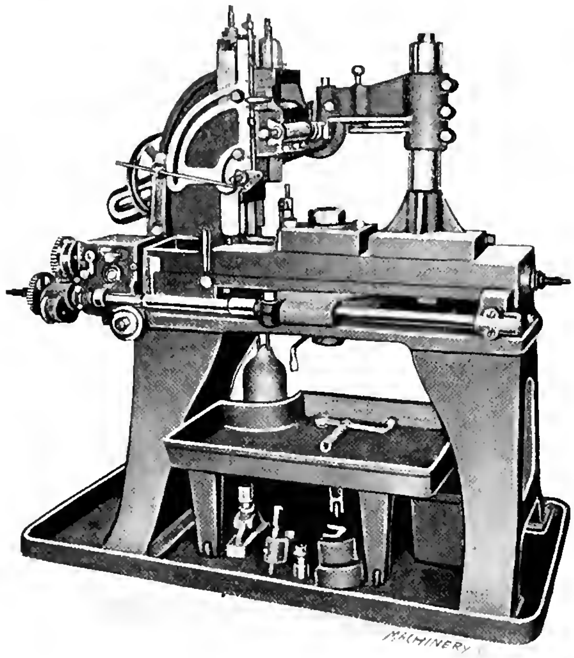

Fig 32. The Whiton Automatic Gear-cutter.

An American machine of the same structural type, built by D. E. Whiton Machine Co., New London, Conn., is shown in Fig. 32. It is fully automatic, and one of the features of its mechanism is a provision for making the starting of each movement dependent on the successful completion of the previous one. That is to say, the mechanism is so arranged that

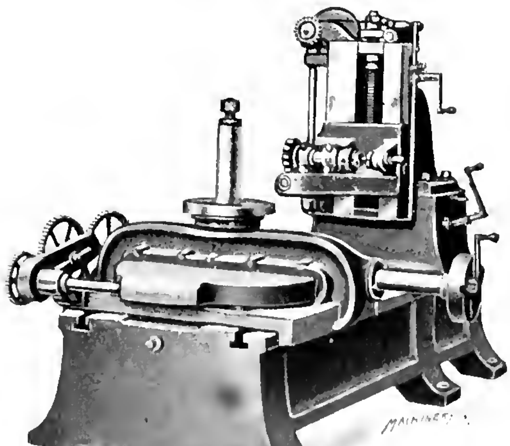

Fig. 33. Heavy Armstrong Whitworth Gear-cutting Machine.

the reverse feed is locked until the forward feed has been completed, the indexing is locked until the reverse has been properly indexed. There are no frictional devices, and but one stop adjustment—that for length of stroke, which also releases the indexing device. Unlike other machines of this type to be described, this one is arranged for cutting bevel

gears as well, the cutter slide being mounted on an adjustable sector which may be set to the cutting angle of the bevel gear which is to be milled.*

The first of the heavier machines here shown in Fig. 33 is another built by Sir W. G. Armstrong Whitworth & Co., of Manchester, England. In this machine the index wheel is carried above the bed, while a second bearing for the work spindle is provided by the arm which springs from the work slide on either side, and spans the index wheel. This brings the top of the base rather low, so the column is carried on an upward extension of the bed, giving the whole structure a distinctive appearance. The change gears for indexing are mounted on the slide, and carried with it when adjustment is made for diameter. In this machine the indexing is either automatic or hand, as may be thought best. There is less gain in automatic indexing in very heavy work than in the medium size, since the time of feeding is proportionately longer, while the large machine should have at least as much attention as is required for indexing. The cutter head of this machine can be set on an angle if desired, for gashing worm-wheels. The cutter spindle is supported at the outer end by a bearing and is driven by a coarse lead worm-gear. The machine is adapted to the cutting of wheels from 12 to 96 inches in diameter, up to 14 inches face.

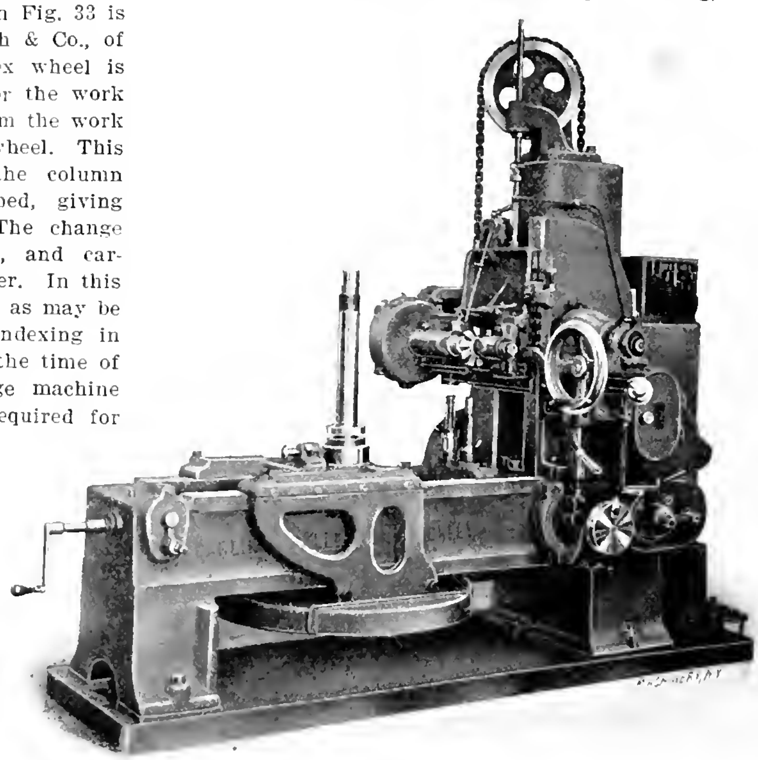

Fig. 35. The Darling & Sellers 4-foot Automatic Spur Gear Cutting Machine.

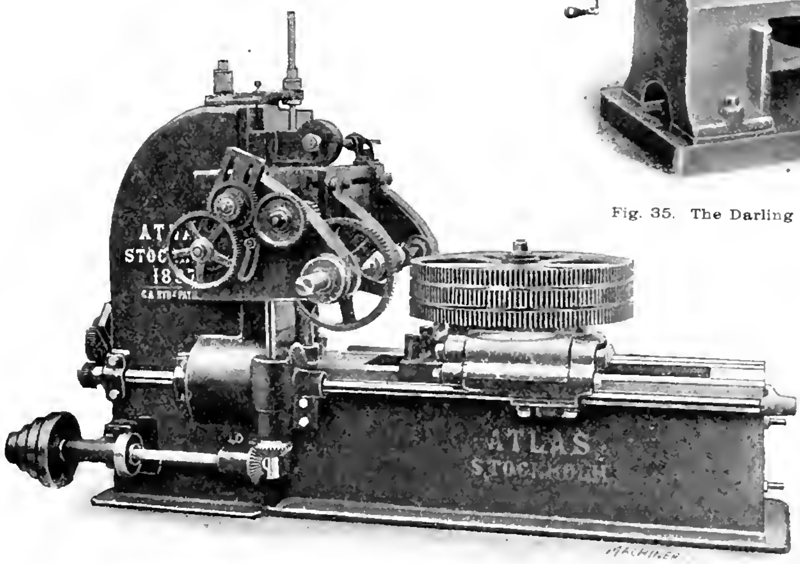

Fig. 34. An Example of Swedish Design—The Atlas Machine, as arranged for Cutting Spur Gears.

The machine shown in Fig. 34, built by Nya Aktiebolaget Atlas, Stockholm, Sweden, is shown cutting a stack of large spur gears. It is in reality, however, a universal machine, being adapted to making spiral and worm-gears as well as spur gears, so that it has mechanism in addition to that needed for cutting spur gears only, as may be seen from the cut. The heavy cross rail and the change gearing mounted on it are part of the mechanism required for hobbing worm-wheels. Its action as a spur gear machine is automatic and similar to that of the machines previously described. Like the Armstrong machine in Fig. 33, it has the index wheel above the bed. The machine will cut gears up to about 8 feet in diameter. Other applications of this tool will be described later.

The machine shown in Fig. 35, built by Darling & Sellers, Keighley, England, has the index wheel carried below the bed with the work spindle passing up through it. It will also be noted that the work carriage encircles the bed, having bearings on its sides, as well as being gibbed at top and bottom. The cutter spindle is driven by spiral gearing, and the head is counterbalanced. The spindle is hardened and carried in a long taper bearing, which is carefully ground to fit. The endwise adjustment for centering the cutter is effected by moving the main spindle bearing bodily to the left or right. A permanent gage is attached to the cutter slide which can be instantly lowered to test the centering of the cutter. A novel feature of this gear-cutting machine is the way in which the quick return of the cutter slide is effected by the excess weight of the counterbalance, which returns the slide immediately to its upper position when the feed is released, stopping against an air cushion. The feed change is accomplished by

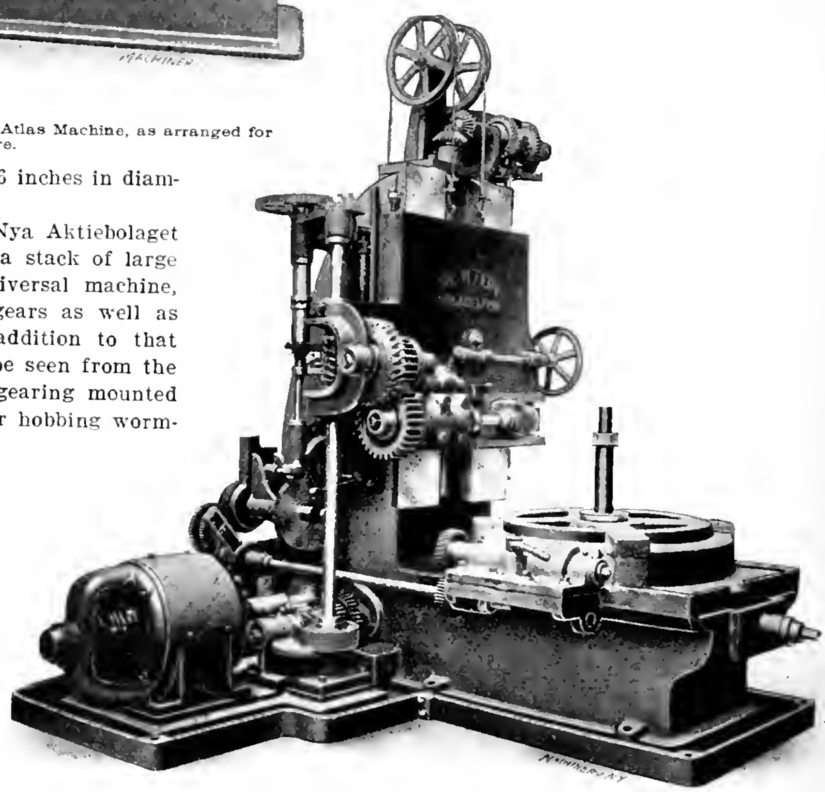

Fig. 36. A Newton Machine, especially designed for the Cutting of Heavy Motor Gears and Pinions.

* See article entitled "A New Automatic Gear Cutter" in the January, 1898, issue of MACHINERY.

change gearing. The indexing device is of the friction type, but so interlocked with the feeding mechanism as to prevent the feeding of the cutter before the indexing has been completed. A larger size of this machine is provided with a clamping arrangement which firmly holds the rim of the work while the cut is being taken. This works automatically; a friction drive acting through a screw presses it down onto the work, while a positive clutch raises it again. The machine shown in the cut has a feed of 16 inches and will swing a 4-foot gear. The whole design of the machine is unusually interesting and attractive.

In Fig. 36 is shown an automatic gear-cutting machine built by the Newton Machine Tool Works, Philadelphia, Pa. This is intended especially for the cutting of heavy gears made of high carbon steel, such as are used in motor gears for electric cars, locomotives, etc., with the expectation of cutting two or three teeth at once. The massive proportions of the machine give evidence of the duty for which it is intended. It is provided with a mechanism which renders it impossible to engage the downward feed until the dividing has been successfully completed for the next tooth. The machine shown is directly motor-driven, the spindle being connected to the motor through a train of spur, spiral, and worm-gearing. The indexing worm-wheel is mounted above the slide, as may be seen.

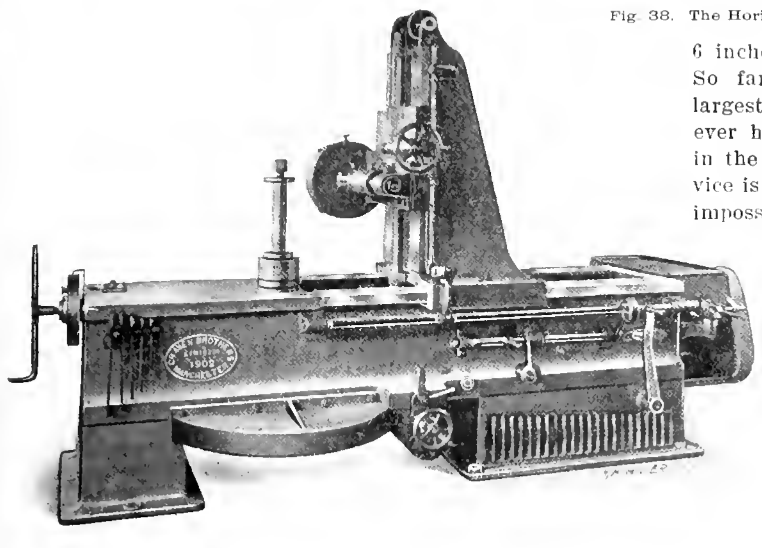

Fig. 37. The Craven Automatic Gear-cutting Machine.

Machines for Heavy Work with Column Adjustable for Diameter.

A common modification of this type of machine consists in making the column carrying the cutter slide adjustable on the bed to suit the diameter of the work, instead of adjusting the work spindle. A machine thus arranged, built by the Newton Machine Tool Works, has been illustrated in these columns.* It is not automatic, however, since it requires that the indexing be done by hand.

An automatic machine of this type is shown in Fig. 37. This tool is built by Craven Bros., Ltd., Manchester, England. The spindle head is counterbalanced, and is provided with four feeds which may be changed by the quick change mechanism seen at the front of the machine. The cutter spindle is driven by a quick feed worm and gun-metal worm-wheel. The outer end is supported in an adjustable bearing. The dividing mechanism can be operated either by hand or power. The design is a neat one and shows evidence of careful planning.

The adjustable column machine shown in Fig. 38 is built by Gould & Eberhardt, of Newark, N. J. This is the 15 foot size of a line of three, of which the largest will cut, entirely automatically, gears up to 20 feet in diameter, 36 inches face and 6 inches circular pitch in cast iron, or 4½ inches in steel.* So far as the writer knows, this latter machine is the largest entirely automatic spur gear cutting machine that has ever been built. There are a number of interesting features in the design and construction of this machine. A safety device is incorporated in the indexing mechanism which makes it impossible for the cutter to feed downward before the indexing has been successfully completed. An auxiliary cutter spindle (shown in place in the machine) is provided for finer pitch, small diameter cutters. When the heaviest work is being done, this small spindle and the boxes which support it are removed. The column has rapid power adjustment on the bed with fine hand adjustment for the final setting. This line of machines has been largely used in cutting cast iron and steel gears which had formerly been made with

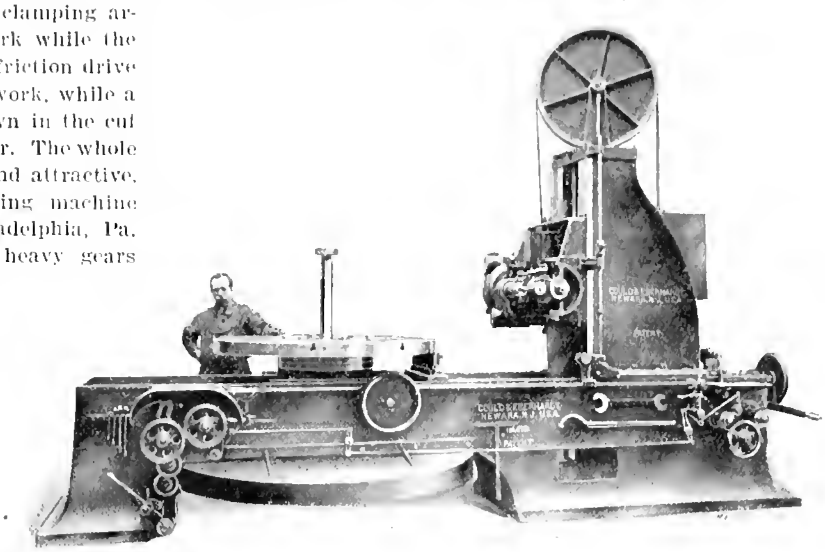

Fig. 38. The Horizontal Type of Gear-cutter, as built by Gould & Eberhardt.

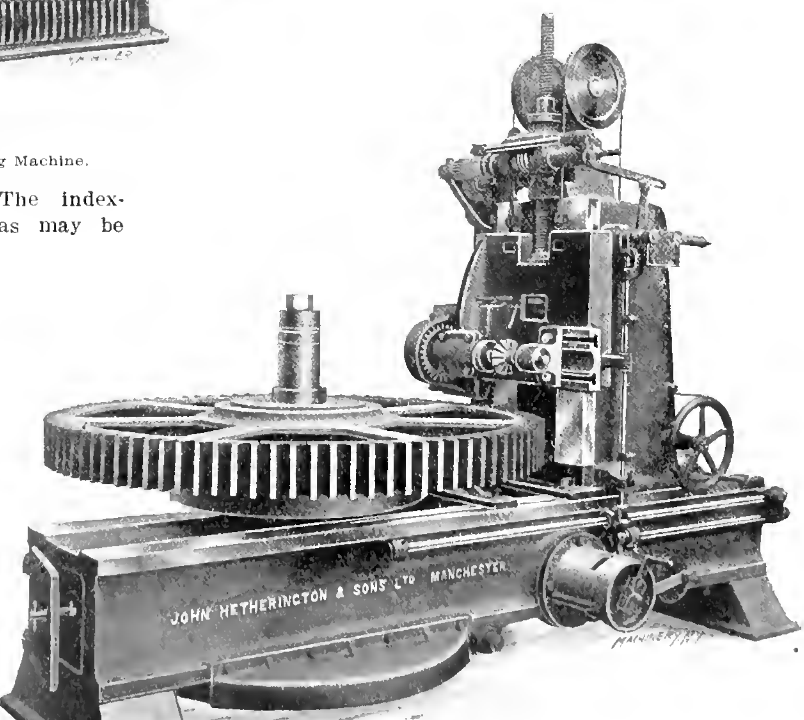

Fig. 39. The Hetherington Automatic Gear-cutting Machine.

* See article entitled "American Gear Cutting Machinery" in the June, 1898, issue of MACHINERY.

* Described in "New Tools of the Month" section of MACHINERY, February, 1901.

cast teeth, giving very much better gears at an expense not much greater than was required with those with cast teeth.

In Fig. 39 is shown a machine of the adjustable column type built by John Hetherington & Sons, Ltd., of Manchester, England. This is a large capacity machine being fitted for cutting gears up to 8 feet in diameter, 16 inches face and 1 diametral pitch. The dividing mechanism may be operated

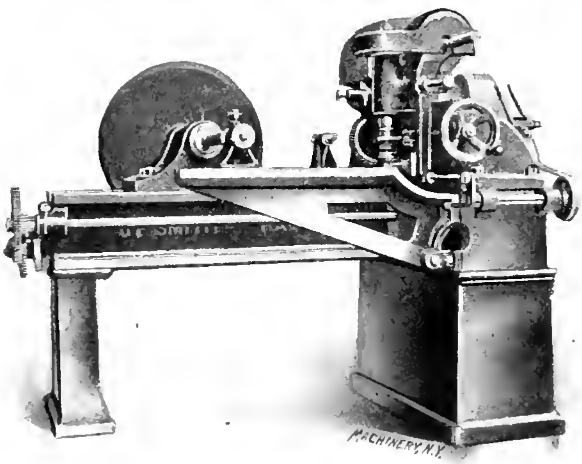

Fig. 40. An Example of Machine with L-shaped Bed, as made by G. F. Smith, Ltd.

either automatically or by hand. In the former case it is effected by means of a ratchet mechanism operated by a crank which starts the movement gradually and stops it in the same way without shock and without danger of over-running. The spindle is driven by worm and spur gears from a 3-step cone pulley for a wide belt of high velocity. The worm-gear is gun metal, and the worm of steel.

Spur Gear Cutting Machines, with L-shaped Bed.

As the machines we have been describing for heavy work were evolved from the orthodox gear-cutter by the expedient of laying that machine on its back and transforming the base into the column and *vice versa*, so a third type, occasionally met with, has resulted from laying the orthodox machine on its side, producing a bed having an L-shape. The Pratt & Whitney gear-cutting machine was an example of this. This is familiar to most mechanics engaged in gear-cutting, as there are many of them in use in various shops in this country for cutting spur gears and hobbing worm-wheels. The builders have discontinued making the machine, however, so we do not show it here.*

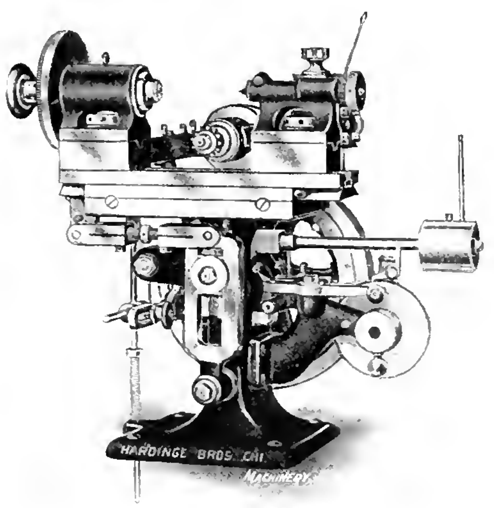

Fig. 41 The Hardinge Automatic Precision Gear-cutter.

Fig. 40 is an example of this type. Here is shown an automatic gear-cutter built by G. F. Smith, Ltd., of Halifax, England. As may be seen, one branch of the L furnishes ways on which the horizontal work spindle is adjusted to set the machine for the proper diameter of work. The other portion of the bed furnishes ways for the slide carrying the vertical cutter spindle. This cutter spindle is driven by spiral and worm-gearing from a counter-shaft cone. The indexing worm on the dividing wheel shaft is adjustable in the center to take up wear. All changes of feed and indexing are by positive gearing. An outboard support for the work spindle is plainly shown in the cut attached to the outer end of the cutter portion of the bed.

Another example of this type of machine, though arranged with adjustments permitting the cutting of bevel gears, is that built by Messrs. G. Wilkinson & Son, Keighley, England; it will be shown in a succeeding installment of this article.

Precision Machines using the Formed Cutter.

The machines we have described are suited for the cutting of gears ranging from those used in machinery of ordinary size, up to the largest and heaviest built. There has been a development along somewhat different lines, in machines for cutting teeth in minute pinions and gear blanks, such as are used in watches, fine instruments, etc. Some of these small machines cost as much as, or more than, larger ones for ordinary work. This is due in part perhaps to their complexity, but more to the accurate fitting necessary. An amount of looseness which would be just sufficient to provide oil space in the spindle of a large automatic gear-cutting machine, would give so loose a fit to the spindle of one of these minute mechanisms as to make it totally unfit for the work it has to do. Where the thickness of the teeth of the gear being cut is a matter of a few thousandths only, the required accuracy in the fitting of the spindle, slides, etc., must be expressed in tens of thousandths or even hundreds of thousandths of an

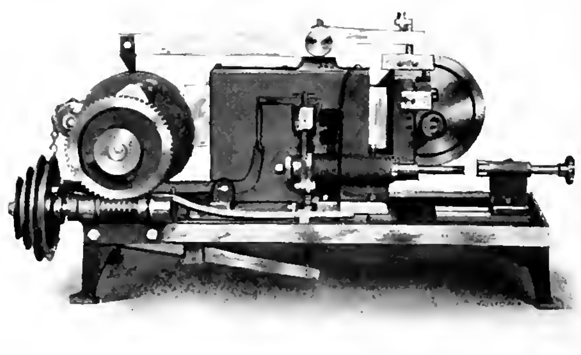

Fig. 42. The Standard Mfg. Co.'s Automatic Precision Gear-cutter.

inch. Even though a high degree of accuracy in fitting is obtained in these machines, it is still found necessary in some cases to take two or three and sometimes more cuts through each tooth space, in order to make sure that the desired outline is obtained. In one of the machines shown, provision has been made for this.

In Fig. 41 is shown a precision gear-cutting machine built by Hardinge Bros., 1036 Lincoln Ave., Chicago, Ill., it will be seen to follow somewhat in its mechanism the Slate, and Sloan & Chace machines, shown in Figs. 18 and 19, being derived in form from the ordinary or column type for milling machines, though greatly reduced in size. In adjusting for diameter, however, the cutter spindle is moved up or down by swinging about its fulcrum, the arm on which it is carried; the table or slide carrying the work head-stock and foot-stock is not adjustable vertically for this purpose. The feeding and indexing movements are effected by a cam shaft driven by the large wheel shown at the back of the machine. The feeding is governed by the slotted link mechanism at the front, connected by the adjustable reach rod shown with the bracket extending downward from the work table, beneath the dividing head. Index plates are used instead of the index worm-wheel common in larger machines. Separate disks are used for locating the spindle and locking it in position after the indexing, the disk for the latter purpose being covered to prevent accidental injury. An arrangement is provided by which the cutter is lowered from the cut on the backward movement to prevent injuring the finished tooth space, and to allow the indexing to take place without loss of time. The ratchet wheel shown below the machine at the right is indexed

* See article entitled "American Gear-Cutting Machinery" in the June, 1898, issue of MACHINERY.

a step for each tooth cut in the work, and may be set to lower the cutter out of the work and stop the feeding mechanism when all the teeth have been cut. The cutter spindle still runs, however, and the indexing still proceeds, so that the working parts are constantly kept at the working temperature.

In Fig. 42 is shown a precision gear-cutter made by the Standard Mfg. Co., of Bridgeport, Conn.* This machine

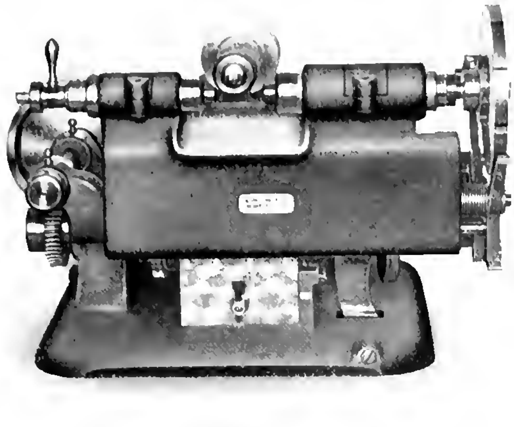

Fig. 43. The Sloan & Chace Automatic Precision Pinion-cutter, arranged for taking Three Cuts through Each Tooth.

has the indexing and feeding mechanisms operated by a cam shaft driven by the worm and worm-wheel shown at the left of the machine. It will cut gears up to 4 inches in diameter in stacks 2 inches long. As in the previous machine, the cutter is raised out of the work while the blank is being indexed and the feed is being returned to commence the next stroke. Two speeds are provided for the cutter spindle, and nine feeds. The cutter works ninety per cent of the time, the indexing and returning movements being very rapid. Both the work and cutter spindles have tapered bearings which can be compensated for wear.

The machine shown in Fig. 43, built by the Sloan & Chace Mfg. Co., Newark, N. J.,† is built on the same general plan as the previous machines so far as concerns the use of dial plates for indexing, and cams for performing the various movements. This machine, however, can be arranged to carry three cutters on the spindle, if desired. The first cutter is used for roughing, the work being indexed clear around for that purpose. The cutter spindle is then shifted endwise to bring the second cutter central with the work, when the operation is continued as before. The spindle is then shifted a

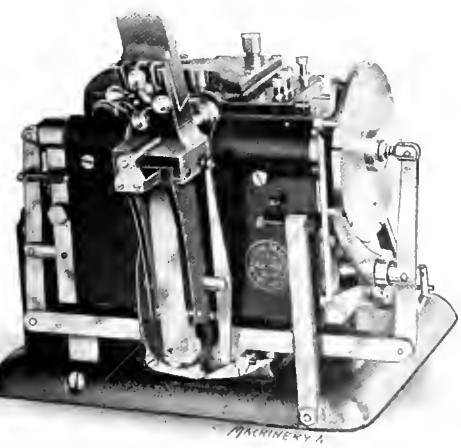

Fig. 44. The Waltham Automatic Pinion-cutter, with Magazine and Self-feeding Mechanism

second time to bring the third or finishing cutter into position for operation, whereupon the work is completed. This little machine is ingeniously arranged to allow all three of the settings, the roughing, secondary and finishing, to be separately adjusted for centering the cutter and depth of cut. All the movements are entirely automatic. The machine is essentially a pinion-cutter rather than a gear-cutter, as it is best adapted for gears having comparatively few teeth.

The automatic pinion-cutter shown in Fig. 44 is made by the Waltham Machine Works of Waltham, Mass. In this machine the automatic principle has been developed to a high degree, in that the machine feeds itself and takes out the work as well, after it is completed. The long slide seen extending upward from in front of the cutter is a magazine in which pinion blanks are placed. This magazine is brought in line with spindles of the head- and foot-stock, which (by the action of the cams by which they are controlled) grasp the shanks of the blank and hold it firmly in position to be cut. The cutting and indexing then proceed as in previous machines. When the indexing has been completed, the hold of the chucks on the work is released, and the work ejected. This operation is continuous as long as the cutter stays sharp and the magazine is kept full.

The Formed Tool Principle applied to the Grinding or Abrasion Process.

The only representative of this process, so far as we know, is the machine shown in Fig. 45. This tool, built by Upton & Gilman, Lowell, Mass.,* is intended primarily for smoothing up teeth of cast gears, so perhaps it does not really belong in the category of gear-cutting machines; as the only representative of its class, however, we have included it. The grinding wheel is formed to the shape of the tooth space of the gear to be finished. The gear is mounted on the vertical

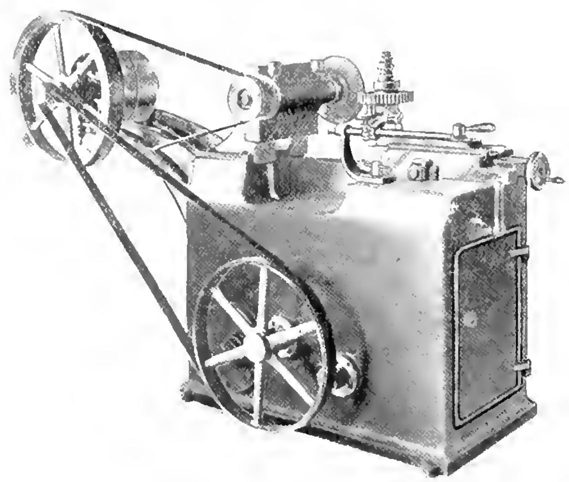

Fig. 45. The Upton & Gilman Machine for Finishing the Teeth of Cast Gears by grinding with a Formed Wheel.

spindle shown. When the machine is in operation the emery wheel is brought down through the tooth space, cleaning it out, and is then withdrawn. The work is indexed, and the operation is repeated. Owing to the fact that the shape of the space and the shape of the wheel are the same, the latter tends to preserve its form, being used merely to remove irregularities in otherwise perfectly shaped surfaces.

The Templet Principle applied to Cutting the Teeth of Spur Gears.

The templet principle is practically limited, in the cutting of spur gears at least, to the shaping or planing process. It has been used principally for large gears having teeth of very coarse pitch, too large to be formed by a formed tool or cutter covering the whole outline. It has the advantage over the formed cutter process of being comparatively simple in operation and adapted to special work at a minimum of expense, it being considerably cheaper to make a templet than to make a formed and relieved cutter of the same size.

Fig. 46 shows a templet spur gear planing machine built by the Gleason Works, Rochester, N. Y. In this tool the work spindle is horizontal, a pit being provided for gears of large diameter. The capacity of the machine is very great, it being adapted to cutting teeth in blanks up to 20 feet in diameter. The cutting tool is mounted in a traveling head at the right side of the machine. This traveling head is driven by a screw controlled by open and crossed belts and shifting mechanism similar to that used for a planer. The scale of

* See "New Machinery and Tools" section of MACHINERY, May, 1907.
† See article entitled "Making Small Relieved Gear Cutters in the Sloan & Chace Shops," January 1907, issues of MACHINERY.

* Described in "New Machinery and Tools" section of MACHINERY, January, 1907.

the engraving is too small to show the templet mechanism clearly, but it is identical in principle with that illustrated in Fig. 2, in the first installment of this article. For varying the diameter adjustment to suit the blank being operated on, the head-stock carrying the work spindle is moved toward or away from the tool slide. The machine shown is motor driven.

Another remarkable example of templet machine for spur gears is shown in Fig. 47. In this case the tool is a modified slotter instead of being a modified Richards planer as in Fig. 46. The column part of this tool is, in fact, practically the portable slotter built by its makers, the Newton Machine

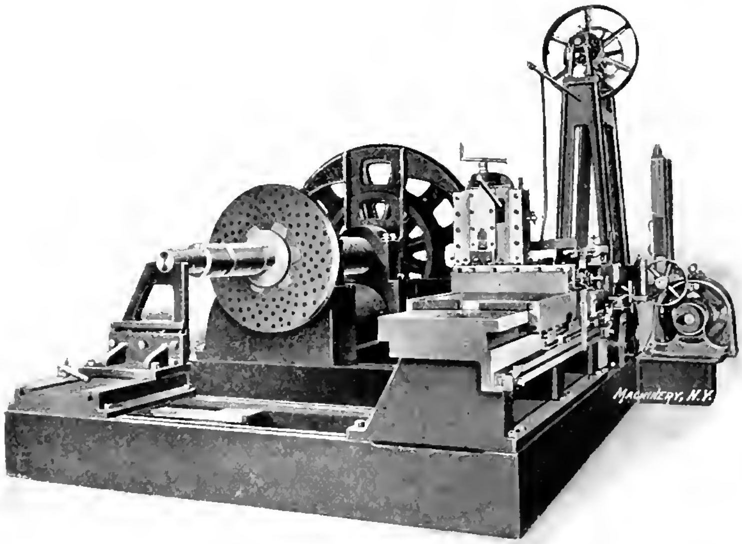

Fig. 46. The Gleason Templet Spur Gear Planer.

Tool Works, Philadelphia, Pa.* It is mounted on a long base plate and may be set at any desired position thereon to agree with the diameter of the gear being cut. The work is supported on a rotating table which is indexed by a worm and worm-wheel operated through change gears by a separate electric motor provided for that purpose. The head may be moved back far enough to swing the work 40 feet in diameter. The templets for shaping the tooth outline are mounted in brackets on the tool head on either side of the tool-post of the portable shaper. The tool-post is pressed toward the right- or left-hand former by a spring, as may be required, and as it is fed outward by the feeding mechanism provided, it is thus shifted sidewise in such a fashion as to reproduce the outline of the templet on the teeth of the gear.

The next installment will describe the various machines and methods used for cutting spur gears by the molding generating process.

* * *

NOTES ON CASE-HARDENING.

The following notes on case-hardening are from papers presented before the International Railway Master Blacksmiths' Association.

The method of case-hardening practiced at the shops of the Cincinnati, New Orleans & Texas Pacific Railroad, at Ludlow, Kentucky, was described by Mr. George Masser. The case-hardening compound used at the Ludlow shops is made by mixing 100 pounds prussiate of potash, and 50 pounds bichromate of potash, with one barrel of salt. The potash is pulverized before it is mixed with the salt. The pieces to be hardened are packed in a cast iron box of suitable size, in such a way that each piece will be covered with a sufficient quantity of potash when it is dissolved. The edges of the box lid are luted with fire clay, to make the box as air-tight as possible. The box is then placed in a furnace, where it is allowed to remain eight or ten hours, the length of time depending somewhat upon the sizes of the pieces being hardened. The pieces are cooled in a cooling tub, which is 6 feet long, 26 inches deep, and 28 inches wide. On the inside of this tub there is a screen which is made of heavy wire netting, such as is used in the front end of a locomotive. This screen is about 4 inches from the bottom of the tub, so that the cold water can circulate freely around the pieces being cooled. It is supported by angle-irons which are fastened to the sides of the tub. The screen has a bail at each end, to facilitate handling. The pieces when taken from the cooling tub, should be clean and white; if they are spotted it is an indication that the furnace was not kept at a uniform temperature.

In a paper presented by Mr. J. J. Ryan, some additional information was given on the subject of case-hardening. He has attained good results with a compound consisting of a mixture of carbonated bone black and salt. The pieces are packed in a cast iron box, which has a close fitting lid which can be bolted into place. All the joints of the box are sealed with clay, so

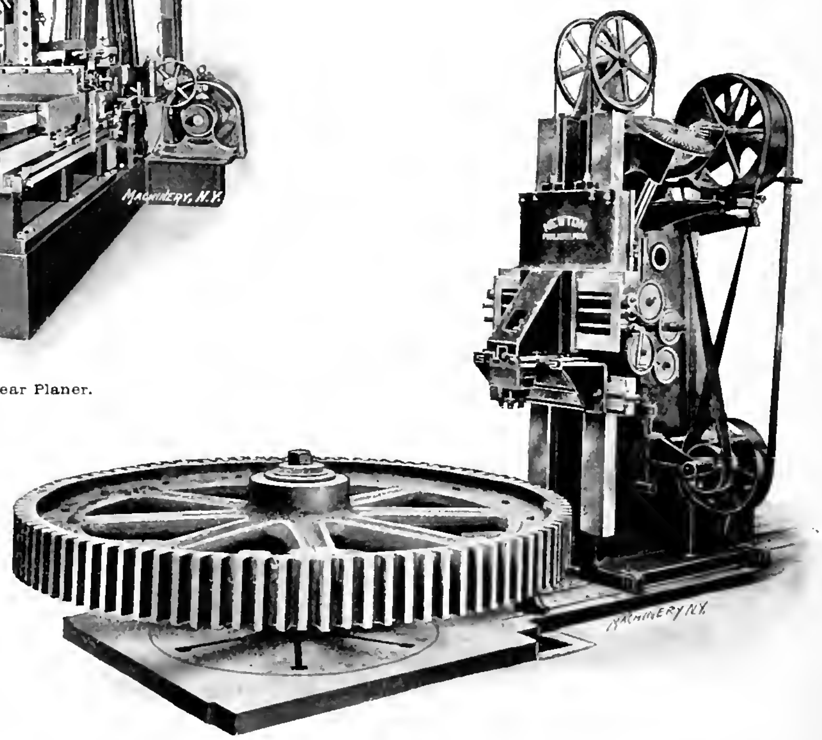

Fig. 47. The Newton Portable Slotter, arranged with Templet Mechanism and Indexing Base for Cutting Spur Gears.

that it will be practically air-tight. The box is kept in a furnace from twelve to fourteen hours, and a special effort is made to keep the furnace at an even temperature during that time, as any great fluctuation in the temperature has a tendency to make the material brittle. A temperature of 1,350 degrees F. is considered maximum. The cooling tub is provided with a water inlet at the bottom, and an overflow at the top, so that the water will be kept cool. All pieces such as links and quadrants should be let down into the water edgewise, to avoid springing them.

Mr. R. A. Mould, master blacksmith at the Omaha shops of the Union Pacific Railroad, made some comments on the subject which will be found of value and interest. Mr. Mould believes that the first thing to be considered in connection with case-hardening, is hardness; and the second, the condition of the material after the process of heating and cooling has taken place. The best results are not always obtained by hardening the pieces to the greatest possible depth. If a depth of 1/16 inch is sufficient to meet all requirements, nothing is gained by hardening to a greater depth. The length of time that it is necessary to keep the work in the furnace will depend upon the class of the work, and upon the depth required for the hardened part. The furnace should be so constructed that a uniform temperature can be maintained, and Mr. Mould believes that an underfeed oil furnace will give the best results, as the degree of heat can be more easily regulated.

* See article entitled "Spur Gear Planer" in the November, 1902, issue of MACHINERY.

THE MANUFACTURE OF SMALL STEAM TURBINES.

K. G. SMITH.*

K. G. Smith †

Owing to the widespread interest in the steam turbine at the present time, the writer believes that a short article describing some of the constructive features of small sized turbines would be of interest to shopmen in general.

The Kerr steam turbine, in the manufacture of which the writer has been engaged for some time, is of the multi-stage nozzle-and-bucket type made in three sizes, ranging from 5 to 300 horse-power. The division into stages is made by cast iron partitions known as diaphragms into which are riveted the steam nozzles. The horse-power of any size of turbine is determined under a given set of conditions by the number and size of these nozzles. For this reason a turbine may be quickly changed to meet different or unexpected conditions. For example, in one turbine installation it was suddenly found necessary, after all plans were made, to run the unit non-condensing instead of condensing as originally intended, owing to the non-arrival of the condenser and the necessity of getting the plant started. A set of non-condensing nozzles was at once designed, and they were made and placed in the turbine in ten hours. The plant was then operated successfully and economically on a non-condensing basis.

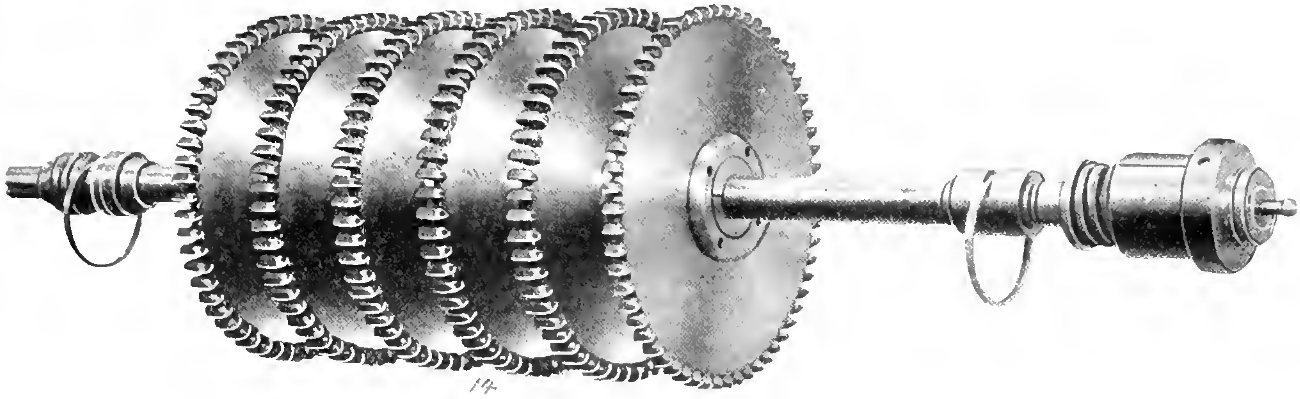

Fig. 1. Assembled Rotor of Kerr Steam Turbine.

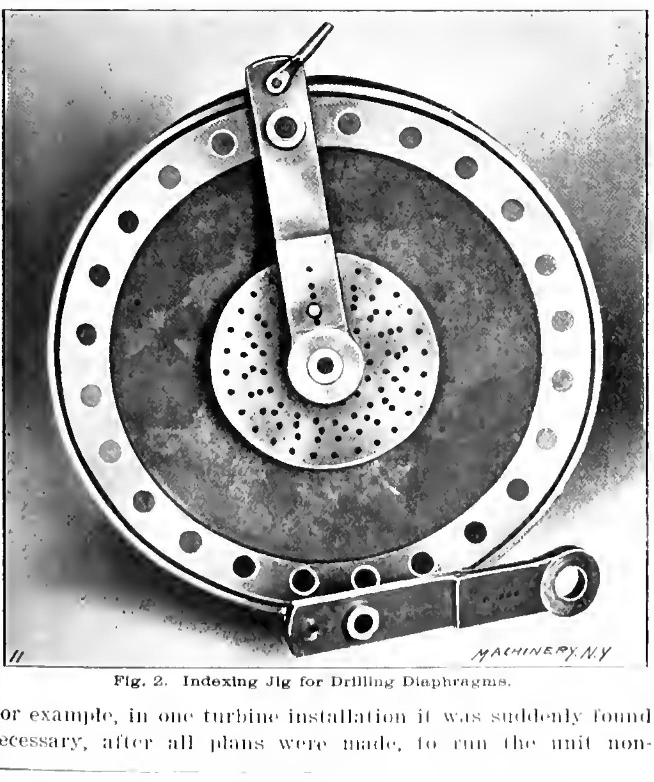

Fig. 2. Indexing Jig for Drilling Diaphragms.

Such flexibility of design necessarily entails careful thought on the part of the machine shop force to avoid an overwhelming number of jigs and special tools. Diaphragms, as shown in Fig. 1, are kept in stock ready for drilling at any time.

The jig shown in Fig. 2 will drill any required number of holes, and by changing the movable arm the drilling radius or size of hole may be varied. Two index plates like the one shown cover all the numbers of holes called for on all sizes of turbines.

To set the nozzles at the proper angle and give clearance on the buckets, a templet, Fig. 3, with a thin clearance shim is used. Once set against the templet, they are beaded in like boiler tubes with a special beading tool and pneumatic hammer. Before being set in the diaphragms, all nozzles must of course be reamed to the proper size and taper. This is done by special reamers held in the spindle of a high-speed sensitive drill, thus giving them a good clean finish on the interior surface. On the testing block all stage pressures are taken, and from the calculated pressures the accuracy of the reaming can be checked. Any marked variation from the proper pressure must be corrected. Such mistakes, however, seldom occur.

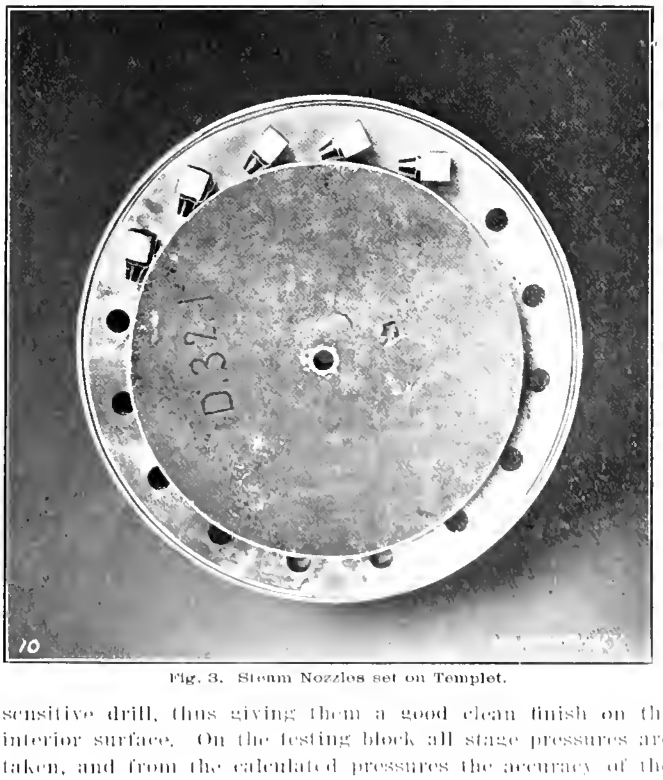

Fig. 3. Steam Nozzles set on Templet.

The most important parts of a turbine, so far as its running qualities are concerned, are the bearings and rotor. The

* Shop superintendent Kerr Steam Turbine Co., Wellsville, N. Y.

† Kenneth G. Smith was born in Dixon, Ill. He graduated from the mechanical engineering department of the University of Illinois, and served an apprenticeship with the Brown Corliss Engine Co., Corliss, Wis. He has worked for the Illinois Central R. R. Co., Westinghouse Machine Co., East Pittsburg, Pa., and the Kerr Steam Turbine Co., Wellsville, N. Y., having held the positions of assistant erecting engineer, erecting engineer, and shop superintendent.

bucket wheels, which form the main part of the rotor, Fig. 1, are of flange steel into which are set drop-forged steel buckets. The wheels are first dove-tailed in a slotting machine of special design operating like a gear cutter. The buckets are then riveted in under a heavy pneumatic riveter. So firmly are they fastened that the bucket itself will be destroyed before it can be pulled from the disk. By the use of properly formed dies the buckets are accurately aligned while being riveted.

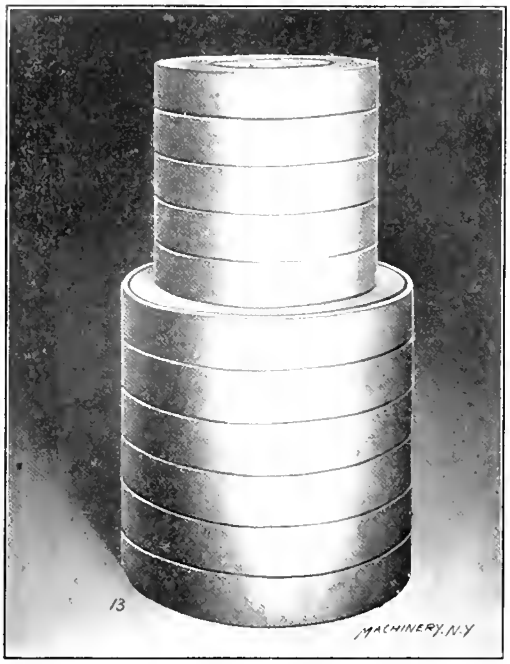

Fig. 4. Stock Diaphragms for Kerr Steam Turbines.

As is any high-speed machine, the balancing of the rotating parts is of paramount importance. For thin steel disks, like the bucket wheels, a static balance is sufficient when carefully and accurately made on a hardened mandrel rolling on hardened knife-edges. See Fig. 5. Each disk is balanced separately on its own hub, and any slight inaccuracies in individual disks tend to counterbalance each other when the whole rotor is revolving.

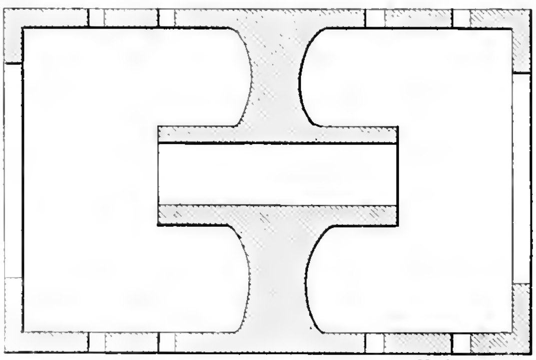

Fig. 6. Hollow Brake Pulley.

For shafts, nickel steel is used as giving the most satisfactory results. It stands heat best and is freest from internal strains. The shafts are first roughed out, and then all drilling and keywaying is done before the final cut is taken, thus insuring an absolutely true running shaft. With shaft sizes of $1\frac{1}{2}$ to $2\frac{1}{4}$ inches, the critical speeds are comparatively low, but as the turbines are never run at these speeds, the slight jar occurring when the critical speed is passed has no effect whatever.

The bearings are of bronze fitted with a special ring oiling device. For any bearing running at high speed the lubrication must be perfect; otherwise vibration will occur even if the bearing does not heat seriously. This is frequently the cause of intermittent spells of vibration in turbines and other high-speed machinery. Oil grooves large enough and numerous enough to carry a good supply of oil must be provided with the edges well chamfered, and care must be taken that the oil actually enters and circulates through the bearing so as to keep a continuous film surrounding the shaft. A well lubricated turbine bearing will last indefinitely, because, being direct connected, there is no belt pull and the bearing pressure is always light.

The testing of small turbines quickly developed a number of problems. When connected with fans, blowers, or pumps, at the shop, the unit, of course, can be tested as a whole, but for testing turbines alone a special form of Prony brake had to be devised.

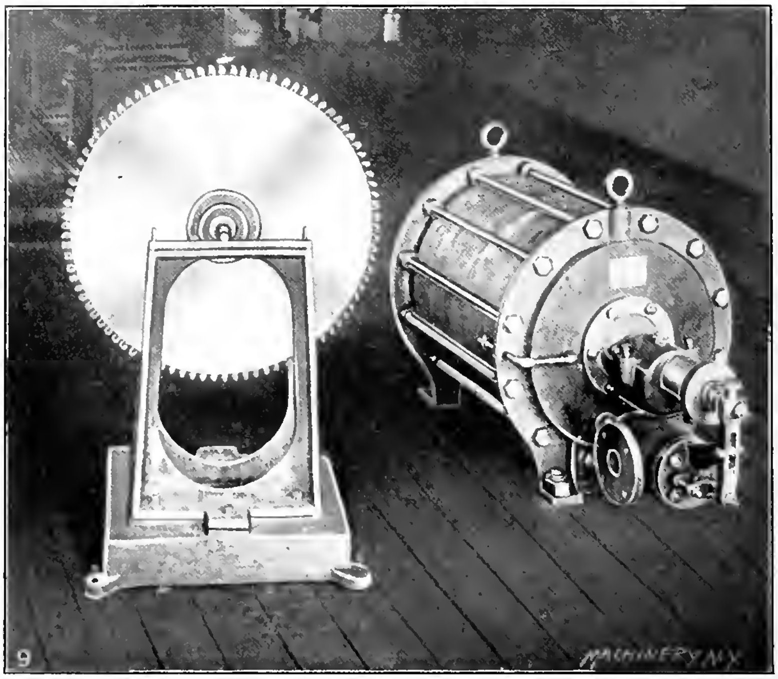

Fig. 5. Balancing Disk on Knife-edge Bearing Ways.

For high speeds and high powers the ordinary form of brake cannot be used as it heats too rapidly, causing jarring and gripping of the brake pulley. The special form of hollow pulley shown in Fig. 6 has been found to give satisfactory results at speeds of 2,400 to 3,600 R.P.M., and for 10 to 300 horse-power. Water is delivered to the interior of the hollow pulley, and is thrown out through holes in the circumference by centrifugal force. The ordinary form of smooth, solid, externally lubricated pulley will carry as high as 40 to 50 horse-power at speeds up to 3,600 R.P.M. fairly well. In using a new brake for the first time it is a good plan to run it at a high speed, for a few seconds, with no water whatever. This burns off any high spots, and puts a glaze on the surface of the wood, causing it to bear smoothly on the pulley and to wear well.

One thing I would say in conclusion as to the manufacture of turbines and high-speed machinery in general. Faulty balance, faulty alignment, imperfect bearings and other faults of construction are evident as soon as the machine goes up to speed the first time. In other words, turbines will not run for a while and slowly develop troubles the germ of which was present at the beginning. Anything apt to cause trouble

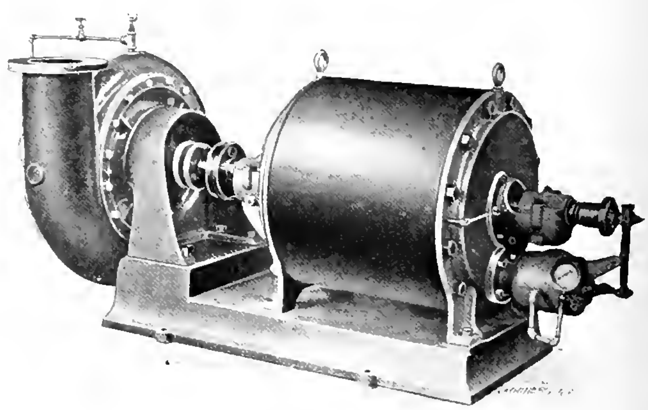

Fig. 7. Assembled Kerr Steam Turbine Unit.

will appear at once on the testing floor, where it can be remedied. A good turbine, once installed, is a thoroughly reliable and durable machine. In one foundry installation with which I am familiar, the turbine runs a fan for one hour and thirty minutes each day during the heat, requiring only the opening and closing of the throttle, and a pint of oil once a month.

* * *

BARR'S RULES FOR POWERING MACHINE TOOLS.

The following simple empirical rules compiled some time ago from the averages of many tests and observations by Mr. J. A. Barr, of the Westinghouse Electric & Mfg. Co., will be found useful in equipping machine tools with individual electric motors. The power ratings indicated for the conditions named agree, generally, with the average of shop requirements.

Lathes.—Engine lathes using one cutting tool of water-hardened steel at about 20 feet per minute:

H. P. $= 0.15\ S - 1$.

For heavy engine lathes such as forge lathes:

H. P. $= 0.234\ S - 2$.

In both engine and forge lathes $S =$ swing of lathe, in inches.

Example: Find the power required to drive a forge lathe of 48-inch swing. Then $(0.234 \times 48) - 2 = 9.23$ H. P.

Boring Mills.—For the operation of standard boring mills, using one cutting tool of water-hardened steel at approximately 20 feet per minute, the following formula will be found to represent good practice for heavy work:

H. P. $= 0.25\ S - 4$, wherein $S =$ swing of mill, in inches.

Milling Machines.—For normal milling machines, using water-hardened steel cutters running at about 20 feet per minute, the following formula will be found useful:

H. P. $= 0.3\ W$, wherein $W =$ distance between housings, in inches.

Drill Presses.—For normal drill presses, using water-hardened steel drills, running at a peripheral cutting speed of approximately 20 feet per minute the following formulas apply:

H. P. $= 0.06\ S$.

For heavy radial drill presses:

H. P. $= 0.1\ S$,

wherein $S =$ swing, in inches.

Slotters.—Normal crank slotters, using water-hardened steels at cutting speeds of from 15 to 26 feet per minute, require:

Stroke.	Horse-power
10 inches.	5
18 "	7
30 "	10

Shapers.—Shapers using water-hardened tool steels at cutting speeds of from 15 to 20 feet per minute have the following power requirements:

Stroke.	Horse-power.	Stroke.	Horse-power.
16 inches.	3	24 inches.	5
18 inches.	3½	36 inches.	6½

Planers.—For normal planers using water-hardened steel at cutting speeds of from 15 to 20 feet per minute, the power is approximately as follows:

H. P. $= 3\ W$.

where $W =$ width between housings, in feet.

For heavy forge planers:

H. P. $= 4.92\ W$.

By normal planer is meant a planer in which the length of the bed in feet is approximately two-tenths the width between the housings in inches. For example, a 48-inch planer would have a length of platen of approximately 9.6, or 10 feet.

The above formulas are for planers having a ratio of cutting to return speeds of approximately 1 to 3, and cover planers with two tools in operation. If more than two tools are used, or if the ratio between the forward and return speeds is more than 1 to 3, the horse-power given by above formula should be increased. It should be noted that where the length of bed is greater than that mentioned above the horse-power should be increased.

THE TRIBULATIONS OF AN INVENTOR.

JOHN.

A long, long time ago, when the Teddy bears roamed wild in the cities, and the rushing red devil wagons tore up and down throughout the land, there was a noted country on our planet called Yewessay. In this country, besides the high financiers, railroad presidents, and captains of industry, there was a very large number of common, ordinary people like ourselves, though one could never have guessed it from the newspapers. Among these common, ordinary people there lived quite a number of peculiar people, who mostly belonged to either one of two classes. The brains of these people were abnormally developed, or, perhaps, abnormally undeveloped; their temperament was such that they could not let well enough alone. In one class the abnormity appeared as de-structiveness. These were called lunatics. When a lunatic saw something which did not suit him, he immediately smashed it, or tried to. In the other class, the abnormity appears as con-structiveness. These were termed inventors. When an inventor saw something which did not suit him, he immediately invented something better, or tried to.

The lunatics were treated kindly and provided with food, shelter, and raiment by the government, but, though the inventors were often, yea, generally, without money, and all other modern conveniences, the government never even appointed a commission to investigate them, let alone doing anything substantial.

The great aim of every inventor, at that time, was to obtain a patent. A patent was really merely a document setting forth that, whereas the inventor had petitioned the Commissioner of Patents for a patent for an alleged new and useful improvement, and had complied with the various requirements of the law in such cases made and provided, and etc., etc., that the inventor, his heirs, or assigns should have the exclusive right to make, use, and vend the said invention throughout the land of Yewessay and the territories thereof for the term of seventeen years.

These patents were held in great reverence and awe by the poor inventors, and were believed (at least by those who never had obtained one) to be of great value—a sort of Midas' touch by which everything could be turned into gold. As a matter of fact, the patents were generally worth very little, and had it not been for the active advertising campaign carried on by certain interested parties, the inventors would soon have realized the true state of things, and the number of patents applied for each year would have been less by a great many thousand. There was a great host of patent attorneys who grew fat on the fees they obtained from the inventors for preparing their applications for patents, and the country was flooded with little books published by these men telling of how inventor Jones had made a million out of his patent everlasting steel-pointed lead pencil, how inventor Smith had made three millions on his patent airless pneumatic tire, and of how sixteen billion dollars had been offered for a cheap substitute for water, and twenty-three cents for a new car coupler.

After reading a few hundred of these little works of art (and craft), the inventor usually began to long for some of the golden dollars dangled so temptingly before his eyes, and, as it is the easiest thing in the world for an inventor to invent, the fees were soon in the hands of the attorneys, which you must admit is quite the proper place for them to be, seeing that they went to so much trouble to secure them. It seems a peculiar oversight, as we look at it now, that none of the little books drew attention to the fact that, while about fifty thousand patents were granted every year, about forty thousand did not profit the inventor at all, and, of the remaining ten thousand, but a very small proportion realized any substantial sum. Perhaps the publication of this information might have discouraged some of the inventors, and as that is the last thing any of the attorneys ever wanted to do, may be the information was accidently omitted for that reason.

Well, this little fairy story is about an inventor that lived in those good old times, in the remarkable land of Yewessay. This inventor, like most others of his kind, was poor, but he had a great idea. Every inventor in those days had a great

idea. This was the principal symptom of the malady, and, though it really did no good to treat the patient, as the malady was practically incurable, it was, then, considered good practice, since hydrotherapy had become the fashion, to use the cold water treatment. Liberal quantities of H_2O, temperature $32\frac{1}{2}$ degrees F., were applied to the great idea whenever convenient, and the wet blanket pack was frequently used. No one was ever permanently benefited by this method, though the treatment was a source of much discomfort to the patient.

But to resume, the great idea of this inventor was a method of making water run up hill. This idea was the result of much study, and much burning of the midnight gas (to the great disgust of the landlady). It was evident to all that if the inventor's claims proved true, he had indeed made a great and valuable invention, but, strange to relate, though all the friends of the inventor congratulated him on the making of such an excellent invention, not one of them would invest one single shekel to help build an experimental machine. The inventor was thus forced to go among strangers seeking the mighty dollar to develop his idea.

Many were the men he visited, and many were the opinions he received, also much experience, but no money, and the inventor was almost discouraged. At last he fell into the hands of the brokers. These, after hearing the inventor's description of his wonderful invention, said: "We must have expert advise upon this."

And many were the experts they visited, and many were the opinions they received (all different), and much advice how not to do it, but no money, and the inventor came to the conclusion that he knew more about his own invention than any of the wise experts could tell him. So also thought the brokers. Then said the brokers, "We must have the patent records searched."

And many were the attorneys they visited, and many were the flattering opinions they received, and many were the searches the attorneys made, but not one anticipating patent did they find, nor any device even remotely related to the invention.

Then said the brokers: "This is very much of a speculation, a gambler's chance; we must have a large commission for telling our friends that this is a sure, get-rick-quick, 520 per cent a year, and no-chance-of-loss investment. You must assign 66 2/3 per cent of your invention to us, and we will then find you the $713.30 you require to build your machine." (This is an exceedingly compact, abridged, and expurgated edition. A verbatim report was recorded on 33 miles of steel wire by the telegraphone, and may be found in exhibit K331,107 court records.)

The inventor was then kept busy for a long time signing assignments, sealing seals, transferring transfers, and performing other little acts necessary in the premises, not otherwise more particularly mentioned or described.

Having secured the money, the inventor then started to build his machine. In a few months it was completed, but alas! when tried it would not only not make the water run up hill, but it would not keep it from running down (and the wise experts looked very wise and smiled behind their hands). The poor inventor scarcely knew what to do. He was sure the principles were all right, but—there was the machine. For forty days and forty nights he labored over it, and at last, by changing one little thing here, and another little thing there, he managed to fix the machine so that it would at least keep the water from running down hill, and that was quite an achievement, you must admit (but the wise experts looked very wise and smiled behind their hands).

About this time the inventor had spent all of the $713.30 supplied by the brokers, and $23 besides, and what he owed made a bit beside that, and he had only one shirt and no credit, so you see he was, technically speaking, pretty hard up. At last the inventor went to the brokers again, and after talking and talking and talking (he was a good talker) again and again, he obtained $479.17 more. This was the exact amount required to finish the invention. The inventor knew that this was the right amount because he had carefully figured it out.

Well, to shorten this long story, after many moons of tedious, heart-breaking work the machine was made to run successfully, the water ran up hill (the wise experts stopped looking very wise and looked foolish instead), and the inventor bought himself a new suit of real store clothes (on credit).

During the time the invention was being perfected, the inventor, who, by the way, was a deacon in the Methodist Church, had learned a new language, which was then extensively used in intimate conversation with unruly and obstreperous, animate or inanimate objects. It was generally written, at least in print, in dots and dashes, much after the fashion of the Morse code, thus, "Oh ——— ——— the ——. ——— — — to — —— —— what in ——— is the next thing to go wrong?" To the ordinary man this will, of course, be unintelligible, but here and there throughout the land, there will be found men who have passed through the deep seas of mechanical trouble, and of necessity learned the language, and also a few individuals to whom is given the power to speak this language in moments of supreme exaltation. These will understand the writing.

The machine having proved successful, it was necessary that a patent should be obtained. Now, the preparing of a patent application was supposed to be a most abstruse and difficult art, only to be discovered after many years of apprenticeship and much study (afterward the inventor changed his mind about this), so certain skilled attorneys were employed to make out the application and prepare drawings of the machine.

Now that the inventor was really going to have a patent of his own, he began to read up a little on the subject. He found that the exclusive right to make, use, and sell his own invention, for a limited time, was given him only in exchange for a full and complete description, so that others might work the invention when the patent expired, that the patent cost the government nothing, that there was no guarantee went with the patent, and that a patent was not generally considered of any great value until it had been confirmed by the courts.

The application was soon prepared, duplicated, triplicated, sworn, witnessed, signed, sealed and delivered, bound hand and foot to the Philistines, or rather, to the patent office, and,

"There it lay, there it lay,
'Til it began to rot."

After the aging process was sufficiently completed, the office took action, the application was rejected, the device claimed having been shown in patents to—

T. Edinghouse: 1719—Improved silent phonograph.

G. Westingson: 1760—Donble duplex hair breaker.

B. Brown: 1492—Machine for removing tails from Teddy bears.

The inventor was dumbfounded. The patents to these men showed nothing remotely connected with his inventions, but, ah! there was a slight similarity in the pictures. That must be the reason. A long letter was written to the examiners, carefully pointing out that the devices were entirely different, and that it was hoped that the patent would soon be allowed.

After another long interval (so long that the inventor had to have his hair cut three times, and you know how long inventors wear their hair when times are hard) another action came; the first references were dropped; application rejected on patents to—

Charles Parsconi: 1711—Improved steam windmill.

G. Marsons: 1769—New barb-wireless telephonograph.

The inventor was dumbfounded again, for this time there was no similarity even in the pictures. Perhaps the examiner was confused by the mention of water in all of the specifications.

The attorneys wrote another long letter, carefully explaining that the inventions cited had no bearing on the case, and then the inventor started in to set out some century plant cuttings so that he might raise a little money selling blossoms, and so keep body and soul together while the patent office was getting ready to issue the patent.

The patent office in those days published a paper each week, and in it, besides a list of patents granted, etc., was given a statement of how many weeks, months, years, or centuries, each department was behind in its work. The inventor used to make great calculations from this report. The action would be due, say, Friday, the 13th; allow three days in the

mail, that would be Monday, say Wednesday for sure; and then the poor old Inventor would hang around the post office, day after day, week after week, month after month, waiting for that action. By and by it would come, another damned, discouraging, heart-breaking rejection on some trivial point of resemblance to some ancient unworkable device that happened to present itself to some incompetent examiner.

And in those days there was famine in the land.

After some more valuable time had been lost, the patent office suddenly discovered that the application covered too much ground—it must be divided. A few months more lost, more fees, more signing, more sealing, more waiting, more damning.

But the Inventor found that the office had only been playing with the case so far, now it was getting down to real business; the next citations made it necessary to cut off some of the less important claims. The attorneys amended the application to avoid conflict with the references, and advised the office that the case was now in condition for allowance. But was it? Guess again.

Some more months delay, some more references, 'nother letter, some more months, more references. It reminded one of the Kansas farmer story, "More hogs, more land, more corn, more hogs, etc.," but in this case it was more references, and the inventor was getting poorer all the time.

The inventor gradually found out a good many things about the patent office. He found that the space occupied by the office was entirely too small for the work to be done, that there were not enough examiners, and that not all those in the office were competent to fill their positions. But the most surprising fact, in view of the state of things in the office, was that it had a surplus of several million dollars which it had collected from the inventors of the country and for which it had given them no return. The inventor thought that the government of his great and glorious country would at least have made some effort to give the inventors a square deal and a quick deal, when they put up all the money, but he was only one of those idealists who believe that the government is of the people, for the people, and by the people.

About the time the inventor's youngest great-grandchild was getting married, the patent office allowed the claims then standing, and, after extracting another fee from the inventor, issued the patent. Fortunately, there was still left to the inventor, after the continual hacking and chopping of the patent office, some really good claims that would protect the invention from those who would try to copy it, else the fate of the inventor had been sad indeed.

How the inventor got along with his patent after he got it, is, as my esteemed contemporary says, another story.

* * *

CORRECTING PERSPECTIVE IN SHOP PHOTOGRAPHY.*

S. S. NEW.†

As stated by Mr. Dow, in his article on Shop Photography, in the December issue of MACHINERY, a long focus lens should be used wherever possible when photographing machinery, a wide angle lens being sure to produce distortion. There are cases, however, where, owing to the lack of space or great breadth of the subject photographed, it is imperative that a wide angle lens be used. When this is necessary, it is often possible to correct the distortion, particularly when the subject consists of several parts.

A case of this kind is illustrated by the accompanying cuts, representing a gas-engine-driven Crocker-Wheeler alternator with direct connected exciter. Owing to the small space available at the time the photograph was taken, it was necessary to use a wide angle lens to include the entire set. This, however, produced a negative as shown in Fig. 1, in which the exciter, owing to its nearness to the camera, appears as large as the generator. To reduce this with all important details by retouching would have been very expensive. A print of the photograph was put in front of the camera at a distance such that the image of the exciter on the ground glass was of such a size that it appeared in its true proportion, and a negative was made. The exciter was cut out of a print from this reduced negative and pasted over the abnormal exciter on the original print. The artist then had only to paint in the brick work, windows, etc., around the edges of the exciter and shorten the supporting brackets.

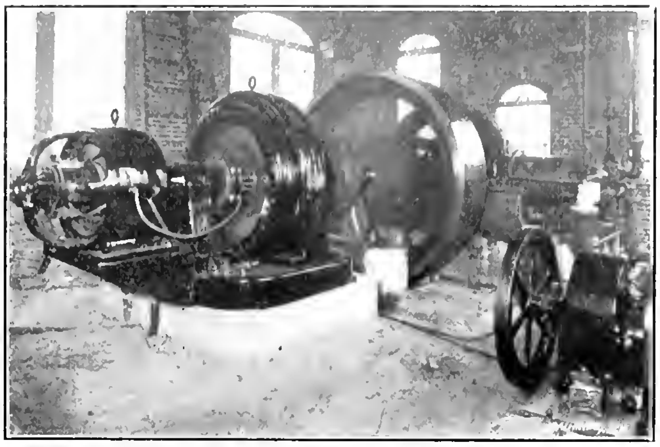

Fig. 1. Photograph taken with Wide Angle Lens showing the Objects to the Left in Exaggerated Proportions.

This method is often used in "faking" photographs, but this example is given as a case where "faking" was necessary to correct the "faking" of the wide angle lens. The retouched photograph is thus more accurate than the original print.

* For previous articles on shop photography, see "Shop Photography," December, 1907, and other articles there referred to.

* * *

The cable companies, anxious to maintain their monopoly on the sending of messages between the new and the old world, have made the statement that they can send a message from the London Stock Exchange to the New York Stock Exchange, and receive a reply, in four minutes. These messages, however, are usually very short, and under such circumstances it makes very little difference whether the message itself is transmitted at the rate of 50 words a minute or 25 words a minute. The records are, of course, obtained by arranging everything beforehand, so that no obstacles have to be overcome, working the line direct between London and New York without any delays at all over the land lines. It is most likely that if similar arrangements were made in connection with the wireless stations, it would be possible to achieve similar results by wireless telegraphy, and ultimately, no doubt, the speed of working wireless telegraphy will be greater than that at present possible for cables, or, at least, fully as great. It seems unreasonable to condemn the wireless system because it has not sprung forth perfect from the start. It has, in fact, developed much quicker than the telegraph, and there are reasons to believe that its future development will be accelerated even in a greater proportion.

STANDARD DRAWING-ROOM METHODS.*

M. R. KAVANAGH †

M. R. Kavanagh.‡

The theme of the standardization of methods in the drawing-room is one which is of vital interest to a large number of the readers of MACHINERY, who are connected more or less directly with this line of work. There are so many leaks possible in the drafting department of any firm, so many ways in which time may be saved by having a way to do things and a place to put them, that a few words upon this topic cannot fail to interest many.

Of course, good light and the least possible amount of noise and confusion in the room during working hours are a foregone conclusion, while the equipment and size of the quarters devoted to this branch of the business must necessarily depend upon the size of the company. Beyond this, however, the way in which the drawing-room ministers to the wants of the factory, and the accuracy and speed with which the drawings are turned out, depend greatly upon the efficiency of the system and the longheadedness of the chief.

About the first step in any good system is the adoption of a number of general rules, governing the production of any

TABLE I. REMOVABLE BUSHINGS FOR TAPPED HOLES.

new work, which may be easily blue-printed and handed to any new man on his arrival, thus giving him a line on the general way in which the work is desired to be gotten out. These data may conveniently cover such points as sizes of drawings, methods of dimensioning, limits to be used on the work, methods of indicating varions finishes, styles of lettering, cross sections, etc. We have gone a good deal further than this in the drafting-room where the writer is employed, and have what we term our data sheets. These, in addition to the above, comprise a list of the stock of steel in the various sizes, shapes, and qualities, carried by the firm; stock patterns, examples and explanations of the various formulas in use in the shop; and, in general, a collection of data relative to our work, which the draftsman or designer might spend much valuable time in looking up. Each man is furnished with a copy of these data sheets, and he retains them while in our employ. That they are appreciated and valued by the men is evident from the tenacity with which they hold on to their copies. This system is by no means original with our firm, being in use in a number of the large firms throughout the country, such as the Westinghouse Co., the General Electric Co., the Brown & Sharpe Mfg. Co., and many others.

TABLE II. STANDARD PERMANENT BUSHINGS—PLAIN.

It is a fact, deplorable though it may be, that a large number of our American draftsmen are not really capable of sitting on the job. It is seldom that we find a man who combines with accuracy and expedition the knowledge of shop methods and practice which would make impossible some of the rather amusing "bulls" we find from day to day. It is on this account, as well as on account of the fact that everyone, no matter how careful, will occasionally go wrong, that an efficient checking method is essential to good work. We all know how glad the shopman is to find a mistake made by the drawing-room, and how quickly he will come back on the draftsman if he does find one. Mistakes, too, are always costly, and the fewer there are, the more valuable the drafting room is to the business. The method we follow is this: The chief explains to the draftsman, by sketch or verbally,

† Address: 22 Bethune Ave., East, Detroit, Mich.

‡ M. R. Kavanagh was born in Chicago, Ill., 1882. After being graduated from the high school, he took courses in mechanical, electrical, and bridge engineering, in the American and the International Schools of Correspondence. He has been connected with the C. B. & Q. and Lake Shore Railroads; Burroughs Adding Machine Co., Detroit; Cadillac Automobile Co., Detroit; and has had charge of office, drafting-room, and cost department for National Mfg. Co. Mr. Kavanagh is now with the Ford Motor Co., Detroit, in the capacity of tool designer. His specialty is designing tools for interchangeable manufacturing

what he desires, and the drawing is made under the supervision of the chief who gives it his approval as regards design. It is then submitted to a committee consisting of the chief engineer, his assistant, and the two head designers. They either approve it or order such changes as they think advisable, and the drawing is returned to the draftsman for alteration, if necessary, or, if not, is passed to the checker, a competent man who does nothing but check the drawings. The drawing is then thoroughly checked by him for accuracy as to scale, dimensions, and mathematical calculations, as well as for its compliance with our system. If any corrections are found necessary, the drawing is again returned to the draftsman, who makes the necessary alterations and returns it to the checker, receiving his approval on same. The drawing then goes to the tracer, who makes the tracing and returns the original and the tracing to the checker. If any corrections are necessary on the tracing, the tracer makes them under direction from the checker, who finally approves the tracing. It is then ready for the blue-print room, and any errors which show up later are held against the checker. This system is very thorough and the errors that occur are few and far between.

Another feature of value, is the grouping of the various blue-prints covering the manufacture of a certain machine, or a number of machines of similar character, in bound packs or books, located at various points throughout the plant. This

obviates the continual replacement of lost prints, which consumes so much time where loose prints are used. Each book is reccipted tor by the foreman who has the work covered by it in charge, as are also the new prints made necessary by changes in design or dimensions. A record of the location of these books is, of course, kept in the drawing-room, and a man is detailed to keep them up to date. There is an exception to this rule in the screw machine department, as the prints of the parts are here mounted on boards and shellaced, the operator having one of these cardboard mounts on his machine where he can refer to it. The mounts not in use are kept in a cabinet for that purpose, where they are easily accessible to the foreman of the department in planning his work. In this connection it might be well to note that all the prints necessary to go into any one department are those referring to operations performed in that particular part of the works, and the drawing-room is generally the only place where a complete set of prints is available.

For some time a good system of handling and recording the changes in the various parts bothered us, but the system we are now using seems to fill the bill very well. If the change is a slight one, as for instance the change of a dimension, the tracing is changed, the date of change being noted in the lower right-hand corner, and the various prints are changed by the man in charge of that work. If the design is changed, a new tracing is made, the old one marked obsolete, new prints made and put in the books, and the new tracing filed with the old one. In each case a record of every change is made by the clerk in a book kept for that purpose, and as the parts are all arranged numerically it is very easy to refer to this record to find the details of the change in making repairs or filling order for old parts.

It is remarkable what a number of drawings will accumulate in the course of a few years, where old designs are being constantly brought up to date, and new machines being added to keep abreast of the times. Owing to this fact, we found it necessary to design and have built a number of cabinets, with drawers made to fit the different sizes of drawings. In these drawers the tracings are filed, as has been said, accord-

ing to numerical order. We have also installed, and find it a great help, a card index giving the exact location and size of the drawing of the particular part sought, and in case the number of the part is not known, a cross index gives an alphabetical classification. As an auxiliary to this index we have a smaller one in which are grouped such tools as bits, reamers, special drills, counterbores, etc., which we find to be a great aid and convenience to the designers in making up similar tools, or, as often happens, in adapting the old tool to a new part. This leads on to the statement that in our drawing-room, as in many others that I know of, there are two distinct divisions, one for the design and production of the drawings covering the machines themselves, and one for the design of the tools necessary for the economic production of these parts. In the former department the data utilized can for the greater part be found in the standard mechanical works or the trade catalogues. In the tool designing department, however, we have a number of standards of which a few examples are here given, compiled mostly from the book of experience, of which, so far as I have been able to learn, there is no authentic edition.

Tables I, II and III give data covering the more common type of drill jig bushings. These bushings may, with the

proper allowance for finish and lapping, be made up in quantities in the screw machine department, and sent to the toolroom for use when required. The material used in making bushings varies in different shops, and although some designers claim that tool steel is the best for this purpose, I have seen both tool steel and soft machine steel used with equal success, the latter of course being case-hardened. To prevent the movable bushing from turning with the drill, we use a simple knee pin placed as near as possible to the outside

diameter of the bushing, and just fitting over the pin shown in the bushing itself. This provides an efficient stop and allows the bushing to be turned nearly completely around in removing. The knurled portions of the bushings are also made ample, to allow of their being easily grasped by the operator.

Table IV gives dimensions of clamping screws used on fixtures where the head of the screw binds directly onto the strap or clamp. It is sometimes advisable to make the stud permanent in the body of the tool, and use a nut with a handle through it similar to the head of the screw here shown. Table V gives data for another form of clamping screw. In this case, however, the screw works through a plate or cover and clamps directly onto the work. These clamping screws are made of machine steel, case-hardened, and the handles, of cold rolled stock, are pressed into them.

In Table VI dimensions are given for a form of jig screw used for clamping the cover or bushing plate on a jig, the plate being so slotted that a turn of the screw will bring the head in such a position that the cover may be thrown back, releasing the work quickly. This is often used on fixtures where a slight pressure is all that is needed, and a quick release of the work is essential to rapid operation. These screws are made of machine steel and case-hardened.

Table VII gives the general dimensions of the standard wing nut, and is merely for convenience in laying out. Table VIII gives data for the inserted feet we use in our cast iron jigs. These feet are made of machine steel, case-hardened, and are a press fit in the jig. Finally, Table IX gives dimensions of counterbores that we use in the works, and is exceedingly handy in working out counterboring fixtures for the various parts, and in proportioning the removable and permanent bushings in jigs where it is desired to drill and counterbore without removing the work.

There are a number of other tables of data, but as they are too highly specialized to be of general interest they will not be given here. There is a point in connection with the design of special screws for the different parts that merits mention. All screws of special shape are designed with the slot in the head having a certain relation to the diameter of the threaded portion. This prevents much of the trouble generally experienced in the assembling department due to screws being screwed in with such force as to break off the head, when the head is large and the body diameter small.

* * *

THE CONVENIENCE OF FORMULAS.

One of the difficulties of editing MACHINERY is the presentation of engineering matter necessarily requiring mathematical formulas in a way that will not be objectionable to the readers who have not acquired a certain amount of technical education. A few articles on design, no doubt, are beyond the comprehension of some readers, but if such readers could realize that much of the stuff that they call algebra is nothing more than a shorthand method of expressing very simple ideas, it would be very much to their own profit, and would often save needless criticism of editorial policy. To illustrate what we mean, we will quote from the the November issue. On page 159, engineering edition, in an abstract from a paper, "Modern Machinery and Its Future Development," the following expression appeared:

$$\text{Cost per piece in cents} = \frac{\text{Wages per hour in cents} + \dfrac{\text{Price of machine in dollars}}{125}}{\text{Number of pieces made per hour}} + \frac{\text{Cost of tools and setting up in cents}}{\text{Total number of pieces}} + \text{cost of material per piece in cents.}$$

This formula, for such it is, is expressed in kindergarten form, but please take notice how confused it is, how easily its meaning may be mistaken, and how long it takes to really figure out what the meaning of the formula is.

Now, if instead of using this form, we indicate each element by a letter, and define each letter, we will note a great improvement in the clearness of the expression. There are no typographical mix-ups as to what is a numerator or what is a denominator, or where the expression begins and leaves off.

Let W = wages per hour in cents,
P = price of machine in dollars, divided by 125,
C = cost per piece, in cents,
N = number of pieces made per hour,
C_{ts} = cost of tools and setting up, in cents,
T = total number of pieces,
C_m = cost of material per piece, in cents.

Then, instead of the cumbersome expression referred to, we have the following:

$$C = \frac{W + P}{N} + \frac{C_{ts}}{T} + C_m$$

* * *

The correspondents to MACHINERY, who send us descriptions of special tools for publication, would greatly increase the value of their contributions if in every case they made it a rule to plainly describe, in the first place, what the tool is to be used for, showing, generally, an illustration of the piece to be produced or to be worked upon. This would make it a great deal easier to at once grasp the idea. To simply describe a device, without making clear its use, or what parts it is to produce, often makes the descriptions almost valueless, or of much less value than they might have. It is, therefore, desirable to proceed in a logical manner when describing a tool or device: First, explain what the tool is intended for, showing the piece operated upon or produced; then, proceed to describe the device, showing how it produces the results desired; and, finally, if the making of the device involves operations of more than common interest, give a description of the manner of making the device last. If these simple rules are followed, the contributions will be of greater value to the readers, and less time will be required of the editors for preparation.

SCREW THREAD SYSTEMS.*

ERIK OBERG.†

Notwithstanding all that has been written about standard screw thread systems, data which completely cover all the recognized standards are very scattered, and it is often necessary to search for information in many different handbooks and works of reference. For this reason a review of the most important information regarding the more common screw thread systems has been compiled in the following article. While a great many more systems than are here reviewed have been proposed from time to time, only those which have been officially recognized by mechanical men, or which have gained prestige by means of universal use and adoption, here or abroad, will be treated.

The United States Standard Thread.

The United States standard thread, usually denoted U. S. S., has a cross section as shown in Fig. 1. The sides of the thread form an angle of 60 degrees with one another. The top and bottom of the thread are flattened, the width of the flat in both cases being equal to one-eighth of the pitch of the thread. In this connection it may be appropriate to define the expression pitch as well as lead, as these two expressions are very often confused, and the word pitch, in particular, often, through erroneously, used in place of "number of threads per inch." The pitch of a thread is the distance from center to center of two adjacent threads. It is equal to the reciprocal value of the number of threads per inch, or, if expressed in a formula:

$$\text{Pitch} = \frac{1}{\text{Number of threads per inch.}}$$

The lead of a screw thread is the distance the screw will travel forward if turned around one complete revolution. It is evident that for a single threaded screw the pitch and the lead are equal. In a double threaded screw, the lead equals two times the pitch, in a triple threaded, three times, etc. The definitions given for pitch and lead should be strictly adhered to, as great confusion is often caused by improper interpretation of the meaning of these terms. Confusion is also caused by indefinite designation of multiple thread screws. The most common way to state the lead and the class of thread is perhaps to say ¼ *inch lead, double*, which means a screw with a double thread, which, when cut, has the lathe geared for four threads per inch, but each thread is cut only to a depth corresponding to eight threads per inch. The same condition is also expressed by: 4 *threads per inch, double*. These two ways of expressing the number of multiple threads are both correct, but the expression which ought to be used in order to avoid misunderstanding under any circumstances would be: ¼ *lead*, ⅛ *pitch, double thread*.

Returning to the form of the U. S. S. thread, we find that if the thread is flattened one-eighth of the pitch at top and bottom, the depth of the thread is equal to three-quarters of the depth of a corresponding thread, sharp both at top and bottom. If p equals the pitch of the thread; d, the depth; and f the width of the flat, the following formulas express the relation between these quantities:

$$p = \frac{1}{\text{Number of threads per inch.}}$$

$$d = \tfrac{3}{4} \times p \times \cos 30^\circ = 0.64952\,p.$$

$$f = \frac{p}{8}$$

Formula for the Number of Threads in the United States Standard Thread System.

In order to fix definitely the number of threads per inch corresponding to any given diameter in the U. S. S. system, Mr. William Sellers, its originator, proposed the following approximate formula:

$$p = 0.24 \sqrt{D + 0.625} - 0.175,$$

in which formula p equals the pitch of the thread for any bolt or screw of the diameter D.

This formula is applicable to all screws ¼ inch and larger in diameter. For diameters below ¼ inch the formula is modified so as to read:

$$p = 0.23 \sqrt{D + 0.625} - 0.175,$$

This modification, which has met with general acceptance, changing the coefficient 0.24 to 0.23, was proposed by Mr. George M. Bond in 1882. The purpose of the change was to make the formula applicable to screw threads for bolts smaller than one-quarter inch in diameter. Mr. Bond's formula tends to increase the number of threads more rapidly as the diameter decreases, a distinct advantage in the case of small screws.

It will be proper to remark in this connection that screws 11/16, 13/16 and 15/16, which according to the formula given ought to have 10, 9 and 8 threads per inch, respectively, are in usual manufacturing practice made with 11, 10 and 9 threads per inch, respectively.

The Sharp V-thread.

The sharp V-thread, Fig. 2, is very similar to the U. S. S. thread, except that theoretically it is not provided with any flat, either at the top, nor at the bottom of the thread. In

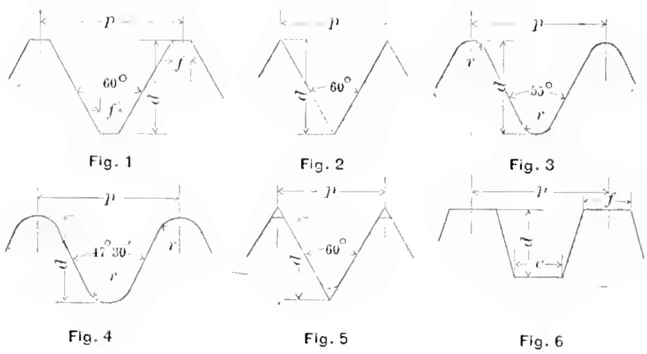

Fig. 1 Fig. 2 Fig. 3

Fig. 4 Fig. 5 Fig. 6

Machinery N. Y.

Figs. 1 to 6. Standard Screw Threads.

common practice, however, it has proved necessary to provide this thread with a slight flat on the top of the thread. The reasons for this were referred to in a short article in the engineering edition of MACHINERY, October, 1906. In this article the difficulties caused by providing a flat on the top of sharp V-threads were also mentioned, the principal one being that no definite standard for this flat has been settled upon. Some manufacturers have used the same flat as is used for the Briggs standard pipe thread, which, although theoretically rounded at top and bottom, is, in this country at least, made with a small flat on the top of the thread. The width of this flat is selected so as to give exactly the same angle diameter as is obtained when rounding the thread in accordance with Briggs' original proposition. This flat is equal to about one-twenty-fifth of the pitch.

If p equals the pitch of the thread; d, the depth; and f, the width of the flat on the top of the thread, the following formulas express the relation between the various quantities of the sharp V-thread:

$$p = \frac{1}{\text{Number of threads per inch.}}$$

$$d = p \times \cos 30^\circ = 0.86603\,p.$$

$$f = \frac{p}{25}$$

Attention must be called to the fact that the formula for the width of the flat is selected simply to give an arbitrary value, which is *not* recognized as any *standard element* of the sharp V-thread. In figuring the depth of the thread, this flat is not considered, and the depth is arrived at as if the thread were exactly sharp.

Comparison between the U. S. S. and the Sharp V-thread.

The two standards referred to hitherto are the two forms of thread most commonly used in the United States. The objections to the sharp V-thread, as compared with the U. S. S. thread, are that the comparatively sharp points of the teeth

* The following articles relating to screw thread systems have been previously published in MACHINERY: Whitworth vs. Sellers Thread, May, 1899; Screw Pitches in Foreign Countries, February, 1900; Screws, September, 1903; Proposed Standards for Machine Screws, June, 1906.

† Associate Editor of MACHINERY.

are very frail; that the groove at the bottom of the thread, being sharp, facilitates fracture under strain; that the depth of the thread, being considerably greater than that of the U. S. S. thread, subtracts from the effective area at the root of the thread of the screw, thus impairing the tensile strength of the threaded bolt, and finally, that in case of taps, the sharp V-thread has less endurance and shorter life, and is capable of smaller duty, owing to the frail and easily worn away points of the thread. In spite of all this, however, the sharp V-thread will long continue to be in general use, primarily because it has so thoroughly established itself in the mechanical industries. This form of thread has also another very strong claim, because of being admirably adapted to the making of steam-tight joints. It answers this purpose best of all common forms of thread, and all patch bolt taps, boiler taps and staybolt taps are, as a rule, provided with sharp V-threads.

The Whitworth Standard Thread.

The Whitworth standard thread, Fig. 3, is used chiefly in Great Britain, but to a certain extent also in the United States. Its use here, however, has greatly diminished since the U. S. S. thread commenced to gain general approval. The Whitworth standard is the older one of the two, and was the first recognized screw thread system. In the Whitworth standard thread the sides of the thread form an angle of 55 degrees with one another. The top and the bottom of the thread are rounded to a radius determined by the depth of the thread, which is two-thirds of a thread with the same angle which were sharp at top and bottom. The radius at the top is the same as the radius at the bottom. If p and d equal the pitch and the depth of the thread, respectively, and r the radius at the top and bottom, then

$$d = \frac{2}{3} \times \frac{p}{2} \times \cot 27^\circ\ 30' = 0.64033\ p.$$

$$r = 0.1373\ p.$$

The advantages of the Whitworth thread are that screws with this form of thread have all the strength possessed by screws with U. S. S. threads, and at the same time have no sharp corners from which fractures may start. Screws and nuts with this form of thread will work well together after continued heavy service when other forms of thread would fail. Whitworth threads are used in the United States chiefly on special screws, such, for instance, as screws for gasoline needle valves, where a liquid-tight and yet working fit is desired. It is also often used for locomotive boiler staybolts. The objections to the Whitworth form of thread are that the angle of 55 degrees cannot be measured or simply laid out with ordinary tools, and that the rounded corners at the top and bottom cannot be produced with any degree of accuracy without great difficulty. The Whitworth standard screw system is denoted B. S. W. (British Standard Whitworth screw thread) in Great Britain.

British Standard Fine Screw Thread.

The British standard fine screw thread is a system of threads recently adopted in Great Britain. The form of the thread is the same as that for the Whitworth standard, but there are a greater number of threads per inch corresponding to a certain diameter in the Whitworth system. The fine screw thread system is denoted B. S. F., and applies to screws ¼ inch in diameter and larger. For detailed information regarding this system see the article in MACHINERY, October, 1906, entitled British Standard Fine Screw Thread.

The pitches for the system of fine screw threads are based, approximately, on the formula:

$$P = \frac{\sqrt[3]{d^2}}{10},$$ for sizes up to and including one inch; and on the formula:

$$P = \frac{\sqrt[8]{d^5}}{10},$$ for sizes larger than one inch in diameter.

In the above formulas

P = pitch, or lead of single-threaded screw, and

d = diameter of screw.

This standard is not intended to make the regular Whitworth standard thread superfluous, but simply supposed to offer a possibility of a standard fine screw thread for such purposes where the regular Whitworth standard would be too coarse.

British Association Standard Thread.

The British Association standard thread is the standard system for screws of small diameter in Great Britain. It is, however, hardly used at all in the United States, except in the manufacture of tools for the English market. The characteristics of the thread form are similar to those of the Whitworth thread, but the angle between the sides of the thread is only 47 degrees 30 minutes, and the radius at the top and bottom of the thread (see Fig. 4) is proportionally larger, depending upon that the depth of the thread is smaller in relation to the pitch than in the Whitworth standard thread. If p, d and r signify the pitch, the depth, and the radius at the top and bottom of the thread, respectively, then

$$d = 0.6\ p. \qquad r = \frac{2\ p}{11}$$

The various sizes of screws in this system are numbered, and a certain number of threads per inch always correspond to a certain given diameter. The system is founded on metric measurements. It was first originated in Switzerland as a standard for screws used in watch and clock making. This system is therefore also at times referred to as the Swiss small screw thread system.

Briggs Standard Pipe Thread.

The Briggs standard pipe thread is made with an angle of 60 degrees. It is slightly rounded off, both at the top and at the bottom, so that the depth of the thread, instead of being equal to the depth of the sharp V-thread (0.866 × pitch), is only four-fifths of the pitch, or equal to $\frac{0.8}{n}$, if n be the number of threads per inch. The difficulty of producing a thread with rounded top and bottom has, however, caused the manufacturers in this country to modify the original standard. Instead of rounding the bottom of the thread, it is made sharp as shown in Fig. 5. The top is slightly flattened instead of rounded, the flat being carried down just far enough to tangent the top circle of the correct thread form. This thread, as indicated by the name, is used for pipe joints and for many purposes in locomotive boiler work. Taps for producing Briggs standard pipe thread are provided with a taper of ¾ inch per foot on the diameter.

Whitworth Standard Thread for Gas and Water Piping.

The form of the Whitworth standard thread for gas and water piping is simply the regular Whitworth thread form, and the only difference from the regular Whitworth standard is the number of threads per inch. Manufacturers of taps, when making what is called English pipe taps, use the Whitworth form of thread and the number of threads according to the Whitworth pipe thread system, but make the dimensions for the taps the same as for the Briggs standard in all respects. The taper is also made the same as for the Briggs standard, or ¾ inch per foot.

Square Thread.

The square form of thread is usually made about twice as coarse in pitch as the V or U. S. S. threads, and partly for this reason and partly because of the perpendicular sides of the thread, it is a troublesome thread to cut with taps and dies. There is no standard for the number of threads corresponding to a certain diameter. The depth of the thread is equal to the width of space between the teeth, this space being equal to one-half of the pitch. While theoretically the space between the teeth is equal to the thickness of the tool, each being one-half of the pitch, it is evident that the thickness of the tooth must be enough smaller than the space to admit at least an easy sliding fit. This form of thread is largely used in adjusting and power conveying screws.

The Acme Thread.

The Acme thread, shown in Fig. 6, has of late become widely used, having in most instances taken the place of a square thread on account of its better wearing qualities, and the comparative ease with which this thread can be produced.

Of all standard thread systems the Acme thread is the only one which has a standard provision for clearance at the top and bottom of the thread. The screw is made of standard diameter, but the nut is made over-size. The relationship between screw and nut is illustrated in Fig. 7. If the diameter of the screw is A over the top of the thread, and B at the foot of the thread, the corresponding diameters of the nut are $A + 0.020$ and $B + 0.020$ inch. The sides of the thread form an angle of 29 degrees with one another. Considering the screw only, if p is the pitch; d, the depth of the thread; f, the width of the flat at the top of the thread; and c, the width of the flat at the bottom of the thread, then:

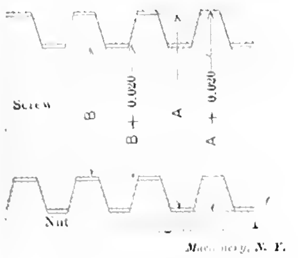

Fig. 7. Acme Standard Screw and Nut.

$$d = \frac{p}{2} + 0.010 \text{ inch},$$

$$f = 0.3707\ p.$$

$$c = 0.3707\ p - 0.0052 \text{ inch}.$$

The Acme thread has many good points, not the least of which is its strength, and the ease with which it may be cut compared with the square thread. This thread is recommended as a substitute for, and to be used in preference to, the square form of thread.

French and International Standard Threads.

The French and international standard threads are of the same form as the U. S. standard, and the formulas given for the latter form of thread apply to the former. The pitches, however, are stated in the metric measure, and are somewhat finer for corresponding diameters than the U. S. S. thread. This is a distinct advantage, especially in the smaller sizes. The standard thread of the international system is denoted S. I. and was adopted by the International Congress for the unifying of screw threads held in Zürich, 1898. This system conforms with slight variations with the system earlier adopted in France, the French standard thread, denoted S. F. In order to provide for clearance at the bottom of the thread in the nut, the congress referred to above specified that clearance at the bottom of the thread shall not exceed 1/16 of the height of the original triangle. The shape of the bottom of the thread resulting from such clearance is left to the manufacturers. However, the congress recommends rounded profile for said bottom. By this provision choice is given to the manufacturers to make the bottoms of their threads flat or rounded as desired, and yet have them conform to a common standard so as to interchange.

Instrument and Watchmakers' System.

The standard screw system of The Royal Microscopical Society of London, England, is employed for microscope objectives and the nose pieces of the microscope into which

WHITWORTH STANDARD THREAD SYSTEM FOR WATCH AND MATHEMATICAL INSTRUMENT MAKERS.

0.020	210	0.045	120	0.100	50

these objectives screw. The form of thread is the Whitworth form, the diameter of the male gage is 0.7626 inch. The number of threads per inch is 36.

In the table above are given the sizes and corresponding number of threads for Whitworth standard screw thread systems for watch and mathematical instrument makers. This system is adopted by many instrument makers both in the United States and Europe.

Lag Screw Threads.

There is no recognized standard for the sizes and corresponding number of threads for lag screws. The following table, however, gives the number of threads according to common practice. While lag screws are largely made according to this system, there are, however, a number of different systems in use.

Gas Fixture Threads.

Thin brass tubing is threaded with 27 threads per inch, irrespective of diameter. The so-called ornament brass sizes

LAG SCREW THREADS.

Diameter of Screw.	No. of Threads per inch.	Diameter of Screw.	No. of Threads per inch.

3/8	8	3/4	5
7/16	7	7/8	4
1/2	6	1	4
9/16	6	...	..

have 32 threads per inch. The standard diameters of the thread are 0.196 inch (large ornament brass size) and 0.148 inch (small ornament brass size).

Fine Screw Thread Systems.

We have previously referred to the British fine screw thread system recently adopted. There is a demand for the adoption in this country of a standard system with a U. S. S. form of thread but with a finer pitch than called for by this standard. The Association of Licensed Automobile Manufacturers has adopted such a standard, but it is, of course, not universally recognized. The objection to the adoption of a standard by a single body of manufacturers is obvious. Even if the standard is one which would recommend itself to general use, it would be better if the opinion and the needs of machine builders in general were considered. On the other hand it may be said in defense of the adopted system that automobile construction is so specialized a manufacture that here doubtless may arise requirements which would not present themselves elsewhere.

KEEP MONEY MOVING.

We hope that by the time this note is published the tight money trouble will be over and business will have resumed its normal channels. Whether it is or not, the advice contained in the little slips here reproduced is worth taking to heart by every business man:

Put Your Shoulder to the Wheel---NOW

In sending you the enclosed check for our account we do so in the hope that you will immediately continue it on its way to do its full share in restoring confidence and prosperity for us all.

The spirit of patriotic co-operation should govern us all at this time—and the most practical method is for us to pay the bills we owe

American merchants and manufacturers have never been found wanting in a patriotic emergency. Put your shoulder to the wheel with the rest of us—NOW

Yours for continued prosperity,

The S. Obermayer Company

To "The Man Who Signs the Checks"

The spirit of patriotic financial co-operation should govern us all at this time—and the most practical method is for us to pay each other the bills we owe

We are doing what we can in that direction. Will you help us? We'll promise to start your remittance on its way immediately upon receipt, to do its full share in restoring confidence and prosperity for us all

The S. Obermayer Company

The cause of business panics is fear, *i. e.*, simple cowardice. They belong in the same class as the stampede, caused in a crowded theater by some hare-brained monkey yelling "Fire!" when he has smelled only the smouldering butt of a bad cigar. But the majority does not stop to investigate. Men and women rush madly out, tearing clothes, bruising flesh and breaking bones as they go. The saner-minded set an example in calmness by quietly staying in their places. So it should be in the business world. In time of money trouble the solid business man who has his own best interests and those of the community at heart, will not withhold payment of debts as they come due so that he can hoard his cash. On the contrary, he will pay them with more than usual promptness, if possible, and so help "keep the ball a-rolling."

* * *

The results of the trials with the new turbine German cruiser, *Stettin*, are given by the *Mechanical Engineer*, as follows: The ship achieved a speed of 24 knots within 1 minute, 8 seconds, of starting the engines, and came to a dead stop, from full speed, in 1 minute, 45 seconds.

LAYING OUT CAMS FOR RAPID MOTIONS.*

F. H. SIBLEY.†

We may consider a cam mechanism as being made up of two elements. As generally constructed, one element is a revolving plate, cylinder, cone or sphere, and the other element is a bar or a roller which has some form of reciprocating motion. The revolving piece is usually made the driver, although the mechanism may be made to work in the reverse order. The shape of a cam will depend upon the kind of motion that the follower is required to have. The motion of cams that are used for driving parts of machinery may be one of four kinds, *viz.:*

1. *Uniform motion*, in which the follower is made to pass over equal spaces in equal intervals of time.

2. *Intermittent motion*, periods of motion being interrupted by periods of rest.

3. *Simple harmonic motion*, in which the follower is accelerated from rest to a maximum velocity and then retarded again to a state of rest, following the harmonic cycle.

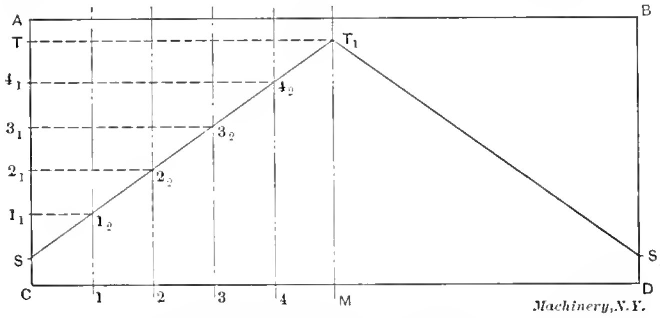

Fig. 1. Development of Uniform Motion Curve.

4. *Uniformly accelerated motion*, in which the follower is accelerated from rest to a maximum velocity and then retarded again to a state of rest, the acceleration being uniform, as, 1 inch per second, 2 inches per second, etc.

In slow-moving machinery it may not be important whether the follower moves with uniform, simple harmonic, or uniformly accelerated motion, but in machines where the cams have a high rotative speed, and the follower a reciprocating motion, as in the case of sewing machines and in some textile machinery, a uniform rate of motion will be unsatisfactory or impossible. The reason for this is that the follower is impelled from rest to its maximum velocity instantly, and also brought to rest from a maximum velocity instantly. This gives it a sudden jerk at each end of the motion, which is very trying to a machine when the reversals take place rapidly. Cams for high rotative speeds, where the follower has a reciprocating motion, should, therefore, be so designed that the follower will start gradually, attain its maximum speed near the middle of its path, and then gradually come to rest. In other words, the follower should have a uniformly accelerated motion during the first half of its movement, and a uniformly retarded motion during the last half.

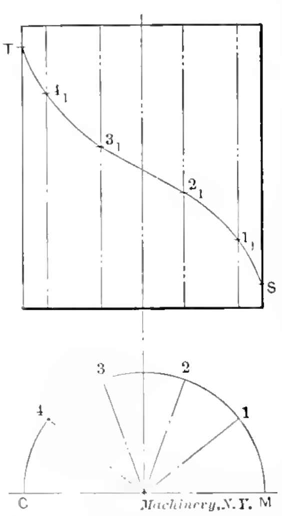

Fig. 2. Uniform Motion Curve scribed on Cylindrical Surface.

In uniformly accelerated motion $S = \frac{1}{2} Pt^2$ where S = the distance passed over, P = the acceleration and t = the time. This is the same as saying that the distance which the body has passed over at the end of any number of units of time varies as the square of the number of such units. For example, if a body has a uniform acceleration of 2 inches per second $S = \frac{1}{2}\ (2)\ (1)^2 = 1$ for the first second; $S = \frac{1}{2}\ (2)\ (2)^2 = 4$ for the next second; and so on. This is also the law of falling bodies whose motion is not resisted by the air or other medium. Uniformly retarded motion obeys the same law. If the time intervals of such a motion be plotted as abscissas and the corresponding space intervals as ordinates, with reference to coordinate axes, the resulting curve will be a parabola, and this is the curve that should be used for the outline of cams that are designed for high rotative speeds.

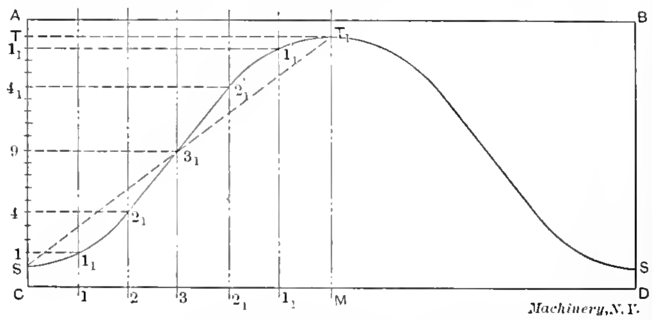

Fig. 3. Development of Uniformly Accelerated Motion Curve.

The cams shown in the following sketches do not necessarily represent any existing forms; they simply illustrate how the principle may be applied to certain shapes of cams and paths of followers. In Fig. 1, lay out on a sheet of paper $A\,B\,D\,C$ a line constructed as follows: Bisect $C\,D$ at M and divide $C\,M$ into any convenient number of parts, say five. Lay off on $C\,A$ any distance $S\,T$, and divide $S\,T$ into the same number of parts as there are in $C\,M$. Through the points 1, 2, 3, etc., on $C\,M$, erect perpendiculars to $C\,M$, and through the points 1_1, 2_1, 3_1, etc., on $C\,A$, draw parallels to $C\,M$ intersecting the perpendiculars at points 1_2, 2_2, 3_2, etc. A line $S\,T_1$ drawn through these intersections will be straight. The line $T_1\,S_1$ can be found in the same way. Now if the sheet of paper $A\,B\,D\,C$ be wrapped around the outside of a cylinder

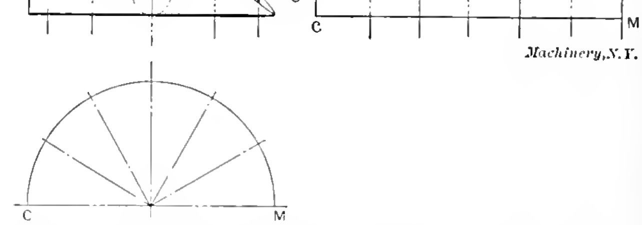

Fig. 4. Transferring Uniformly Accelerated Motion Curve to Cylinder.

whose circumference is equal to the distance $C\,D$, the line $S\,T_1$ will take the position $S\,T$, Fig. 2, and the line $T_1\,S_1$ will form a similar curve on the reverse side of the cylinder. If this curve be made the center line of a groove, as the cylinder revolves on its axis, the groove will drive a follower up and down, parallel to the elements of the cylinder, with a uniform speed. The follower will start and stop at either end of its motion with a sudden jerk.

In Fig. 3 let $A\,B\,D\,C$ represent the paper as before. Bisect $C\,M$ at 3, and $S\,T$ at 9. Divide $C3$ and $3M$ into any convenient number of parts, say three; then divide $S9$ and $9T$ into the square of three parts, or 9, as shown. Erect perpendiculars to $C\,M$ at the points 1, 2, 3, etc., and draw parallels to $C\,M$ through the points 1, 4, 9, 4_1, and 1_1. Through the points S and T_1 and the intersections 1_1, 2_1, 3_1, $2'_1$ and $1'_1$, draw a smooth curve. This line will be a parabolic curve, reversing at 3_1. The curve $T_1\,S_1$ is constructed in the same way. Now wrap the sheet of paper $A\,B\,D\,C$ around a cylinder whose circumference is equal to $C\,D$. The curve will take the position $S\,T_1$, Fig. 4, and the curve $T_1\,S_1$ will take a similar position on the reverse side of the cylinder. A groove made with these curves as center lines will drive a follower P up

* For additional information on this subject, see "Notes on Cam Design and Cam Cutting," August, 1907, and other articles there referred to.

† Address: Case School of Applied Science, Cleveland, O.

and down through the distance K, as the cylinder is rotated on its axis. The follower will start gradually at S, attain its maximum velocity, and then come gradually to rest again at T_1, the motion being uniformly accelerated and retarded. The sides of the groove are made parallel to $S T_1$, and drawn at a distance away from it equal to the radius of the follower P.

Fig. 5 shows the distortion of the curve $S T$ when the follower moves in the arc of a circle, with center at some point Q, instead of in a straight line. Points on the new curve are found by setting off from the intersections $b_1 d_1$, etc., the ordinates $a b$ and $c d$. The curve $S a_1 c_1 T$ is then made the center line of a groove which will drive the hinged follower with the same variation in speed attained by the follower in Fig. 4.

Fig. 6 shows how the parabolic curve is applied to a plate cam. The roller follower is supposed to oscillate between P and P_1 as the cam rotates about O. The curve $P 3_2 P_1'$ corresponds to $S T_1$ in Fig. 4, being the center line of the parabolic groove in the face of the plate. Only one-half of the cam is shown in the figure. Suppose this cam is to rotate 180 degrees, while the follower moves from P to P_1. Draw the base circle with radius $O P$, the length of which will depend upon the size of the cam. Draw $O A$ perpendicular to $O P$, and divide the arc subtended by $P O A$ into any convenient number of parts, say three. Draw radii $O1_2$, $O2_2$, etc. Divide $P P_1$ into two equal parts at 9, and divide $P9$ into the square of three parts, or 9, as shown. With O as a center, and radius $O1$, find the intersection 1_2. In the same way find the other intersections 2_2, 3_2, etc., and draw a smooth curve through these points. This curve has the same relation to the curve of uniform motion shown dotted, that the parabolic curve has to the straight line in Fig. 3. If a similar curve be laid out on the other side of $P P_1'$, and made the center line of a groove then the follower P will be pushed up and down mechanically by direct contact. If a curve parallel to $P3_2 P_1'$, and drawn at a distance equal to the radius of the follower away from it, on the inside, be made the outline of the cam, then the follower will be pushed up mechanically to P_1, and allowed to fall by its own weight. It will remain in contact with the cam theoretically, because the principle of uniformly accelerated motion is the same as that of a falling body. In practice, however, the friction and the inertia of the connected parts would probably prevent the follower from remaining in contact with the cam on its return motion if the oscillations were rapid.

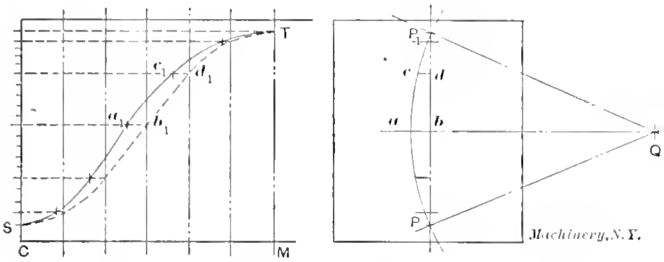

Fig. 5. Accelerated Motion Curve, when Follower moves in the Arc of a Circle.

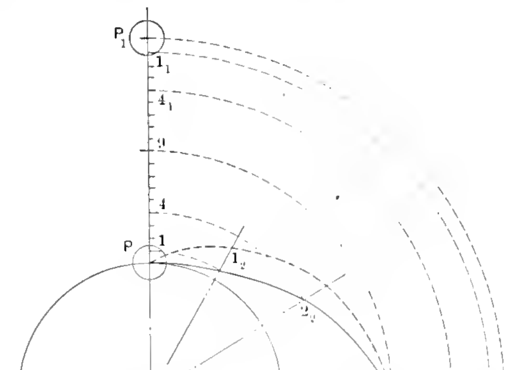

Fig. 6. Accelerated Motion Curve applied to Plate Cam.

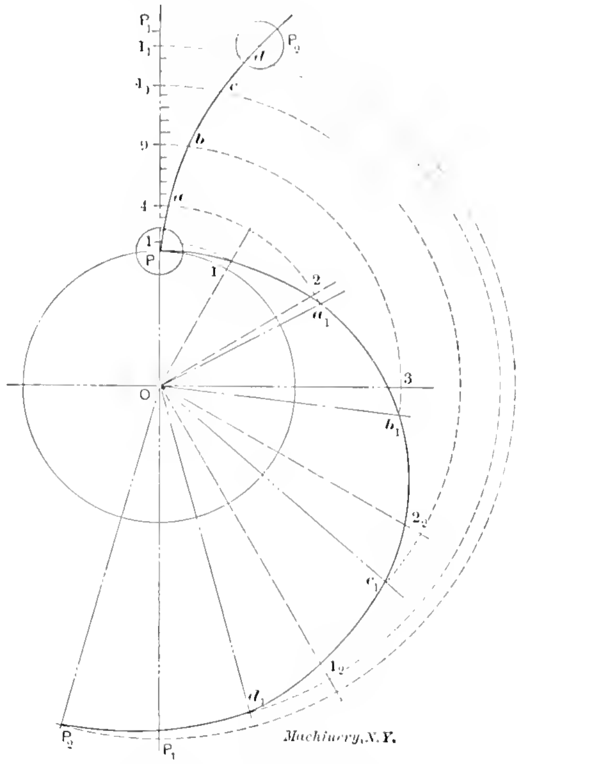

Fig. 7. Accelerated Motion Curve applied to Plate Cam, with Follower moving along a Curve.

Fig. 7 shows the parabolic cam constructed for a follower which moves in any curved path. The construction is the same as in Fig. 6 except that points in the curve are located on radial lines Oa_1, Ob_1, etc., offset from the first radii by the distances $2a_1 = 4a$, $3b_1 = 9b$, and so on.

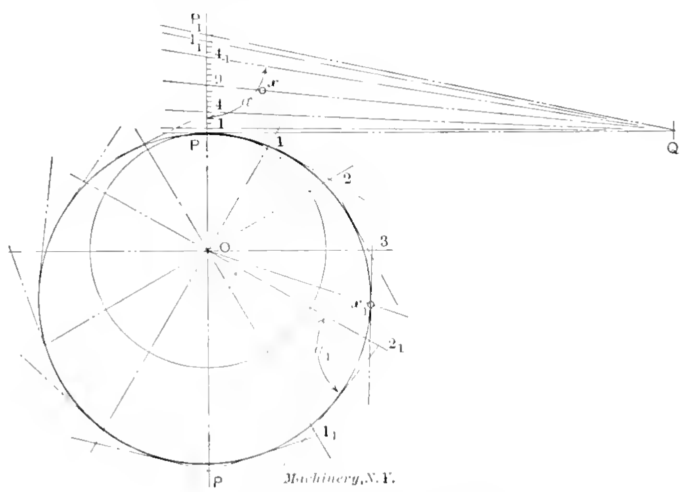

Fig. 8. Plate Cam for Bar Follower.

When a plate cam is to be laid out to drive a bar follower through a certain cycle of operations, the construction is more complicated. The base circle is divided as in the previous case into any convenient number of parts and the square of the number of such parts laid out from P to 9 and from 9 to P_1, Fig. 8. If the bar is to oscillate about Q as a center, it will take the positions $Q1$, $Q4$, $Q9$, etc., as the radii $O1$, $O2$, $O3$, etc., come to the position OP. The intersections 1, 2, 3, and so on, are found just the same as in the previous cases. Now instead of drawing the curve for the cam outline through these

points, straight lines which represent the edge of the follower must be drawn through the points making the same angle with a given radius as the follower makes with OP when the radius in question is in the position OP. For example, angle a equals angle a_1. Now the cam outline is a smooth curve drawn tangent to these straight lines. If the bar follower, instead of being centered at Q, moves up and down parallel to its first position, then all these angles are right angles. If the face of the bar is curved, then the cam outline must be drawn tangent to the curves after they have been properly located with respect to their several radii.

In drawing cams like Fig. 8, the proper relation between the diameter of the base circle and the distance PP_1 must be assumed. If the base circle is too small, the cam outline will not be tangent to the edge of the follower in all positions, and the latter will not have uniformly accelerated and retarded motion. There is a rolling and sliding contact between the cam and its follower in the case of Fig. 8. The rolling action tends to carry the point of contact outward to the right of OP, during the upward motion, and to bring it back towards OP during the downward motion. The point of contact x does not necessarily occur when Ox_1 is perpendicular to Qx.

VERTICAL CAMERA BRACKET.

ETHAN VIALL.*

In photographing small objects that cannot be readily hung up or pinned to the wall, one is often at a loss to know how to get a satisfactory picture. This is especially true of drills, reamers and objects of that class, and makeshifts of various kinds are resorted to to hold the camera in a vertical position in order that the articles may be laid on the floor.

None of the camera catalogues that I am familiar with list a bracket for this purpose, and so I made one, which is

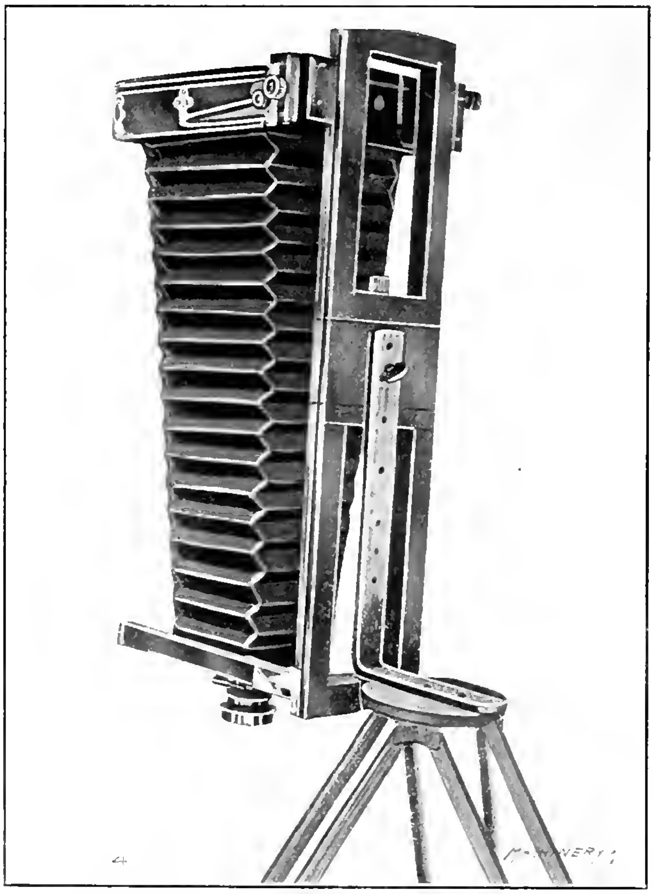

Fig. 1. Bracket in Use with Long Arm screwed to the Camera.

strong, rigid, and answers every requirement. It is easily carried in the camera case, taking up but little room. My camera is a large, heavy, view camera, and so the bracket I made is heavier than would be needed for a light instrument.

The bracket was made of a flat piece of stiff steel, ¼ inch thick, 1¼ inch wide, and 18 inches long. This was bent into the form of an L, the long arm being 12 inches and the short one 6 inches long. Holes were drilled and tapped in several places in each arm. These holes were tapped the regular ¼ inch 20 threads, used almost universally for camera fittings. A thumb-screw similar to the one in the tripod top was made. The bracket was polished and was then ready for use.

In Fig. 1 the camera is shown with the bellows drawn out full length and the camera fastened to the long arm. This position is often very convenient. For copying pictures I generally use the long arm down, as this position, with the bellows extended, brings the lens close to the floor.

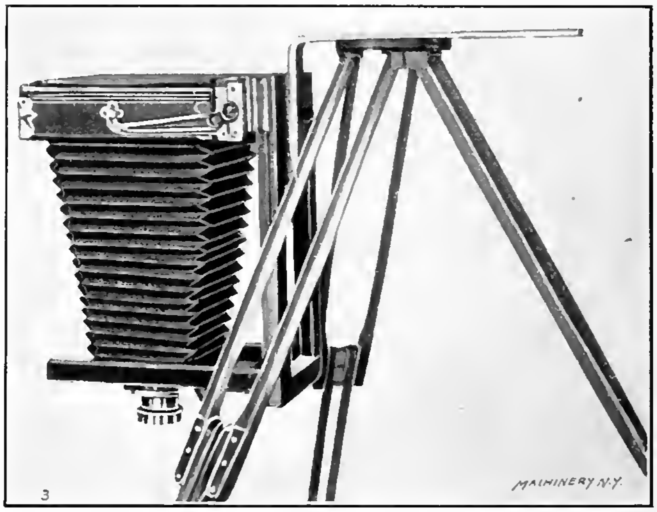

Fig. 2. Bracket in Use with Short Arm screwed to the Camera.

Fig. 2 shows the bracket in place with the short arm screwed to the camera, and the long arm extending over the tripod top. This was done so that if it were necessary to set the tripod legs in such a position that the camera would overbalance, a weight could be hung on the long arm. In ordinary work where the tripod legs are properly spread no tendency to tip is noticed.

A photographer will soon find that this bracket quickly pays for the hour's time taken to make it, and he will wonder how he ever got along without it. By using the different holes in the bracket and the adjustments of camera and tripod, any position may be obtained as one using it will quickly see.

* Address: 805 N. Mercer St., Decatur, Ill.

* * *

A committee of the Chicago Association of Commerce has reported adversely on the question of the inauguration of a parcels post, proposed by the Postmaster-General. The chief objection stated is that a parcels post would involve a much larger annual loss in the running of the post office department than is at present the case. A number of other reasons are also mentioned, amongst others, that it would cause the government to enter into business competition with private concerns. This probably is, if it were possible to analyze the true reason of the opposition, the main objection. The monopoly of the express companies must, by all means, be considered, even if the public at large is the loser. While it seems that a question of this kind does not strictly pertain to mechanical matters, such as are dealt with in MACHINERY, it is still worth while mentioning the fact, because it is undeniable that the benevolent influence that would in reality be the result of a parcels post, would react on all kinds of business in the country, placed on a legitimate basis, and therefore it is in the interest of mechanical men, as well as others, that reforms of this character are carried through. Progress in one direction always tends to stimulate progress in all other lines.

* * *

A CORRECTION.

An error was made in the note, appearing in the December issue, which described a novel machine foundation built in the Stockbridge Machine Co.'s shop, Worcester, Mass. The machine erected on this foundation is a Bullard "vertical turret lathe." This machine was described in our October issue on page 119, engineering edition.

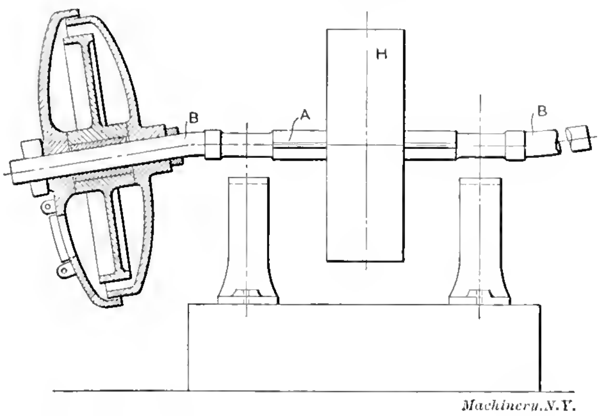
ITEMS OF MECHANICAL INTEREST.

NOVEL USE OF ELECTRIC FLAT-IRONS.

It is not often that heating units from electric flat-irons are put to as severe a test as in the instance given below. The problem was to replace a crank-pin on the high-pressure side of a 500-horse-power cross-compound Russell engine. The new pin, 6 inches diameter with a taper of 1/64 inch, was to be fitted into a crank-disk, 5 inches thick, which was fixed on a 12-inch shaft. To expand the disk by heating it with blow-torches would have taken too long, besides making a dirty and unsatisfactory job, so several heating units from General Electric 6-pound flat-irons were grouped around an iron core 3¼ inches diameter, and placed in the 6-inch hole in the crank-disk. In four hours after the current was turned on the disk had expanded sufficiently to allow the crank-pin to slip in. Although the heating units were at about white heat all of the time, they were not injured except that the brass tubing on two was slightly melted in one place. After having served for fitting the crank-pin, the heating units were replaced in the flat-irons and continued in their normal use.

CLEANING CAST GEARS.

Some time ago a new procedure for cleaning cast iron gears from scale and molding sand was shown in the *Zeitschrift für Werkzeugmaschinen und Werkzeuge.* This process consists in placing the gear inside a casing, together with any desired cleaning material, the casing being fastened on a bent shaft, so that when revolved, the whole mechanism gets a kind of



Device for Cleaning Cast Iron Gears.

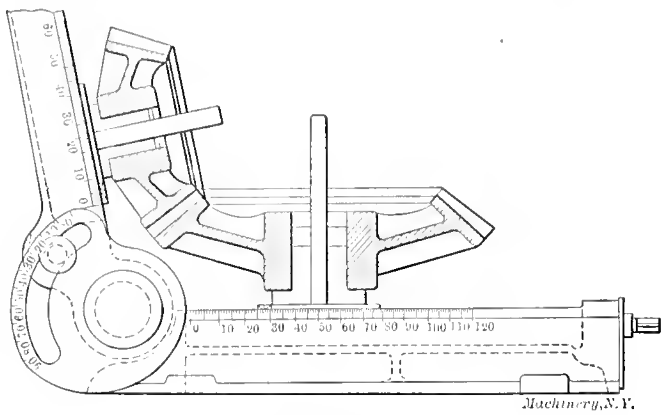
oscillatory motion. Referring to the cut herewith, *A* is a shaft having bent portions *B* at each end. The device is driven by pulley *H* on shaft *A*, to each of the bent portions of which gear wheels are clamped. The advantage of making the apparatus double, that is of having a bent portion on each end of the shaft, the bends being made in opposite directions, is to secure a balance at the high rotation of speed desirable. A perfect balance, however, cannot be obtained in this manner, as it is easily seen that the cleaning material, for instance, will not be distributed equally in the casings, but will always tend to fall toward the bottom, thus preventing a balanced condition to be produced. At anything but the very highest speeds, however, this question of balancing cannot be of very great importance in an apparatus of this kind.

R. G.

GERMAN BEVEL GEAR TESTING DEVICE.

A recent issue of the *Zeitschrift für Werkzeugmaschinen und Werkzeuge* contains a description of a fixture for testing bevel gears. As shown in the cut, it is essentially a protractor, provided with sliding blocks carrying pivots on which are mounted the gears to be tested. Besides the protractor graduations for setting the gear axes to the required angle, graduations are provided for showing the setting longitudinally of the sliding blocks on the two arms. The only use we can see for these graduations would be in case the device was opened out to 180 degrees, and used for testing spur gears, in which case it could be set to give the required center distance. In measuring bevel gears the angle is generally a matter of prime importance, the hub lengths being fitted to suit. As may be seen, the lower member or bed of the device is provided with a traversing screw for adjusting the sliding block, carrying the pivot and the gear; doubtless the upper one is also so arranged. Means are provided for clamping all adjustments after they are made.

This device serves the same purpose as those made for sale in this country by firms making a specialty of gear-making

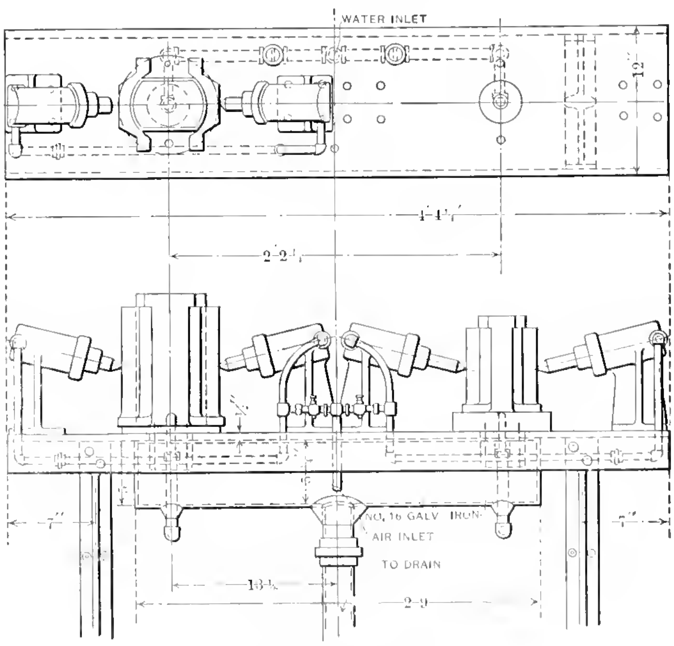


Protractor for Testing the Accuracy with which the Teeth of Bevel Gears are cut.

machinery. They are in common use in gear cutting. Such advantage as this particular device appears to have lies in its comparative smallness and lightness, and being a fixture or bench tool rather than a complete machine.

LINING CAR BRASSES.

The accompanying cut reproduced from the November issue of the *American Engineer and Railroad Journal,* shows a device in use at the Collinwood shops of the Lake Shore & Michigan Southern Railway, for lining car brasses. The apparatus consists of two pairs of air cylinders, suitably mounted on a 12-inch channel beam, as shown. The cylinders are bored to 2 3/16 inches diameter. The piston rod is inclined downward and pointed at the end, so that, when air is admitted to the cylinders, the brasses are held firmly against



Device for Holding the Car Brasses.

the mandrel. A coil spring is fitted in the cylinder, so that, when the pressure is released, the piston will be forced back, and the brass can easily be removed. The mandrel is cored hollow, and streams of water are played on the inside by means of a pipe cap with four ⅛-inch holes in it, which is placed on the end of the supply pipe, thus cooling the lining metal as it is poured. Guide strips are cast on each side of the mandrel to hold the brasses the proper distance from it. The brasses are tinned before lining.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

FEBRUARY, 1908.

PAID CIRCULATION FOR JANUARY, 1908, 23,286 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

HINDLEY WORM GEARING.

It is generally conceded by designers and intelligent users of worm gearing that the Hindley or hour-glass worm has certain advantages over the common type, and they will in the same breath describe its disadvantages. Its chief advantage is that it fits the worm-wheel over a considerably greater area than is possible with the ordinary worm. The larger area of contact reduces the pressure per unit of surface, and that means better lubrication, longer wear and less frictional resistance. Its disadvantages are that it must be exactly located, it is not interchangeable with worm-wheels of the same pitch but of greater or less number of teeth, and it must be made by special machinery. The disadvantages of non-interchangeability and of requiring special machinery are probably least important; but to locate the Hindley worm exactly and preserve that location are not easy. Change of position due to wear of the thrust bearing does little or no harm to the common worm, but it is absolutely ruinous to the Hindley type. Notwithstanding the drawbacks, its superior efficiency and longer life have made its use considerable. Curiously, however, there is an almost total lack of published data on dimensions, and we would gladly receive contributions on the subject for our data sheets.

* * *

ARE SPRING AND WEIGHT EQUIVALENTS?

In United States patent practice a mechanical equivalent has been legally defined as that which performs the same function in substantially the same manner as the compared device. A recent decision (1905) holds that a spring and weight are equivalents in certain competitive plumbing fixtures, inasmuch as one effects the same action as the other in the infringing device. The decision undoubtedly is sound for the case in contention; but, unfortunately, it reads further on: "The interchangeable use of springs and weights is the stock illustration for equivalents."

Our criticism is that the "stock illustration" holds good only when springs and weights *are* interchangeable; and this condition exists within a narrow range only, as every engineer knows. Springs and weights are not broadly interchangeable. A weight must act in accordance with the law of falling bodies. It can fall at no greater speed than expressed by the formulas $v = gt$, or $s = \frac{1}{2} gt^2$; whereas a spring, having little weight in proportion to the energy exerted within a narrow range of action, may, because of its less inertia, perform functions in a small fraction of the time required for a weight. Hence, a weight often is inoperative where a spring works successfully. Again, a difference of great importance is that a weight must act in a direction toward the earth, or that approximately. A spring, of course, works practically as well in one direction as another.

Now, if the stock illustration means that a spring and weight are equivalents *only* when interchangeable, and being thus interchangeable because of the limitation implied, then there is nothing more to be said. Otherwise the statement is loose and technically untrue, and tends to show that scarcely anything is more difficult than exact definition.

* * *

CHOOSING A TRADE.

The choice of a trade, though important, is often made without investigation. Boys enter a trade blindly, with little understanding of what they are to learn or the position their chosen occupation occupies in the world's affairs. They do not know whether it is lasting or ephemeral. For that matter, of course, no one can judge with certainty of the permanency of any skilled occupation; but we may infer much from past experience and a knowledge of its relative position in the general manufacturing industry. We know that once flourishing trades have become obsolete because of changed customs, improved machinery, exhaustion of materials, etc.; and the skill acquired by their craftsmen is now of no value. Such changes, if they come quickly, are little less than tragedies to the individuals directly affected.

The beginner then should, first of all, get an idea of the probable permanency of his proposed occupation, the prospects for advancement and the possibilities it offers as compared with others. To do this thoroughly is a considerable undertaking, and one beyond the intelligence of most boys; but their mature friends often could prevent bad mistakes if they would make even superficial investigations.

New occupations are constantly springing up. Some of them will be of long duration and well paid, but the majority are short-lived and to be avoided by the prudent. Of all the trades in existence, probably there is no other that is as important or that offers the same permanency as the machinist's trade. It is a basic art upon which all other manufacturing industries depend. In olden times the blacksmith was the chief craftsman, inasmuch as he made tools for all the rest—and for himself; but the supremacy of the blacksmith long ago departed. The cold working of metals has very largely displaced forging to shape while in the hot and plastic state, and, in machine construction forged work now enters to a very small extent. Many tools and machines are made in which the primitive art of the blacksmith appears in no shape whatever. The rolling mill shapes the shafting, and itself is the product of the machine shop. The lathe, drill, planer, shaper, milling machine, power press and other metal-working tools have almost entirely displaced the smith. Now it is the machinist and machine shop that produce tools and machines for all manufacturers. The machine shop is the fountain head of all modern mechanical industry. All machinery of every description, the printing press, sugar mills, hoisting machinery, locomotives, stationary and marine engines, etc., are the product of the machine shop and the skill of the machinist, machine designer and mechanical engineer. So it may be reasonably claimed that no trade to-day offers as much security as those which have to do with the operation of machine tools and the hand processes which should be included in the education of an all-around machinist.

The demand for skilled machinists is growing, and it will continue to grow with the years. We speak of this as a mechanical era, but we are only at its beginning. Not all can be machinists, of course, no matter how great the development; but the fathers who read MACHINERY can safely advise their sons and their friends' sons who have an inclination in that direction, to enter the trade. Specialization which tends to keep the rank and file employed merely as operators, gives all the more opportunity to the bright and ambitious.

LOOK FORWARD.

The bright side is the one to look for always, and the man who has the ability to find it possesses a source of strength that, with work, is almost certain to triumph over difficulty. We should not overdo it as was the case with some of the daily newspapers that recently published misleading reports of trade revivals, doing more harm than good. The more evenly each of us keeps balanced just now, the better it will be for all; and somewhere between the extremes will be found the facts which every business man needs to shape his course.

An investigation of conditions in our branch of the machinery industry shows that since January first there has been considerable general improvement and as much as could be expected of recovery, after the staggering blows in the last months of 1907. The situation is fundamentally sound. Money is becoming more plentiful. Confidence is gradually returning, and although the days go by slowly now, before the end of the year, stronger and perhaps wiser, we shall be looking forward to another period of prosperity.

* * *

PRODUCTION AND USE OF DENATURED ALCOHOL.

The annual report of the Commissioner of Internal Revenue, just issued, shows that the production and use of denatured alcohol has not yet attained much importance in the United States. It states that only ten stills have been set up for producing denatured alcohol, and it is claimed that the cost of the product is much greater than that confidently predicted at the time the industrial alcohol law was passed by Congress. It is further alleged that the present prospects for denatured alcohol competing actively with kerosene and gasoline are not at all encouraging. Those who worked hard for the measure feel considerably disappointed that the good results experienced in Germany have not been realized here.

In our opinion it is still too soon to feel disappointed and discouraged that denatured alcohol has not quickly become an important internal combustion engine fuel or a general illuminant. The change on the part of the public requires time, and time is also required by distillers to get their plants into efficient working shape. Moreover, the internal revenue regulations first prescribed were quite sufficient to discourage any would-be small producers. They were required to work under conditions but little less rigorous than those prescribed for the regular distillers of liquors for general consumption. The revised regulations which went into effect September 1, 1907, are much less restrictive, and considering the nature of the business, are probably all that can be asked for.

There is still another factor to reckon with, and that is the effect of nearly fifty years of stern enforcement of the laws against illicit distilling. Possible small producers have a dread of doing something that will subject them to the wrath of the internal revenue officers, and coupled with that feeling is the prejudice existing in many communities against engaging in a business that is seemingly contrary to temperance sentiments. The fact that the product is distinctly not for drinking will not immediately remove that prejudice. Initiative in production has also been lacking, because of general ignorance of the business, but when the ice is once broken there will be numerous small plants started, no doubt.

While it is possible to make alcohol from almost all vegetable refuse, it appears that it is not profitable under present conditions to make it from corn or other grains. Potatoes offer the cheapest source of alcohol at the present time, but even they are somewhat too costly. It is safe, however, to predict that the ingenuity of our inventors and the enterprise of our manufacturers will develop processes which will utilize the vast quantities of vegetable refuse now rejected and wasted.

We therefore believe that although the farmers have not yet gone into the making of denatured alcohol in large numbers, the prospects for its general industrial use are bright. Prejudice, the opposition of the vested interests, uncertainty as to the meaning of government regulations, and ignorance of the business in general have been quite sufficient to hold back its development. With time will come more knowledge and experience, and a greatly reduced cost of the product, with the correlative of enormous use.

PIRATING SPECIAL MACHINE TOOLS.

Some months ago an incident was brought to our notice which illustrates the peculiar folly into which machine tool builders sometimes fall; that is, pirating special machinery. It is a practice of which we have recently heard little, for almost all manufacturers have had about all they could do to attend to their own work, but as business slackens such incidents may increase. The moral aspect of such competition is elusive, and we will merely point out its unprofitableness in general.

There are those who build special machines intelligently, with the wisdom of long experience in similar lines of work and a comprehensive idea of the needs of the work. Their would-be competitors build with a hazy knowledge of the special requirements, and only a general idea of the essential features of design. The last are copyists; or, more plainly speaking, pirates, who do not hesitate to steal the ideas of men who have spent years to perfect features of machine design.

The incident referred to centers around a Western manufacturing concern which bought a heavy special machine tool from an Eastern builder. It was for a purpose and of a design which precludes a general sale; perhaps not more than five or six could be sold in the whole United States. The concern in question having purchased one machine found that they needed another, but, although the price was satisfactory, could not get delivery from the builders as soon as desired. Thereupon, another machine tool company, young at the business, and of the "unafraid" type, tackled the job and produced a copy of the first machine which was delivered two months earlier than the time stipulated by the Eastern builder. But the pirating concern, building the second machine, lost money, or at least made no profit—and the purchaser got a poor machine. It appears from this incident that three concerns were losers; whereas if strictly legitimate business methods had been followed, there would have been a satisfied customer, a machine sold at a profit, and profitable employment for the "butting in" concern at its own particular business, in which it excels.

To be a successful builder of special machinery, a concern must not only be a specialist in design, but in production as well when it enters into competition; and if this incident teaches any particular lesson it is simply that builders of special machinery make a mistake when they initiate cutthroat competition, because this branch of the machine tool trade generally yields only moderate profits at the best.

* * *

A committee appointed by the Association of Railway Superintendents of Bridges and Buildings to report on the action of sea water on concrete, has collected the opinions of a number of men engaged in work of this kind. The following statements embody the substance of the expressed opinions. Where there is no ice formation, concrete, if made in air with fresh water and then sunk into sea water, works well, but shows a tendency to disintegrate slightly on the faces between low and high water levels. Concrete should not be deposited direct into sea water. Where the salt water permeates the whole mass of the concrete, the faces disintegrate faster than where the concrete is mixed with fresh water and made in air and then sunk into position in the sea water. Between low and high water the faces of the concrete show a tendency to disintegrate. All opinions agree that concrete should be faced with granite above low water, on account of this tendency of the rise and fall of the tide to disintegrate the concrete. It is also agreed that frost and ice formation, where the tide rises and falls, has a greater tendency to disintegrate the concrete. It will be recollected that, in a note in the engineering review of MACHINERY, October, 1907, we mentioned an article on this subject contributed by Mr. M. H. Le Chatelier to the *Annales des Ponts et Chaussées*, in which he claims that all hydraulic binding agents used for cement and concrete may be decomposed by sea water.

ENGINEERING REVIEW.

CURRENT MECHANICAL EVENTS—LEADING ARTICLES OF THE TECHNICAL PRESS.

One of the most complete railroad testing laboratories in this country has been completed by the Union Pacific Railroad, at its new Omaha shops. This laboratory includes complete equipment for physical and chemical tests of all kinds, as well as bacteriological investigations, electrical experiments, metallurgy, etc.

The *Moniteur Industriel* mentions the fact that the "Compagnie des Omnibus" in Paris has found it to be greatly advantageous to use alcohol instead of petrol as fuel for their motor cars. In Paris the price of petrol, at the present time, is about 48 cents a gallon, while alcohol is sold at the price of 34 cents a gallon; but to obtain equal results 5 per cent more alcohol is required.

A new example of the industrial development of Japan has been given by the announcement of the fact that the new armored cruiser *Ibuki* was successfully launched only six months after the keel was laid. All the materials used were of Japanese make, and the building and launching of this vessel is considered in ship building circles as marking an epoch in the history of naval construction in Japan.

It is stated that a new British torpedo boat destroyer, the *Mohawk*, is the fastest vessel in the world. She maintained for six hours at her official trial an average speed of 34¼ knots, and for six runs over a measured mile the speed was 34½ knots, which is equal to about 40 statute miles per hour. The vessel is fitted with steam turbines and uses oil fuel. The oil consumption is so low, comparatively, that the vessel will have a much wider radius of action than have much slower vessels.

The *Journal of the Franklin Institute* contains some interesting figures regarding the magnitude of the Baldwin Locomotive works. According to the figures given, the men employed are about 19,000. The horse-power employed in steam and oil engines amounts to nearly 17,000, and the consumption of coal per week is 3,000 tons, and of iron, 5,000 tons. The machinery is largely driven by motors, there being 1,115 motors in the works, representing 14,200 horse-power. The area of the buildings comprises 6 1-3 acres.

It is stated by the *Zeitschrift des Vercines Deutscher Ingenieure*, which journal had this information from an English source, that the cost of repairs on the English cruiser *Amethyst*, which is driven by steam turbines, has been decidedly lower than the repair costs on vessels of the same type driven by reciprocating engines. If the cost of maintenance of turbines, as compared with that for reciprocating engines, should, in general, prove to be lower, this will be one very important point in favor of the turbine.

An assistant professor at the Paris University, Mr. George Urbain, claims to have discovered a new metal, by separating the element ytterbium into two component parts. The new element he gave the name of *lotherium*, and he is preparing to present a complete report upon the subject before the Academy of Science. According to the *Scientific American*, Mr. Urbain states that he has already made a number of researches regarding the new element, and observed its different characteristics by chemical tests, and that he has come to the conclusion that it possesses some new properties, which will make it of great interest, from a scientific point of view.

In an article on pressure gages in the August 30, 1907, issue of *Engineering*, a few interesting facts about high pressure gages are stated. It is there mentioned that the highest mercury column is that placed in a well at Butte-aux-Cailles, France, which is about 1,650 feet high, and records up to 660 atmospheres. The next highest is that in a mine near St. Etienne, France, which is about 1,330 feet high, recording 530 atmospheres, and the one on the Eiffel tower 1,000 feet high, recording 440 atmospheres. The highest mercury column in England is at the Municipal Technical College at Manchester, which is only 175 feet high. In these very high mercury columns, it is of course impossible to use glass tubes from top to bottom. Steel or iron tubes are, therefore, used with glass tubes fixed either at regular intervals up the entire height, or at those points only where readings of pressures are likely to be taken.

The opening of the famous Simplon Tunnel, under the Alps, between Switzerland and Italy, referred to several times in our columns, has placed the people of the village of Simplon, located by the old Simplon Road, which runs over the Alps at this place, in a rather curious position, and instead of facilitating their communication with their fellow-countrymen, it has made communication somewhat difficult. Since the opening of the tunnel, the highway is not kept open in the winter, but it can be traveled down on the Italian slope, and, thence, it is possible to return to Switzerland by the tunnel, but if any goods are taken along, they have to pass through the custom-houses of Italy, and then, returning to Switzerland, the custom-houses of that country, and cattle are subject to inspection as exports from Switzerland to Italy, and then, within a couple of hours, as exports from Italy to Switzerland. The highway is closed from October to May.

It is stated in *Mercator* that a railway ferry connection between Sweden and Germany has now practically been setttled upon. This railway ferry will make it possible to run direct passenger trains from Berlin to the principal Scandinavian cities. As terminals for the ferry, Trelleborg in Sweden and Sassnitz in Germany have been selected. These two points are about 65 miles distant from each other, and the crossing of the Baltic is intended to be made in three hours and a half. The ferry is expected to be the largest railway ferry in Europe, having a length of about 365 feet. There already are railway ferry train connections between the cities on the Continent and the Danish Islands, and thence from Copenhagen by two routes to Sweden, but the present railway ferry will make it possible to shorten the time considerably, and to run trains from the Continent through to Sweden and Norway, without touching Denmark.

A recent report of the ship-building industry in the United States, issued by the Census Bureau, indicates a constant, though not as heavy an increase as has taken place in other industries. The years compared are 1880 and 1904. In the former year the capital invested was approximately $21,000,000, but in 1904 the investment had increased to $121,600,000, the number of employes increasing from about 21,000 to nearly 51,000 in the same period. The value of the work done was about $37,000,000 in 1880, and about $83,000,000 in 1904. Since 1900 there has been an increase of over 50 per cent in the production of boats under five-ton rating, due to the development of gasoline engines for such craft. Although the number of vessels of five tons and over, launched during 1904, was 167 less than the number launched in 1880, the tonnage had increased 40½ per cent during this period. The average value of the vessels launched in 1880 was not quite $8,000, whereas in 1905 the average value was $32,700.

The secretary of the Civil and Mechanical Engineers' Society of Great Britain called a meeting January 2 at Caxton Hall, Westminster, to discuss the subject of standard notation for engineering formulas. The society asks the coöperation of other engineering societies and associations in this much-needed reform. Our American engineering societies and associations should give their attention to the matter, and, if possible, agree on a standard notation. Scarcely any books agree on the meaning of symbols save a few, and, con-

sequently much space is taken up by the ever-recurring explanations of the notations. Obviously, a symbol used in engineering formulas pertaining to any subject should invariably have a definite significance. The mixed notations now used cause much confusion, and are about on a par with the confused mess of screw thread systems which we had prior to the adoption of the Sellers standard. Engineers should recognize that standards in engineering literature are just as needful as in engineering construction. The Civil and Mechanical Engineers' Society ask that schedules of suggested symbols for use be submitted. These should be sent to the secretary, Mr. A. S. E. Ackermann, 25 Victoria St., Westminster, S. W., England.

According to a recent news item, a Chicago architect by the name of Yorke has devised an arrangement of elevators for tall buildings, which seems, on the surface, at least, to be reasonable as well as ingenious. The inventor proposes to have two elevators in each shaft in a twenty-story building. For instance, the first elevator would be loaded at the bottom floor for passengers for stories from the tenth to twentieth. The second elevator, meanwhile, will be in the basement, awaiting the filling of the first. After being filled, the first elevator will run express to the tenth floor, and thence distribute its load between there and the twentieth. The lower car has, meanwhile, been filling at the first story, and it starts on an upward distributing trip from the first to the tenth stories, reaching the tenth story at about the same time that the upper car does the twentieth. The operation is reversed when coming down, the first car collecting from the twentieth to the tenth and running express to the bottom, which the lower car, running local from the tenth has already reached, discharged its passengers, and descended out of the way to the basement.

The idea is, of course, to reduce the space required for elevators in very tall buildings. This is a serious matter when there are twenty stories or more, as a glance at the floor plan of any such building will show. It ought to be possible to provide the necessary safety devices for preventing the cars from colliding, and, if this is the case, the idea ought to be a feasible one. It is said that the plan is to be tried in the immediate future in buildings in both New York and Chicago.

An interesting note in the *Zeitschrift des Vereines Deutscher Ingenieure*, for December 7, 1907, makes mention of a new means of transmission of power, introduced by the Eloesser-Kraftband-Gesellschaft, Charlottenburg, Germany. The power transmitter employed is made of thin steel bands, used instead of leather belting or rope drive. These steel belts, as they may be called, run either on ordinary pulleys, the same as leather belts, or, better, over pulleys provided with a special covering for giving greater friction. The dimensions necessary for these steel belts may be most easily comprehended by referring to the dimensions of belts used in actual installations, which the company referred to has carried out. Powers from 200 to 250 H.P. with a belt speed of about 5,400 feet per minute, are transmitted with a steel belt 4 inches wide and 0.02 inch thick. It is stated that these steel belts need be made only about one-sixth the width required for leather belts, for transmitting the same power. This, of course, is a great advantage, as it permits pulleys to be much narrower, and, at the same time, permits the bearings for the shaft on which the pulley is mounted, to come much closer together, consequently permitting, in many cases, smaller diameter of shaft, as it often is the case that the diameter of a shaft has to be provided not so much for taking care of the turning moment produced by the transmission of the actual power, but for giving sufficient stiffness to resist the bending moment between the bearings. Another advantage, with this kind of belting, is that the steel belt does not lengthen when in use, at least, not to any appreciable extent, like the leather belt, and that a correct tension in the belt is far easier to obtain. Experiments with these steel belts, carried out by Prof. Kammerer, have shown that it is possible to run them at a peripheral speed of the pulleys of 12,000 feet per minute.

NOVEL USE OF THERMIT.

Industritidningen Norden, December 6, 1907.

Thermit, as our readers may recollect from former references made to this subject, is a welding process, invented in Germany, in which a mixture of aluminum and iron oxide is employed for welding. When the aluminum, which is introduced in a pulverized form, is ignited, it takes oxygen from the iron oxide, thereby producing aluminum oxide, and free iron. By this an enormously high heat is developed, estimated to be over 5,000 degrees F., so that the iron is easily melted, and this makes it possible to employ this means for welding. A new and peculiarly interesting example of the use of thermit has been proposed by the German inventor, Mr. Hasenkamp. In iron structures, particularly in the case of bridges where several members are in tension, it often happens that some of the members do not take their full share of the stress, or, in other words, that they would need to be shortened so as to take their share of the load. For correcting this, in many cases, the members have been taken down, and adjusted as to length through forging in an ordinary blacksmith shop. This way of doing the work takes a long time, is expensive, and, at the same time, it makes it necessary to stop the traffic on the bridge while this work takes place, to prevent any accident from failure of the remaining members. These difficulties are avoided by bringing the members to a red heat while in place, by means of thermit, at several points between their ends. In order to prevent the member from lengthening while it is hot, clamps are provided which are fastened at both sides of the place which is heated. These clamps are connected with one another by means of bolts, and these bolts take the stress while the member itself is brought to a high heat, at which time, of course, the member would be unable to take any stress, without increase in length. Adjusting the bolts connecting the clamps shortens the member to the desired degree and when the member cools off, it will remain short, the adjustment required having been effected. The process can be carried out in a few minutes, and stoppage of the traffic is unnecessary.

TRAINING OF APPRENTICES IN FOUNDRY WORK.

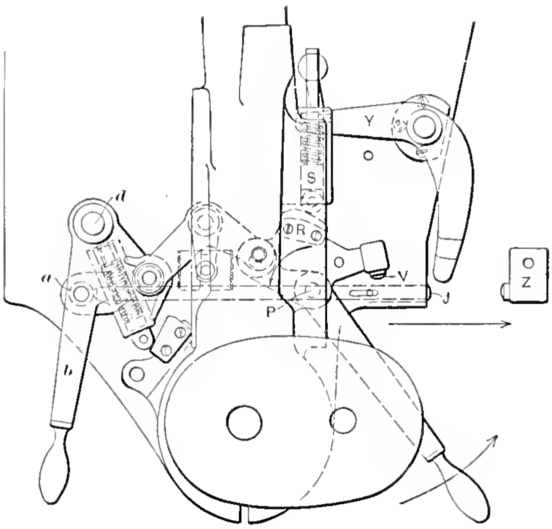
The Iron Trade Review, August 15, 1907

The foundries of the Ingersoll-Rand Co., located at Phillipsburg, N. J., employ some 900 men, and of these fully 98 per cent have been trained in the employ of the company. At a time when particular interest is taken in apprentice systems and industrial training, the plan carried out by this company merits attention. This plan was originally outlined eleven years ago, and, with some modifications, is still pursued.

The minimum age for enrollment of apprentices is fourteen years, and the course covers four years. The core department has been christened "The Kindergarten," as it is here that the embryo molder is first introduced to the mysteries of foundry practice. To acquaint himself with his surroundings, the boy is given only light duties to perform during the first few weeks of his employment, and his tutor, aside from the chief of the department, is a youth who has had not less than three months training. The pair work together during a similar period, when the one most advanced progresses to the side of another who has probably worked for nine months, and the three months' apprentice is charged with the duty of leading another through his first steps. This mode of procedure is carefully followed until the end of the first year, when the boy is graduated from the core department and his compensation increased from $1 to $1.25 per day. Instead of placing him immediately on the floor to acquire the rudiments of molding, he is intrusted to the tender mercies of the melter for three or four weeks, to obtain a knowledge of charging, melting, tapping, and cupola repairs. As a result of this practice every molder in the plant can melt successfully. Objections might be raised to the employment of the apprentices in such large numbers in the core department, but the success of the venture is indicative of the wisdom of this practice. The core boxes, largely metal, have been made practically "fool proof," and after a brief experience the most intricate shapes are produced in large

numbers daily. The boys are taught the various mixtures and the methods of baking, thus giving them the equipment of those making a specialty of core work. Nor is this apprenticeship system limited to boys alone, as laborers in the plant inclined to take up this trade are permitted to take up the course.

With the advent of the apprentice on the molding floor, he is made an assistant to another slightly more advanced, and in some cases works with an experienced molder. His lot is not that of an ordinary helper, as he is given every opportunity to advance, and as he masters the simpler sections, he is given more complicated work. The supply of common labor is liberal, and such duties as are only too often associated with the learning of this trade and are styled as "breaking in chores," are left to the laborers to perform. The undivided attention and effort of the apprentice can thus be applied to obtaining a knowledge of his chosen calling, and his forward strides are consequently rapid. The mode of advancement in the core room applies in the molding department, and with the third year the daily wages are increased to $1.75. At this period many of the boys have the equipment of the average molder and are permitted to make those sections for which they are best fitted. During the fourth year many of the apprentices are paid the same wages as the skilled mechanics, as the question of pay then is governed alone by their ability. No agreements are signed by the company, nor is one required of the parents of the boys. If, after a reasonable period the apprentice shows no talent for the work, he is dropped, and the cause for this action is carefully explained. Notwithstanding the average ages of the employes, the discipline is remarkable. The only penalty is suspension for a week, and it is seldom that this must be enforced. Shop rules have never been posted and those that govern are such as are generally understood and are passed from one employe to another.



COMBINED AUTOMATIC VERTICAL AND HORIZONTAL FEED ON A VERTICAL MILLING MACHINE.

Zeitschrift für Werkzeugmaschinen und Werkzeuge, October 15, 1907.

A German machine tool builder, the firm of de Fries & Co., Düsseldorf-Heerdt, has brought out a vertical milling machine, having a rather peculiar feed mechanism. With this, the tool may first be fed a certain distance vertically into the work, and then a certain distance horizontally, the feed mechanism acting automatically, and being before hand adjusted to the required distance of feed motion. Feeds of this character are commonly required when milling keyways and slots with end mills. In Fig. 1 is shown a plan, front and side view of the most important parts of the machine, and in Figs. 2, 3, and 4, are shown the parts of the operating mechanism at different stages of the cut. Fig. 2 shows the mechanism while the end mill is being fed vertically into the work; Fig. 3 when fed horizontally, and Fig. 4 when the feed motion has been automatically thrown out of engagement at the end of the cut.

The feed mechanism is operated through a clutch *A*, Fig. 1, having teeth on both sides. This clutch is keyed to a shaft, which in turn is driven from the main spindle by a shaft *B* through a combination of spiral gears and worm-gearing. The clutch, while it cannot turn on its shaft, is, of course, free to move sideways into engagement with either of clutches *C* or *D*. When clutch *A* engages with clutch *C* on the hub of gear *E*, a screw *F* is turned through the medium of bevel gears *G*. A nut *H* is mounted on screw *F*, and the rotation of *F* feeds this nut downward, the nut on its downward motion bringing with it the sleeve *K* to which it is connected. The sleeve *K*, in turn, is fastened to the spindle bearings of the machine, and the spindle with its tool is thus fed downward by the downward motion of nut *H*. At the predetermined end of the downward feed, however, clutch *A*, though a mechanism which will be described later, is thrown out of engagement with clutch *C*, and engages clutch *D*, located on the hub of gear *L*. Through this gear the table of the machine is now

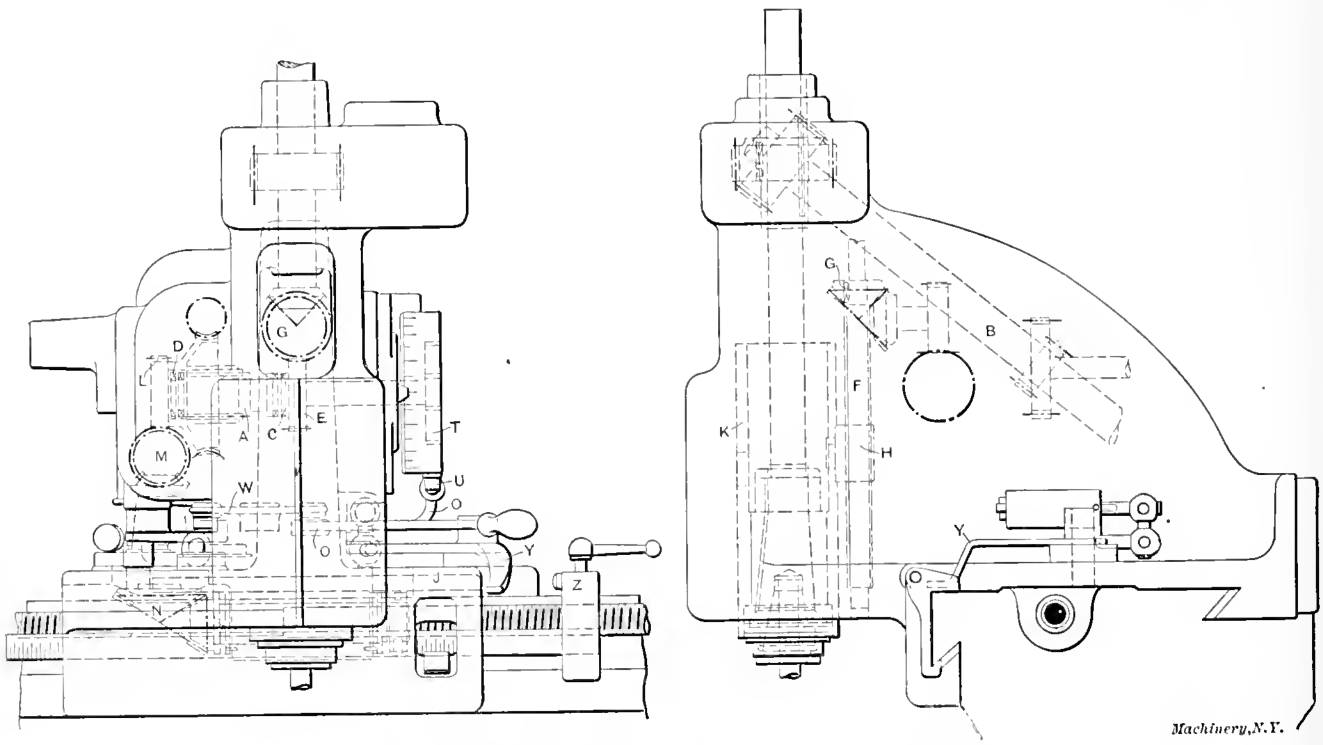


Fig. 1. General Arrangement of Vertical Milling Machine with Combined Automatic Vertical and Horizontal Feed.

fed forward, horizontally, by means of the intermediate gear drives M and N. At the end of the horizontal movement, the mechanism returns the clutch A to a middle position, so that all feed motion ceases.

If we now examine the mechanism operating the automatic feeds mentioned above, we will find it to consist of an ingenious combination of levers. The reference letters in the

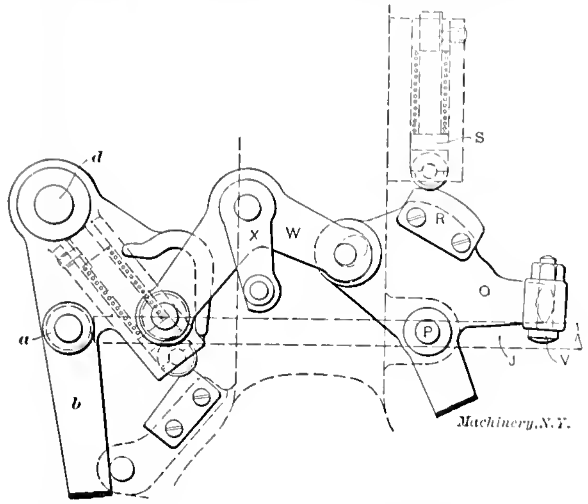

Fig. 2. Position of Levers during Vertical Feed Movement.

following refer to all the cuts with this article, it being necessary during the description, to refer from one illustration to the other, in order to adequately explain the construction. A lever O, turning around a stud P, is provided with a cam surface R, against which a plunger S, at its end provided with a roller, presses under the action of a spring. When the lever O is in the position shown in Fig. 2, the roller of plunger S rests on a surface of cam R which is at right angles to a line through the center of the plunger and the center of pivot P. Consequently, there is no tendency for the lever O to turn around its pivot under the action of the plunger and its spring. In order to make it possible to predetermine the amount of vertical feed, a graduated disk T is provided, on which an adjustable dog U is fastened. This dog is set by means of the graduations to any length of downward travel desired. When the tool has reached the end of its vertical travel, the dog U strikes a pin V in lever O, and turns this lever so that the plunger S with its roller descends on the inclined surface of R, thereby producing a quick turn-

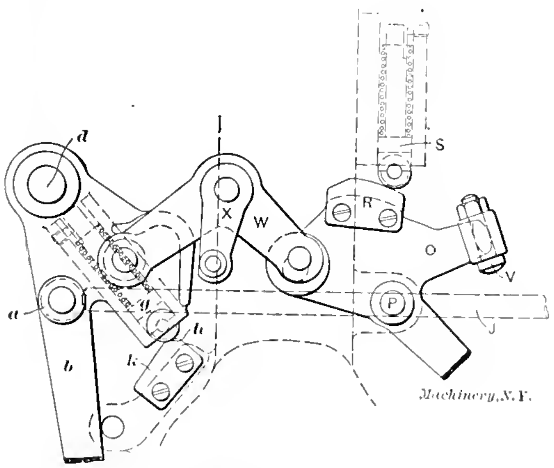

Fig. 3. Position of Levers during Horizontal Feed Movement.

ing motion around pin P. In turning, lever O also turns lever W around its pivot, and as lever X is fastened to lever W, the lever X is moved from its position in Fig. 2 to that in Fig. 3. The lower end of lever X, however, is connected to clutch A, and the motion imparted to this lever throws it out of engagement with clutch C and in engagement with clutch D, thereby throwing out the vertical, and throwing in the horizontal, feed.

This horizontal table feed is automatically stopped at the end of the cut by the following action of the mechanism. The plunger S is first withdrawn from its seat on cam surface R on lever O by means of lever Y, which, in turn, receives its motion from striking the dog Z, as the table advances. The lever O is then free to move, and if a force is exerted to return it to its position in Fig. 2, or to the position shown in Fig. 4, there is no resistance to be overcome. In the next place, a rod J is forced against dog Z, but as this rod is free to move in the table of the machine, it slides back in a direction opposite the direction of motion of the table, and finally, pushes against projection a of the lever b. It thereby turns lever b around its pivot d and, in doing so, permits a plunger g, operated in the same way as plunger S, previously referred to, to descend from a surface h, where it is in equilibrium, to an inclined surface k. The action of the spring back of plunger g then accelerates the motion of lever b until the roller at the end of the plunger rests at the lower corner of the inclined surface k, as shown in Fig. 4. The motion of lever b, however, causes a turning motion of lever W, as can be plainly seen from Figs. 3 and 4, and lever X, connected with

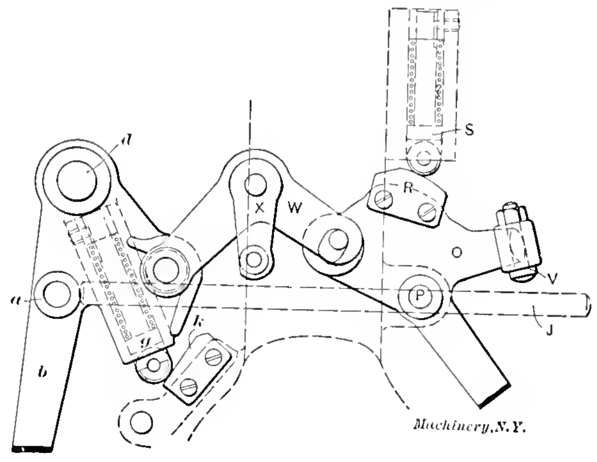

Fig. 4. Position of Levers when Both Feeds are thrown out.

clutch A, is turned back so that the clutch occupies a central position, not engaging with either feed motion. On account of the previous release of lever O from the pressure of plunger S, the return of lever X to its middle position is easily accomplished without the exertion of any great force back of plunger g. When a new piece of work is put into the machine the feed levers are returned to their original position by hand.

THE ART OF GALVANIZING.

Alfred Sang, in *Transactions American Foundrymen's Association.*

One of the most persistent problems which confront the worker in iron and steel is the prevention of corrosion. There are two general ways of preventing this corrosion, which might be called respectively the non-metallic and metallic methods. In the non-metallic method, the articles are coated with an organic substance, usually oil or varnish, the efficiency of which depends on its being more or less air tight. The metallic method consists in coating the iron with some other metal, and it is this method which will be discussed here.

Considered merely as a mechanical protection, the coating should be able to resist impact and abrasion, the latter being the most important. The soft metals, such as tin and zinc, do not stand up well against abrasion, but unless their adherence be very defective, they will stand impact well, on account of their malleability at ordinary temperatures. It would be desirable to obtain a coating which would be as good a protection as zinc but tougher and harder. Aluminum is being used with some success and if the metal were cheaper it would become an interesting competitor of zinc. This latter metal is, of all the commercial metals, the one which most closely fulfills all the requirements placed on a good coating. I shall, therefore, now proceed to describe the various processes which have been used to apply zinc to metal surfaces.

Cold Galvanizing.

In the early years of the last century the process of electrolytic zincing, which is nowadays known as cold or electro-galvanizing, was first discovered, but until about ten years

ago the lack of suitable equipment prevented its commercial application. The articles to be treated by this process are first thoroughly cleaned of scale, rust, and grease, by an acid pickle, sand-blasting, hot lye or by other means, singly or in combination, and are then placed as cathodes in a solution of some salt of zinc—usually the sulphate—in presence of zinc and which regenerate the solution, while a current of low voltage is passed through the arrangement and deposits zinc from the solution upon the articles.

The surface of an electrically galvanized article is matt or frosted, provided the work has been properly done. It always shows a few pores. If improperly done, or if the work was not perfectly clean before treatment, it is either honeycombed with pin holes or spongy. Above a certain limit of thickness, below which the coating is worthless, first class electro-galvanizing is superior to hot-galvanizing, and it is cheaper to produce where automatic machinery can be employed, although less zinc is deposited than by a hot dip. This is no doubt due to the better contact between the zinc and iron.

Hot Galvanizing.

Sixty years ago the process of hot galvanizing was introduced on a commercial scale. It consists in dipping the articles into a bath of molten spelter, with or without other metallic additions, at temperatures ranging from 750 to 900 degrees F. The articles must be first cleaned, as for electrolytic work, but a slight falling short of perfection does not have such disastrous effects on the quality of the work. Very heavy pieces may be heated before dipping, so as not to chill the bath. The coating is crystalline or amorphous, and does not adhere as perfectly as does the electrolytic one. Properly treated sheet metal goods have an attractive spangled appearance, but most articles look like castings, and sharp edges are lost. Metallic chlorides are used as fluxes. They are expected to remove the injurious salts of iron left by the pickling, but it is a question if they themselves are not the main cause of the decay which starts underneath the coating in hot galvanized work. The fumes given off in hot galvanizing are injurious to machinery, and in a manufacturing concern it is necessary to erect a separate building for this work.

Dry Galvanizing.

The latest process for applying a zinc coating is the dry process. This process of galvanizing or Sherardizing metals was awarded a gold medal at the St. Louis Exposition of 1904, and the President's gold medal for 1905 was presented to its discoverer by the British Society of Engineers. The inventor, Sherard Cowper-Coles, is one of the most eminent metallurgical engineers in Europe, and is well known for his reintroduction on a commercial scale of the process of electric galvanizing.

For the purpose of Sherardizing, the articles are placed, after cleaning, in a retort, usually a drum, and are covered with zinc-dust, which is commonly called blue-powder, and is the flue-dust, and, therefore, a by-product of the zinc smelting furnace known as the Belgian furnace. It contains as a rule from 75 to 90 per cent of pure zinc; the supply of zinc-dust is ample at a price below that of spelter, and if the demand increases it can be produced in any quantity that may be required. A small amount of powdered charcoal is added to prevent oxidation of the zinc by the air inside the retort at the beginning of the operation, and the receptacle is closed and heated to a temperature about two hundred degrees below the melting point of zinc. By Sherardizing, a homogeneous deposit of zinc is obtained, varying in thickness according to the length of time the article is allowed to remain in the retort, its lower portion being an alloy of zinc and iron or of zinc and copper, as the case may be. In the case of copper the alloy is a hard brass. The drum is occasionally turned a fraction of a revolution to insure an even coating where the articles are crowded together, and the heating may last from a few minutes to several hours, and two or three drums can be used in connection with one furnace.

A Sherardized surface resembles, in general appearance, an electrically coated surface. It is, however, of a soft silver-gray, more lustrous and metallic, and, on that account, it is to most people, more pleasing to the eye, and it is distributed with great uniformity, which is not the case in hot galvanizing. Whereas in hot galvanizing the amount of zinc which is alloyed to the metal of the article is very small and most of the coating forms an exterior perishable skin, in Sherardizing, the coating is thoroughly incorporated with the metal which it protects, forming an alloy having the appearance of pure zinc, but much harder and more durable. It is on account of this thorough alloying that the protection afforded by Sherardizing is superior to that afforded by either hot or electric galvanizing. The zinc having penetrated the iron, the old surface cannot be recovered by either chemical or mehcanical means.

If an excessive amount of zinc is deposited by Sherardizing, the outside surface is composed of zinc somewhat hardened by the presence of a small percentage of iron, and zinc-dust accumulates and clusters in a way which renders the surface rougher and less attractive. No special advantage is derived from the additional expense unless the conditions under which the articles are to be used are exceptionally severe.

The process of Sherardizing is not confined to zincing; the dusts of antimony and of other metals can be used in a similar manner. The fact that zinc-dust, even at temperatures higher than its melting point, does not melt or cake, is of great value in Sherardizing, as it eliminates the danger of spoiled work from carelessness in handling the temperature. Furthermore, zinc-dust containing as little as 35 per cent of pure metal can be used.

The Efficiency of Dry Galvanizing.

The efficiency of dry galvanizing has been proved by thorough testing both in England and Germany. Considered merely as a covering, it fits as closely as does an electrically-deposited coating, and it is impenetrable because of being free from pores or cracks. As a mechanical protection it resists both abrasion and impact better than work done either by the hot or cold galvanizing process, because of the qualities of the ferro-zinc alloy.

Commercial Scope of Dry Galvanizing.

It is a noteworthy fact that while many articles have appeared in technical and scientific journals about Sherardizing, not one word of criticism or denial of its claims has as yet been offered. The process has always appealed to scientific men because they are in position to appreciate the solid scientific foundations of its claims.

The new process has not entered the field as a competitor to galvanizing alone; in a great many instances it can take the place of coppering, of nickel-plating and of tinning, where the articles are not to be used for the preparation or handling of foodstuffs. To these I should add the large amount of copper and brass articles, from tubing to typewriter and sewing machine parts which are now nickel-plated. An interesting point in relation to the various methods of protecting metals is the price of the metals themselves. Nickel is 7¾ times, tin and aluminum 7 times, copper 4⅛ times, and antimony 3¼ times as high in price as spelter, and at equal efficiency against corrosion, the lightest coating is one of zinc as applied by dry-galvanizing. Analyzing the various items which go to make up the cost of Sherardizing, we find that in every instance there is a saving either over the hot process or over the electric process. A plant for Sherardizing is less expensive than a hot plant and very much less so than an electric plant.

Various Applications of Dry Galvanizing.

Sherardizing will not fill an uncalked seam and act as a solder; this is its one limitation but it has a great variety of new applications to make up for it. A brilliant and permanent polish which can hardly be distinguished from nickel-plating, but bluer and more like silver, and a better reflector of light, can be given to Sherardized articles by means of the usual burnishing tools and machines, but unlike nickel-plating it is absolutely rust-proof. This polish is not temporary like that of electro-galvanizing, and it is hard and durable if worked down, as it should be, to the ferro-zinc.

Sherardized aluminum can be electro-plated, and the objectionable soft surface be overcome, not to mention the finish and appearance. Sherardizing has been found to protect silver

from sulphated hydrogen, which blackens it, and it can be applied very lightly before polishing without altering the color. When aluminum has been Sherardized it can be readily soldered; this is expected to do away with the very unsatisfactory riveting of articles made from aluminum sheets.

SHAFT-TURNING MACHINE.

Bernh. Dreyer in *Werkstatts-Technik*, December, 1907.

The machine here described and illustrated has been designed for the purpose of overcoming some of the difficulties experienced when using cold rolled shafting, and the time wasted when straightening and turning shafting in an ordinary lathe. Machines, turning shafting according to the new method referred to, have been in use in Germany since 1901, and are installed in many of the leading machine shops.

The objections to straightening shafting in the ordinary way, with hammer blows, or, at best, with a shaft straightening device, is that this work is difficult to do, and consumes a great deal of time. Besides, internal stresses are often produced through the hammering and bending, which have an unfavorable influence on the strength of the shafting. The turning of long shafting in ordinary lathes is also difficult, takes a great deal of care and time, and requires a skilled operator, if straight work of uniform diameter is demanded. Cold rolled shafting does not answer the requirements for a high-grade shaft, as it is not perfectly straight, not fully round, and not always of the exact size required. The rolling process also produces internal stresses, which are likely to spring the shaft out of shape. That this is so is proved by cases where a shaft, apparently straight and of the correct diameter, afterward is found to produce considerable friction in the bearings, due to the distortion of the shaft. This often results in serious losses of power, or, at times, in complete derangement of the power transmission system.

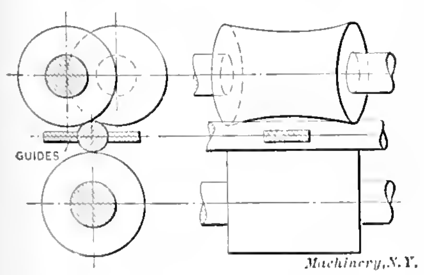

Fig. 2. Straightening Rollers for Shafting.

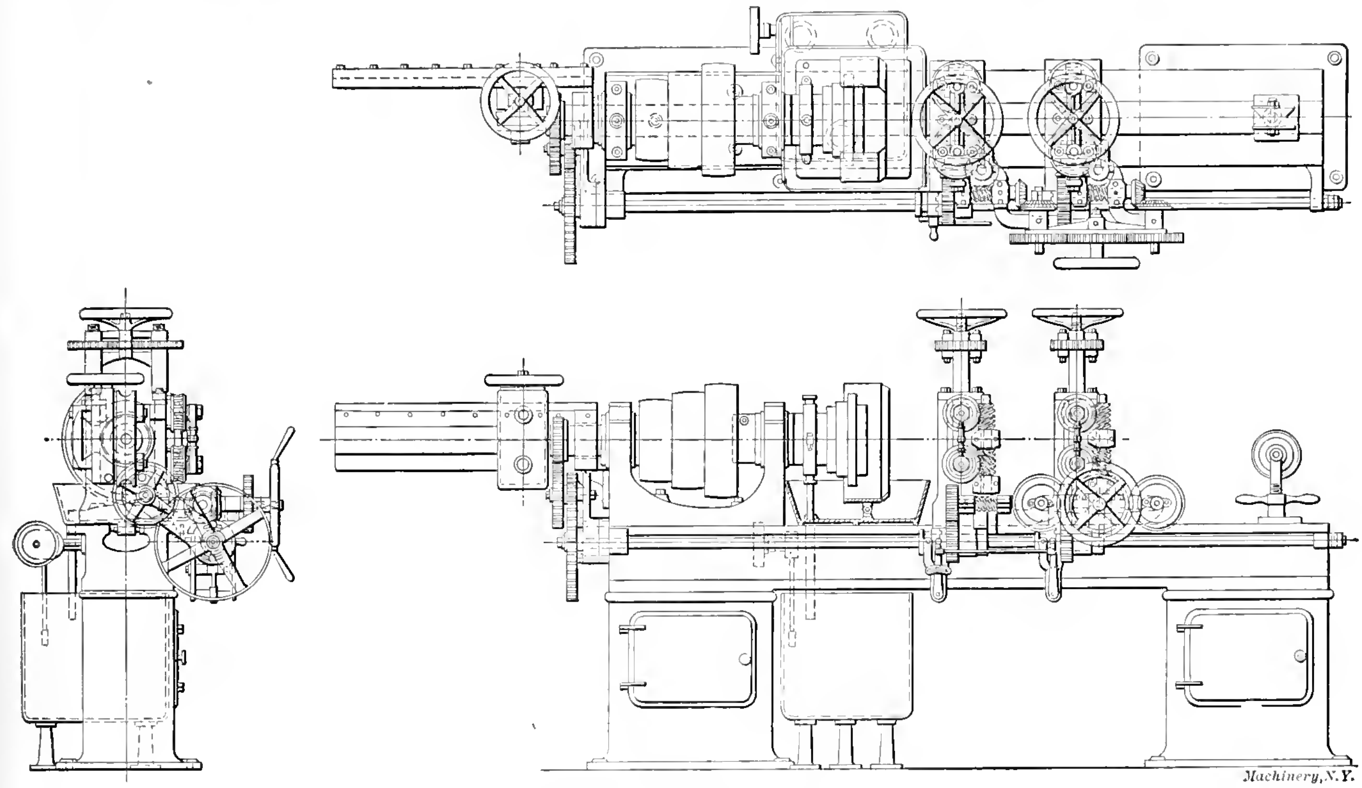

Fig. 1 Machine for Hollow Milling Shafting to Size.

The objections stated to shafting as ordinarily produced seem to call for a better method of straightening and turning. This is supplied by the straightening process, described below, and by the machine shown in Fig. 1. The shaft is first mechanically straightened, and then turned, or rather hollow milled, and finally tested and polished. The straightening is accomplished by straightening rollers, as shown in Fig. 2. These rollers are mounted with their axes at a slight angle with each other. One of the rollers is concave on its face, while the other has a straight, cylindrical surface, the latter roller being placed in line with the shaft to be straightened, while the concave roller is placed at an angle with the axis of the shaft.

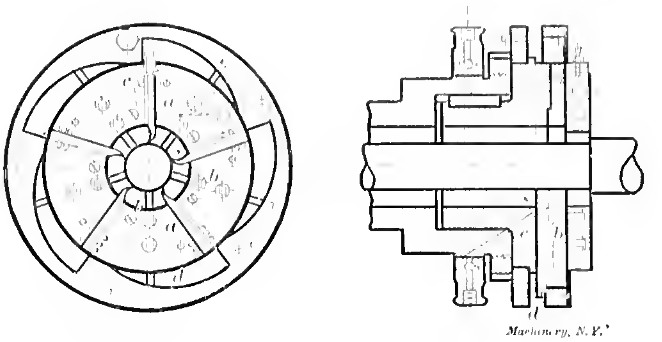

Fig. 3. Hollow Mill used in Machine shown in Fig. 1.

When the shaft passes between the rollers, it is guided on the sides by the guides, as shown in Fig. 2. The rollers are provided with adjustment, so that different sizes of shafts may be straightened between the same pairs of rollers. The angle to which the upper roller is turned is also adjusted according to the size of the shaft. This process permits a more perfect straightening of the shaft than do other commonly used shaft-straightening devices.

When straightened, the shaft is placed in the machine, Fig. 1, already referred to, and is guided and held centrally with the spindle of the machine by guiding rollers placed in the uprights shown where the carriage usually is placed on the lathe. A hollow mill of special construction, as shown in Fig. 3, is mounted on the end of the hollow spindle. This hollow mill is provided with five adjustable cutters, *a*, and five guides or supports, *b*. These latter are so arranged that they are adjustable to any size of work, within a range of the hollow mill, by means of eccentric cam grooves, *d*, cut in a ring bolted to the body of the mill. The hollow mill is cooled off by water entering into channels in its body. When the shaft has passed through the spindle, it again enters between two guiding rollers, at the left-hand end of the

head-stock of the machine. Guiding the shaft in this manner, by two sets of guide rollers before it enters into the hollow mill, and one set to receive it when having passed through the spindle, keeps the shaft in absolute alignment while the process of hollow milling to size is being performed, and obviates all chance of errors from lack of alignment, or from the springing or bending of the work under its own weight.

The cutting speed of the hollow mill is usually from 70 to 100 feet per minute, and the feed from 5 to 8 inches per minute. This cutting speed and feed make it possible to finish about 30 feet of shafting, 2 inches in diameter, per hour.

SECRECY IN THE ARTS.

Extract from paper by Dr. James Douglas, presented before the American Institute of Mining Engineers, November, 1907.

If it is the fact that technical science has progressed of late with such unwonted speed through the coöperation of many workers, and that this coöperation has been made possible by the publication and exchange of ideas and experiences in the technical and scientific journals, would not our progress be even more rapid and thorough if all barriers of secrecy were broken down, and every encouragement were given to our technical workers to describe, in print and by conference, their notions and their actual experiments? This is the attitude of some, I may almost say of most, of our large concerns, but unfortunately it is not that of all. It is impossible to compare, as to efficiency and profit, works, the gates of which are fast shut, and in which obscurity and secrecy are imposed and practiced, with those to which free admission is granted and in which freedom of information is encouraged. But the following reflections force themselves upon us in this connection. We know that very few technical papers issue from certain establishments; that on their officials silence is imposed; and that to these works inquisitive visitors are politely but peremtorily refused admission. There are not many such, but they are and have been very successful. But suppose that in imitation of their practice and regulations all were tempted to adopt it, so that the same policy became universal; what a sudden paralysis of industry would follow! Our secretaries would find it difficult to fill even their shrunken volumes of transactions with papers worth printing; our students would have to content themselves with the antiquated learning which their professors could supply; for there would be no more summer classes for practical work in mines, smelters and electrical factories, and the professors themselves would have to learn from old books. Every manufacturer and smelter would be obliged to bribe his neighbor's workmen and tempt away his neighbor's superintendents for information. As a result, before long, the very works which now find it so profitable, or think they do, to tap their friends' stock of knowledge and experience, and give nothing in return, would be driven in upon their own resources, and would undoubtedly then find them not so complete as they imagine. Of course, I am supposing an impossibility, because the spirit of intellectual freedom in our professions is too strong and too widespread to submit to such tyranny, and because, before such darkness of ignorance had settled down on our great industries, the most pronounced advocates of secrecy would feel and acknowledge the ultimate consequences of concealment, and would become reformers. To-day they may have secrets, as valuable as Sir Henry Bessemer's method of making plate glass and bronze powder, which it may pay them to conceal from their competitors, so long as they are admitted freely to their competitors' open shops; but even this is doubtful. For the spirit of secrecy is intimately allied with the spirit of suspicion and distrust; and the mind which is always suspecting is closed tight against the admission of fresh and fair impressions. Being jealous of others, it is prejudiced against their suggestions, and correspondingly prejudiced in favor of its own preconceptions. Progress therefore ceases.

This is a temper of mind foreign to a new country like ours, whose special industries have not been established long enough to wear grooves of rigid practice, and sink into ruts of self-satisfied indifference. About the best correction we can apply to the growth of dry-rot is the banishment of secrecy. A curious instance of its blighting influence is seen in some of the older, not the newer, industries of the old world. The iron and steel works of Europe have not kept pace with ours in size and production, but the ironmasters of Great Britain and Germany, in coke-making and in blast-furnace economies and in steel-making processes, have been our teachers. Nor have they been shy of communicating their improvements, or, through jealousy of our success, slow in adopting ours. No nobler monument of international comity in thought and experience exists than in the seventy volumes of the *Proceedings of the Iron and Steel Institute;* and with few exceptions the iron and steel works of England, Scotland, Germany, and France are open to any accredited worker in the same domain. Yet before England was conspicuous as a maker of iron, she was famous the world over for her copper and tin production. But, between self-conceit and the inbred habits of trade secrecy, her copper-smelting industry has fallen from its high estate. And it is not accidental, but linked as closely as any effect with its cause, that this decline is in great part the result of habits of secrecy which grew with the growth of age. At Swansea, every gate to the smelting works is guarded, and as a result it has been as difficult for thought to escape out as for suggestions to find their way in. Swansea should still enjoy the leadership which her skilled labor, splendid coal and commanding maritime situation put within her reach; but she has preferred to gloat over her secrets behind closed doors rather than go out into the world in search of new business as well as technical methods, while also inviting the world to enter and exchange ideas with her. What is the consequence? New Zealand copper comes here to be refined, notwithstanding that the first practical application of electrolysis to metals was made by Elkinton in England, and the Vivians adopted the Manhès method before Farrel introduced it into this country.

There are, however, of course, exceptions in England to this too prevalent habit of secrecy. To the works of the Rio Tinto at Port Talbot or of the Cape Copper Co. at Briton Ferry in South Wales, where metallurgical novelties have been tried, introductions are not refused. But the alliance of decay and suspicion in the instance I have given can hardly be accidental; and we may be sure that what is baneful in its effects in Europe is not likely to be beneficial here; for while the Atlantic separates continents it does not delimit the operation of laws.

In political life, vitality is maintained only when every man takes his full share as a debater in the discussion of political questions, and as a voter in the determination of state affairs. So in scientific and technical matters, the banishment of deceit, mystery and jealousy, and the freest admission of daylight by means of the unreserved diffusion of information through the press and personal intercourse, will instill into the whole body of workers a feeling of healthful rivalry, which, while stimulating their mental activity, will correspondingly benefit the financial interests of their employers.

* * *

Vibration in steamships is probably unavoidable, no matter what means of propulsion are employed. The turbine steamers *Lusitania* and *Mauretania* vibrate considerably in certain parts, much to the disappointment of those passengers who expected to be entirely relieved of this discomfort. The steam turbines, being perfectly balanced, contribute little or nothing to the vibrations, but the propelling screws and the action of the waves, which are also important sources of vibration, have to be reckoned with. The steel hull is a highly flexible and elastic structure which responds to every exterior and interior impulse. Even if it were made of one solid mass of steel, the elasticity and flexibility of a structure 790 feet long would still be very appreciable. The possible extensibility of a steel bar 790 feet long when subjected to a stress of 30,000 pounds per square inch is about 9½ inches, taking the modulus of elasticity as 30,000,000. The hull of an ocean steamer is, of course, much more extensible proportionally than a solid steel bar because of the shape and unavoidable looseness of structure. A small fraction of the possible relative motion of the parts of such a structure repeated many times a minute is quite enough to produce a very disagreeable effect.

MAKING THREAD GAGES.*

A. L. MONRAD.†

The method of making thread gages, described in the following, may not be new, but it has very lately come under the observation of the writer. It seems to be the general idea that screw plug gages must be made of tool steel, but it has been found very practical to make them of cold rolled stock, which is very soft and easy to cut, but which, when hardened, gives a surface which is fully as hard as tool steel. This hard surface extends deep enough into the thread gage to permit grinding 0.005 inch deep, enough hard surface still remaining to prevent rapid wear when in use. Another reason for using this soft steel is also that it is not likely to change its shape, after having been finished, the same as does even the best tool steel, if it has not been properly seasoned after hardening.

For setting a thread tool for cutting a correct thread, a cylindrical thread gage is made, as shown in Fig. 3. This thread gage has the advantage over the ordinary thread gage on the market, that it can be placed between the centers of the lathe, and consequently one does not depend upon any secondary surface, against which to set the thread gage. This is the case with the ordinary thread gages, which have to be lined up either against the side of the face-plate of the lathe, or against the side of the work, and in this way small errors are almost always introduced. The thread gage in Fig. 3 is made of machine steel, hardened and ground all over. The main body, *A*, is provided with three grooves, having an inclusive angle of 29, 55, and 60 degrees, respectively, to correspond with the Acme, Whitworth and United States Standard threads, respectively. When the gage is hardened, the grooves are ground with the same setting of the slide-rest, the piece *A* being reversed on the lathe centers while grinding. This insures that both sides of the angle in the gage make the same angle with the axis of the gage.

In one end of the body *A* a hole is drilled, and ground until the bottom of the hole comes exactly in line with the axis, or center line of the body *A*. A hardened and lapped plug *B* is inserted into this hole and held with a set-screw, having a brass shoe at the end. The purpose of this plug *B* is to afford a means for setting the thread tool in the lathe at the correct height, or, which is the same, exactly in line with the axis of the spindle. This is done by merely loosening the clamp which holds the thread tool in its holder, then with the thumb of the left hand on the plug *B*, and the forefinger on the thread tool, it is brought instantly in position, so that the upper face of the thread tool touches the lower side of the plug *B*, as shown in the end view of Fig. 3. When in this position, the clamp of the thread tool holder is again tightened, and the tool is now placed in the correct position as to height. This is the best way of setting the thread tool to the same height as the axis of the lathe centers. [This method of setting of the thread tool to height does not necessarily, however, insure that the thread tool in all cases will be set absolutely correct. If the thread tool holder should be tipped somewhat out of the horizontal position, the top of the thread tool itself would not be horizontal, and consequently, when the gage pin *B* was brought down upon the top of the thread tool, so that the top face would lie perfectly in line with the lower face of gage pin *B*, this pin would not be fully horizontal, and the thread tool would not be set to the exact height of the lathe centers.—EDITOR.]

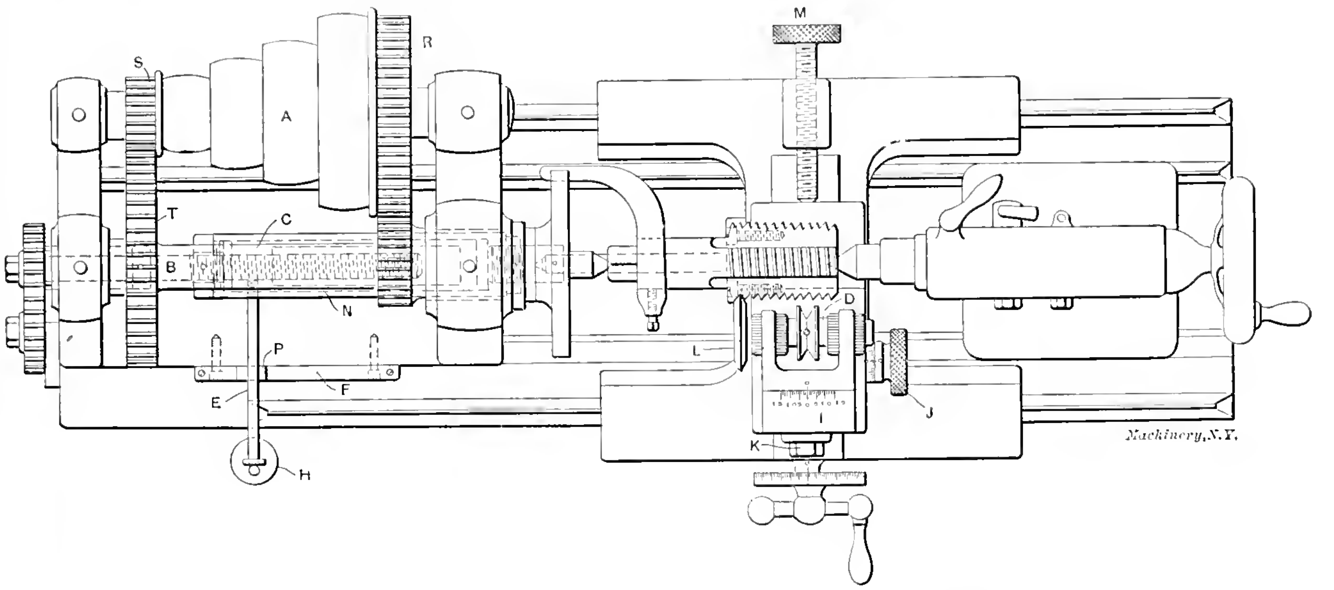

Fig. 1. Lathe for Grinding Taps in the Angle of the Thread.

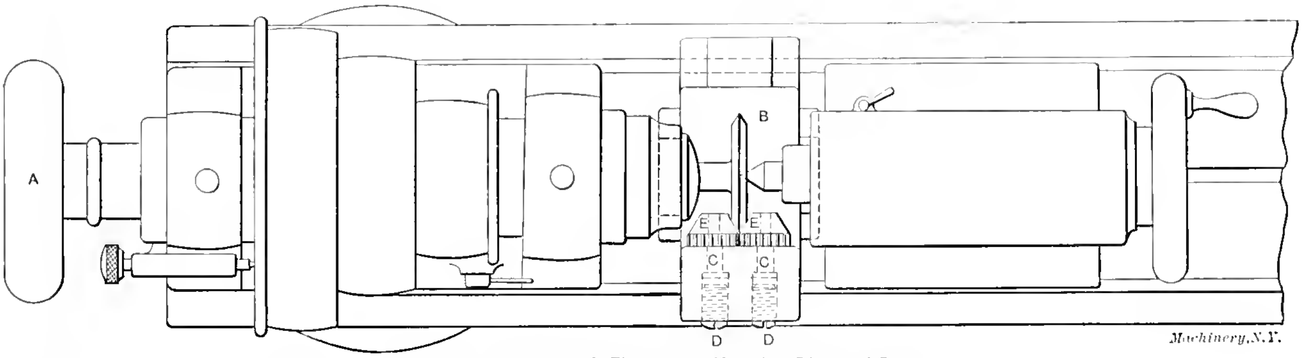

Fig. 2. Bench Lathe with Fixture for Charging Diamond Lap.

With the gage remaining between the lathe centers, the angle of the thread tool is set to a correct central position, sideways. This setting is also a check on the accuracy of the angle of the thread tool. A piece of white paper should be used under the gage and the tool, and a magnifying glass should be employed. First, when the tool fits the gage so that all light is shut off, the setting and the angle may be considered satisfactory. The thread tool being set, we are now ready to proceed to finish thread our screw plug gage, which has previously been roughed out by a chaser having three or four teeth, leaving about 0.005 inch for the finishing single point thread tool. The finishing of the thread is continued

* For additional information on kindred subjects, see the following articles previously published in MACHINERY: Measuring Screw Thread Diameters, September, 1907; Tools and Methods for Accurate Thread Cutting, July, 1903.

† Address: 72 Thompson St., New Haven, Conn.

until 0.0015 inch is left for lapping. The chaser, as well as the single point tool, should have a clearance of 15 degrees on the front face of the thread tool. This angle has proved to be the most advantageous for all practical purposes.

After having been finish threaded, the screw plug is case-hardened and ready for lapping. A lap made as shown in Fig. 4 is used. It will be seen that this lap is somewhat different from those ordinarily used for this work. The con-

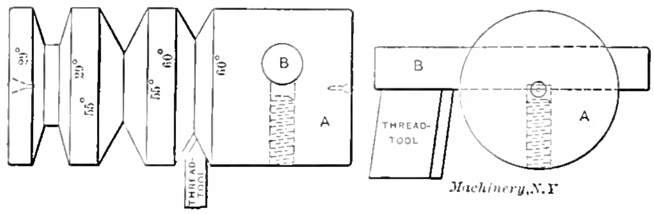

Fig. 3. Gage for Setting Thread Tools.

struction shown has been adopted because of the difficulty met with in circular laps which are split on one side for adjustment, but have nothing on the sides to hold the two sections in perfect alignment. Consequently, each of the sides has a tendency to follow the lead of the screw plug when lapping, and difficulty is experienced in getting a thread with perfect lead. The lap here shown, therefore, has a dowel pin *A* on each side for the purpose of holding the two sections in perfect alignment, and the adjusting screws *C* are inserted outside of the dowel pins. The two screws *B*, finally, clamp the two halves together. When the lap is assembled and screwed together, it is roughed out in the lathe with a threading tool, or tapped with three or four different sized taps, following one another in proper rotation. The lap is then taken apart, and planed on the inside to permit of adjustment; three grooves are cut in the thread on each side of the lap, for holding reserves of emery and oil. This will permit constant lubrication of the lap, and constant charging when lapping the screw plug to size. The lap is finished with a master tap, which must be made with extreme accuracy. This

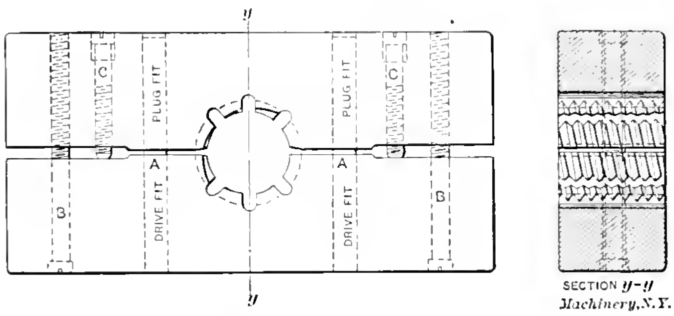

Fig. 4. Lap for Screw Plug Gages.

tap is ground in the angle of the thread, as shown in Fig. 1, and it is finished to a dimension 0.002 inch below the size diameter of the thread plug to be made, in order to permit the lap to wear down to the size when lapping.

The lathe must be revolved very slowly when grinding the master tap, the revolutions of the spindle being from 20 to 100 per minute, according to the size of the tap. As will be seen in the cut, the cone pulley is placed where the back gears ordinarily are located. Gear *R* is disconnected, and the drive is through gears *S* and *T*. The reason for having the cone pulley in the back, is because it is wanted to use the space directly under the usual location of the cone pulley in the center of the lathe for a mechanism intended to permit a slight adjustment of the lead of the tap when grinding in the angle of the thread.

The feed screw *B* is placed in the center of the lathe bed, directly under the driving spindle, and fits into a solid nut, *C*, from which, through the medium of a casing *N* and a connecting-rod, the carriage is moved. A rod *E* is screwed into the nut *C*, this rod extending over the side of the lathe, and resting upon the edge of plate *F*, which can be so adjusted that it inclines from one end to the other from 0 to 20 degrees. Between this plate and the rod *E*, a shoe *P* is placed. On the extreme end of the rod hangs a weight *H* which holds the rod against the plate *F*. This arrangement serves the purpose of giving a slight change in the lead of the tap being ground, as it is evident that when the rod *E* travels along the plate *F*, on the incline upward, it slightly turns the nut and moves it forward a trifle in excess of the regular forward motion imparted to the nut by the motion of the lead screw. By inclining the plate *F* in the other direction, the motion of the nut may be correspondingly retarded.

A grinding fixture *I* fits the slides on the top of the carriage. On the right-hand side of this fixture is placed a knurled handle *J*, graduated to thousandths of an inch. This handle is for the fine adjustment of the fixture, enabling the grinding wheel to be set correctly to the center of the thread, before starting the grinding operation. The top of the fixture swivels in a vertical plane, so that the wheel *L*, which is made of tool steel and charged with diamond dust, can be set at an angle to the vertical, either to the right or the left, according to the pitch and direction of the thread. This adjustment is made by loosening the nut *K* which binds the head in position when set to the correct angle. The wheel *L* is provided with a shank which fits a tapered hole in the

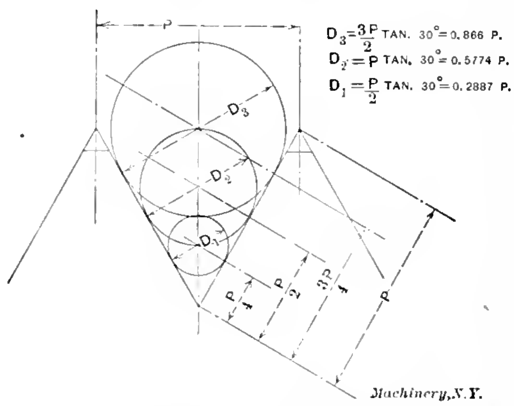

Fig. 5. Formulas and Diagram for Determining Ball Points for U. S. Standard and V-threads.

spindle *D*, which latter runs at a speed of 20,000 revolutions per minute. A solid backstop *M* is provided to hold the fixture securely in place while working. The lathe spindle, with the tap, and the grinding spindle run in the same direction, the same as in an ordinary grinder.

A good supply of sperm oil should be used when grinding the tap, and it is necessary to have a cover over the wheel, to prevent the throwing out of oil. This cover, however, is not shown in the cut. Care should be taken not to force the wheel into the work, as if that is done, the shape will soon be destroyed. The wheel should just barely touch the work, and should be fed in a very small amount, say, 0.00025 inch at a time. A sound magnifier or listener should be used, to hear whether the wheel is cutting moderately.

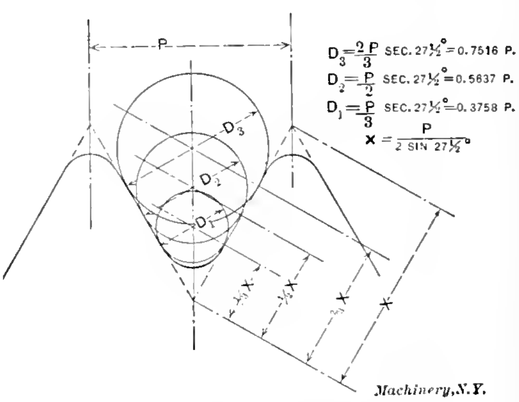

Fig. 6. Formulas and Diagram for Determining Ball Points for Whitworth Standard Thread.

The wheel is charged in the following manner. A chuck, with a tapered hole which fits the shank of the diamond wheel, is placed in the spindle of the bench lathe, as shown in Fig. 2, and the tail-stock center is pushed up at the other end to get a good support when charging. Fixture *B* is placed in the bench lathe, and clamped with a bolt and nut from underneath the lathe, about the same as an ordinary slide-rest. The front end of the fixture extends up vertically

above the center of the spindle. In this projecting part, two holes are drilled, reamed, and counterbored, at the same height as the center of the lathe spindle. In these holes are fitted two studs *C C* having a T-head inside the counterbored hole. Between the T-heads of these studs and the screws *D D* lie

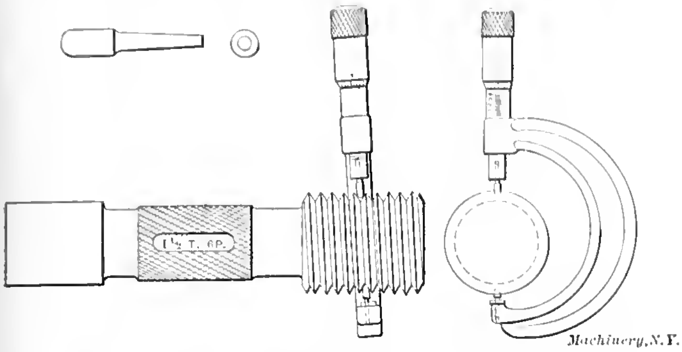

Fig. 7. Comparing Angle Diameters with Ball Point Micrometer.

fiber washers, which act as friction stops. On the other end of plugs *C C* are placed hardened and ground rollers *E E* having one end beveled to a 30-degree angle, while the other end has spur gear teeth milled, which mesh into each other. With the slowest speed of the bench lathe, the fixture is fed in by hand, and having two slides at right angles to each other, the same as an ordinary slide-rest, it can be located to the proper position without much trouble. A piece of soft steel wire should be flattened out to make a spade, with which to take up the diamond dust for charging the wheel. One should not try to use a piece of wood, or a brush, as that will only be a waste of diamond. The master tap, which is to be ground, is relieved up to within 1/16 inch from its cutting edge with a file, this being done in order to prevent any more grinding than is absolutely necessary, and to permit the tap to cut freely. The length of the threaded part of the master tap should be about two times its diameter.

The master tap being finished, the lap for the screw plug gages, Fig. 4, is tapped, and ready for use. When charging this thread lap, great care should be taken not to force the lap too much. The spindle of the lathe, where the lapping is done, should be run very slowly, with the back gears in, until the lap is thoroughly charged with emery mixed with sperm oil. Then the lathe may be speeded up to a higher speed, according to the size of the screw plug. It is poor practice to use too much emery on the lap. Reverse the lap often, and use it the same amount on either side. If a large number of screw plugs are to be lapped, all of the same size, lap them all, one at a time, with the lap at the same setting. In this way the lap keeps its shape better, and can be used a long while before being retapped. Do not attempt to tap the lap with the master tap when charged with emery, but use a roughing tap first, and also wash out the lap in benzine before tapping. When the screw plug has been lapped to within 0.0005 inch of its size, it is ground on its outer diameter, if it be a U. S. Standard thread plug, and then finished by lapping after being ground. This will permit the top corners to be kept sharp, and better results will be obtained all around.

Great care must be exercised during the lapping operation to see that the angle of the thread is correct. The gaging of the angle of the thread is accomplished in the following manner. Three micrometers are used to measure the correct angle. Two ball points of the same size are placed in tapered holes in each micrometer, as shown in Fig. 7. These ball points are ground all over, and made to a shape as shown in the upper left-hand corner in Fig. 7. The body of these ball points is ground parallel, and then the end is turned and ground to a ball shape as shown. Three sets of ball points are used for each pitch, one to measure the thread near its bottom, one at the center, and one near the top, as indicated in Figs. 5 and 6. The master screw plug is used for comparison; one micrometer is set to the master screw plug at the bottom of the thread, in the manner indicated in Fig. 7, and is then tried on the thread plug being made. The difference in diameter between the measured diameter on the master gage, and that on the plug being made, is noted. Then the two other micrometers, measuring at the center and near the top of the thread, are used, and the difference between the master gage and the screw plug diameters at the places where these micrometers measure, is also noted. If all three micrometers show the same amount of difference in relation to the master plug, then the angle of the thread evidently must be correct. After that, the micrometer measuring at the center of the thread is used to measure the size of the screw plug, comparing it with that of the master gage, until the plug is finished to size.

Figs. 5 and 6 show how formulas are derived for the size of the ball points used in measuring. Fig. 5 applies to a

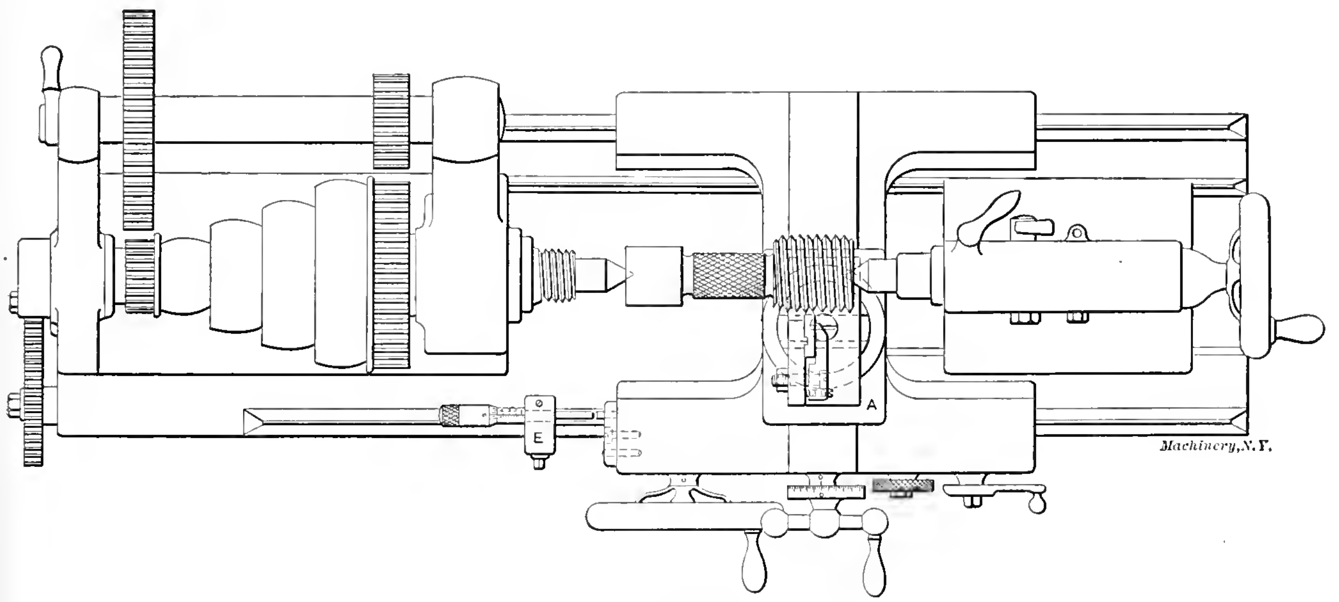

Fig. 8. Final Test of Pitch and Angle of Thread.

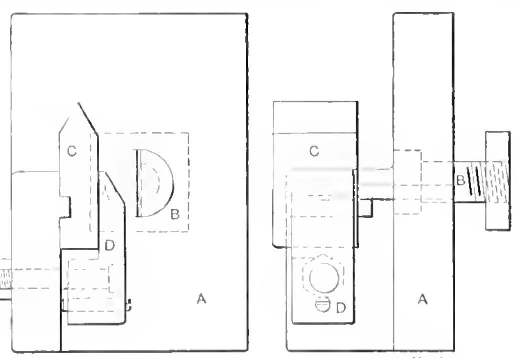

Fig. 9. Gage for Testing the Angle of the Thread.

60-degree thread, either sharp V or U. S. Standard, while Fig. 6 gives the formulas for a Whitworth thread. The diameters D_1, D_2, and D_3, respectively, are the diameters of the cylindrical portions of the ball points used, and are, of course, also the diameters of the half-spheres on the end of the ball points. Tables I and II give these diameters for a number of different pitches, figured approximately from the formulas.

For testing the angle of the screw plug, when finally finished to a limit of 0.0005 inch, it is tried in a testing machine, such as shown in Fig. 8. This machine is simply an ordinary lathe, fitted with a fixture *A*, shown separately in Fig. 9. The tool-post is taken off the lathe, and replaced with this fixture, which is clamped in the T-slot of the tool-post slide, with bolt *B*, Fig. 9. The thread gage *C* is ground all over, and the angle fitted to a master gage. The gage *C* is held by the tongue and groove on the left-hand side of the fixture, and clamped with a strap *D*. To set this gage correctly, in relation to the axis of the spindle of the lathe, as regards height as well as angle, the angle gage, Fig. 3, is used in the same way as has been previously explained in relation to thread cutting. When the fixture has been placed correctly in position, the screw plug is inspected by placing the gage with the hand first to the right and then to the left side of the thread angle. A strong magnifying glass is used with a white paper underneath, and any imperfection of the angle is easily detected, and can be corrected, when lapping the last 0.0005 inch to size. If the test gage shows an opening either at the bottom or at the top, the fault is that the lap is worn and must be retapped, or it may be that too much

emery has been used. If, for some reason or other, it is impossible to correct the screw plug within 0.0001 inch, when lapping, take a piece of hard wood, or flatten a piece of copper wire, charge it with emery, and hand lap the high points of the angle, while the screw plug is revolving slowly in the lathe. In this way, it is comparatively easy to overcome this trouble, but great care must be taken to follow the thread properly with the hand lap.

To find if a screw thread has a perfect lead, the micrometer stop *E*, Fig. 8, is placed on the left-hand side of the carriage. The holder for this micrometer stop is shown separately in Fig. 10. The construction of this stop is very simple. The micrometer head is an ordinary one, as made for the trade by manufacturers of these instruments. The holder *E* is made similar to a C-clamp, with a hole drilled and reamed to fit the micrometer head. A slot is sawed through the upper jaw, with a stop screw on the top, which prevents the micrometer from being clamped too hard in the holder, in which case the thimble would not revolve freely. Underneath this hole

the holder is beveled off, and a V-block *F* is held in position by a screw *G*, entering from the side. The micrometer head is placed in the hole provided for it, with its division reading faced upwards, and the screw *G* clamps the micrometer head and the holder *E* at the same time. When the lead of the screw plug is tested, the carriage is moved one inch along the thread. It is understood that the lead screw of the lathe is not employed in this case, but one depends upon the micrometer for measuring the correct lead of the screw plug.

The master plug may, of course, also be placed between the centers and comparison be made with the master plug. In this case, the micrometer serves as a comparator. A plate is screwed on the left-hand side of the carriage, provided with a hardened stop against which the end of the micrometer screw bears. It is evident that the carriage must not be moved against the micrometer with too much force, but simply brought up to barely touch against the end of the micrometer screw.

Bids were opened by the city of Atlanta on November 25 for one 20,000,000-gallon vertical triple-expansion crank-and-fly-wheel pumping engine with a guaranteed duty of not less than 170,000,000 foot-pounds per 1,000 pounds of dry steam. The following bids were tendered:

Allis Chalmers Company	60-inch stroke	$134,000
Allis Chalmers Company	66 " "	149,300
Bethlehem Steel Company	66 " "	132,000
Camden Iron Works (R. D. Wood & Co.)	66 " "	147,700
Holly Mfg. Co.	66 " "	156,000
William Tod Co.	66 " "	157,400
William Tod Co. (same pump with special terms of payment)		165,000
Wisconsin Engine Co.	60 " "	139,500

The latter company was awarded the contract.

FINISHING GAS ENGINE FLY-WHEELS ON THE GISHOLT TURRET LATHE.

We believe that the following description and the accompanying line engravings will have suggestive value to mechanics interested in the making of automobile or other gas engines, as well as to others who have turret lathe work of a similar character to do.

Operation for Finishing a Fly-wheel at One Setting.

Fig. 1 shows an arrangement of tools by means of which it is possible to finish a fly-wheel complete at one setting. The hole for the shaft has to be bored and reamed, the hub has to be faced on both sides, and the sides and periphery of the rim are to be finished, all four corners of the rim being rounded. The outfit of tools shown is designed to accomplish this. It consists of boring bars, reamer and facing heads in the main turret, a turret tool-post on the slide rest (carrying in this case three tools) and a special supplementary wing rest attached to the front of the carriage at the extreme left.

The work is held by three special hardened jaws *B* in a universal chuck. These grip the work on the inner side of the rim, leaving room for a tool to finish the rear face without striking the chuck body or the jaws. Three rests *C* are provided between the chuck jaws; the work is pressed against these while it is being tightened in the chuck, and they serve to locate it so that the arms will run true so far as sidewise movement is concerned, and so that the work will be properly placed with relation to the stops for the turret and carriage movements. The chuck carries a bushing *R* of suitable diameter to support boring bars in the main turret, as will be described.

In the first operation, boring bar *M* is brought in line with the spindle and entered in bushing *R* in the chuck. Double-ended cutter *N* is then fed through the hub of the pulley to true up the cored hole. While boring the hole, the scale on the front face of the rim and the hub is removed by tool *J*. Tool *K* is then brought into action to rough turn the periphery, after which tool *E*, in the wing rest, is fed down to clean up the back face of the rim. As soon as the scale is removed, the hole is bored nearly to size by cutter N_1 in bar M_1, and finally finished with reamer *Q*, mounted on the floating arbor.

Next, cutters *F*, *G*, and *H*, in the facing head, are brought up to rough face the hub and rim, and round the corners of the latter on the front side. This operation is all done by broad shaving cuts. The facing head in which the tools are held is provided with a pilot bar *T* which fits the finished hole in the work, and steadies the head during the operation. The various cutters *F*, *G*, and *H*, are mounted in holders which may be so adjusted as to bring them to the proper setting for the desired dimensions. This finishes the roughing operations.

The periphery of the rim is now finished by cutter *L* in the turret tool-post, which is brought to the proper position for this operation. The rear face of the rim is finished by tool *E*, the same one with which the roughing is done. *E* is removed and replaced with *D* which rounds the inner corner of the rim. This is in turn replaced with a third tool for rounding the outer corner of the back side. For finishing the front faces of the rim and hub and rounding the corners of the former, a second facing head, identical with the first one, is employed. This is shown in position in the engraving. Blades F_1, G_1, and H_1, correspond with the blades *F*, *G*, and *H*, previously referred to, and perform the same functions.

The only remaining operation, the finishing of the back of the hub, is effected by cutter *P*. This cutter is removed from the bar, which is then inserted through the bore and the cutter replaced in its slot, when the rear end of the hub is faced by pressure on the carriage away from the head-stock. This completes the operation required for finishing the wheel complete at one setting.

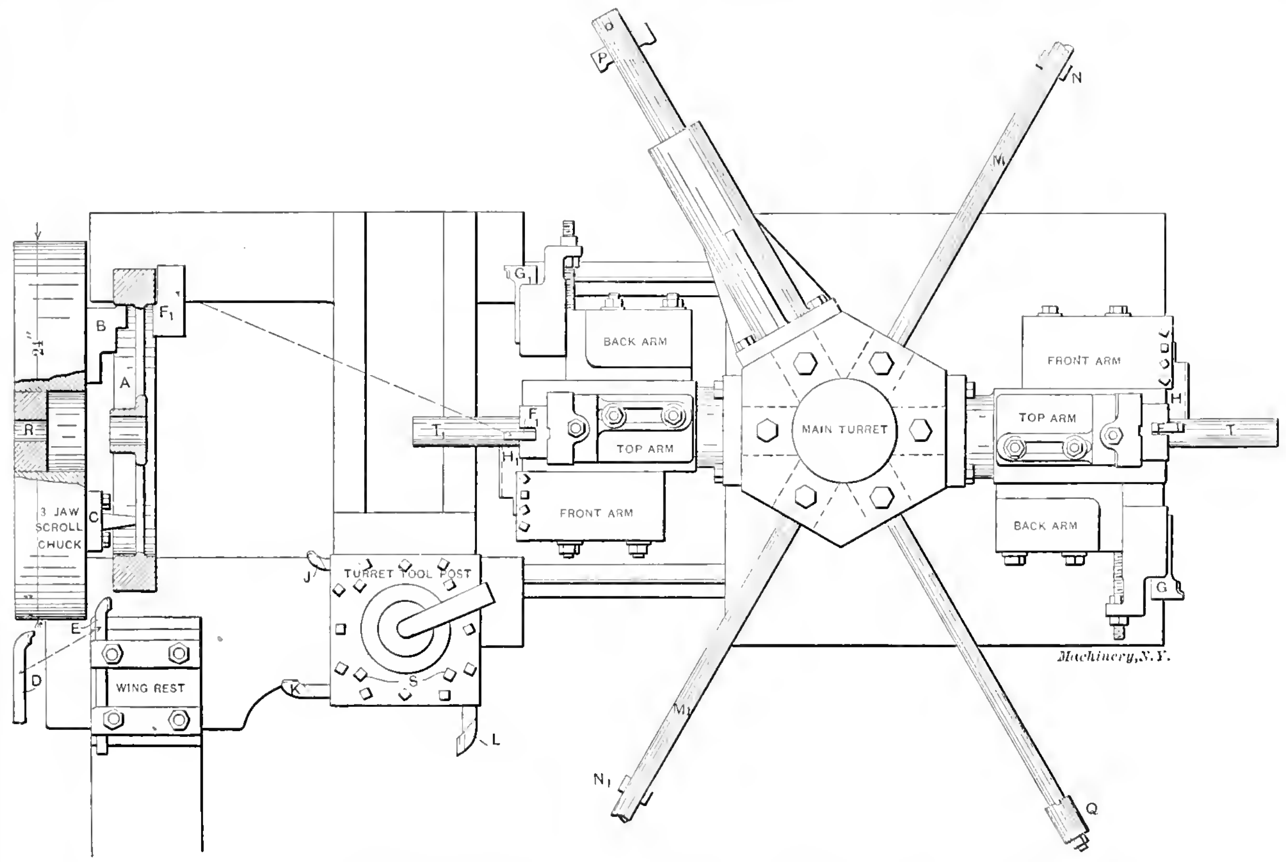

Fig. 1. Arrangement of Machine and Tools for Finishing a Fly-wheel Complete at One Operation.

Finishing a Webbed Fly-wheel All Over in Two Settings.

In Figs. 2 and 3 are shown the arrangement of tools for finishing a webbed fly-wheel which has to be machined all over. This, of course, requires two operations. In the first of these, Fig. 2, the rough casting is chucked at *A* on the inside of the rim with regular inside hard chuck jaws *B*.

The engraving shows the first operation in progress. The cored hole is being rough bored with cutter *N* supported in the end of boring bar *M*, and guided by the drill support *D* pivoted to the carriage. Next, the boring bar M_1 is brought into position, the drill support being thrown back out of the way. This bar is steadied by its bearing in bushing *R* in the chuck, the same as provided in the case of Fig. 1. Two cutters, N_1 and N_2, are used to roughly shape the hole to the desired taper, the small end being finished to within 0.002 of the finished size. While boring with the bar M_1, the scale is broken on the web and hub of the piece with the tool *K* in

the turret tool-post. The latter is then shifted to bring the tool J into position for removing the scale on the periphery of the wheel. Next, the hole is reamed with taper reamer Q, the pilot of which is supported by bushing R.

with the soft slip jaws B, which are bored to the exact diameter of the piece. The work is further supported and centralized by sliding bushing C, which is tapered to fit the finished hole in the work, and has an accurate bearing in bushing R in the chuck as well. As shown, it is provided with a threaded collar for forcing it into the work and withdrawing it.

First, the scale on the web and the inside and face of the rim is broken with the tool K in the turret tool-post. These

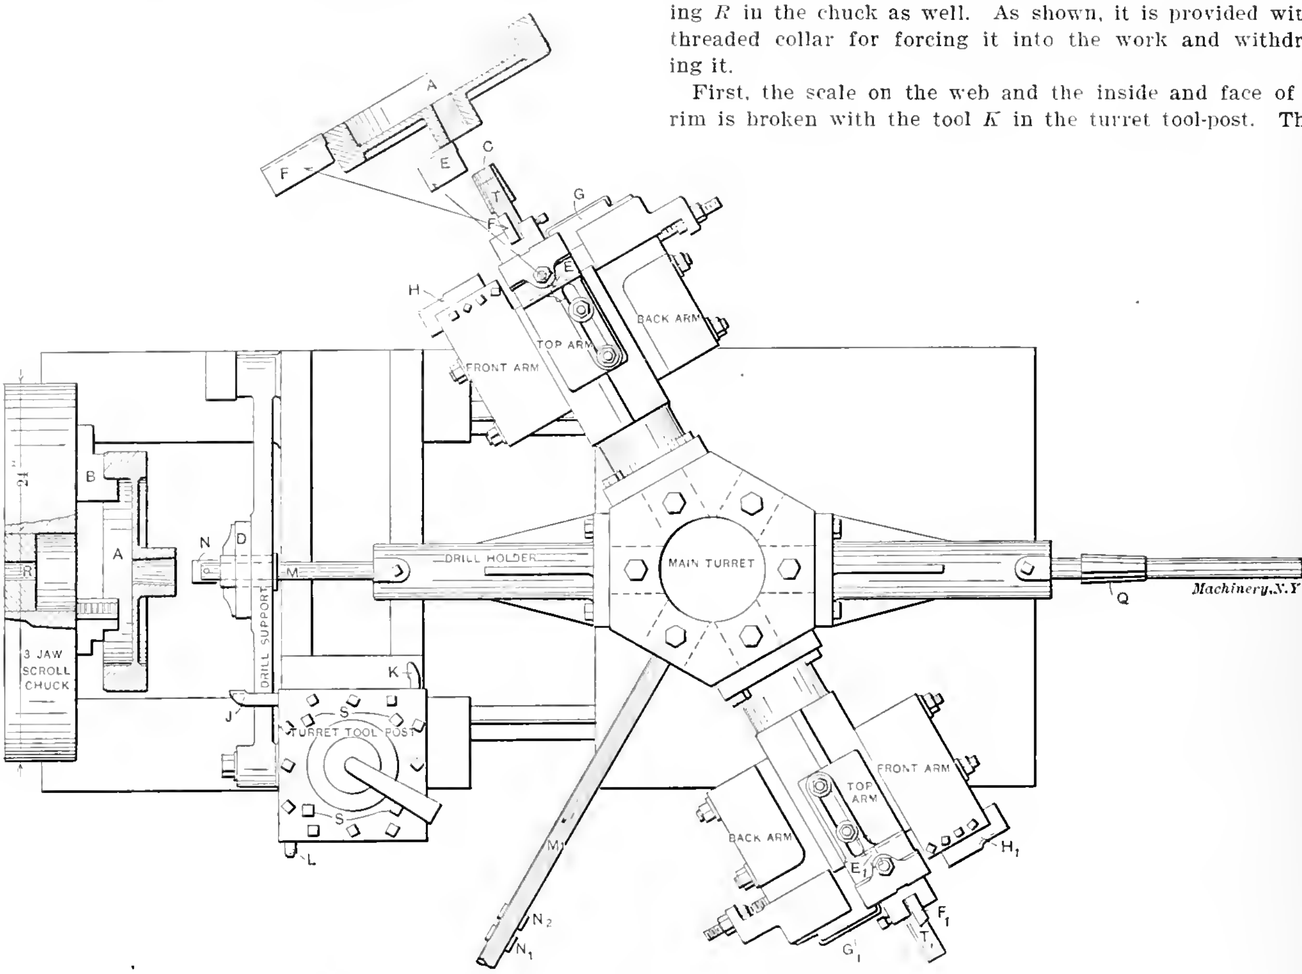

Fig. 2. Finishing the Periphery, Front Face, and Bore of a Webbed Fly-wheel.

The first of the facing heads is now brought into action. This facing head carries a guide T which is steadied in a taper bushing C, driven into the taper hole of the work for that purpose. Blade F turns the periphery, blade G turns the

surfaces are then roughed off with cutters F, G, and H, in the facing head. This latter is steadied by a pilot T which enters the hole in the sliding bushing C on which the work is supported. This brings the piece approximately to size. Next,

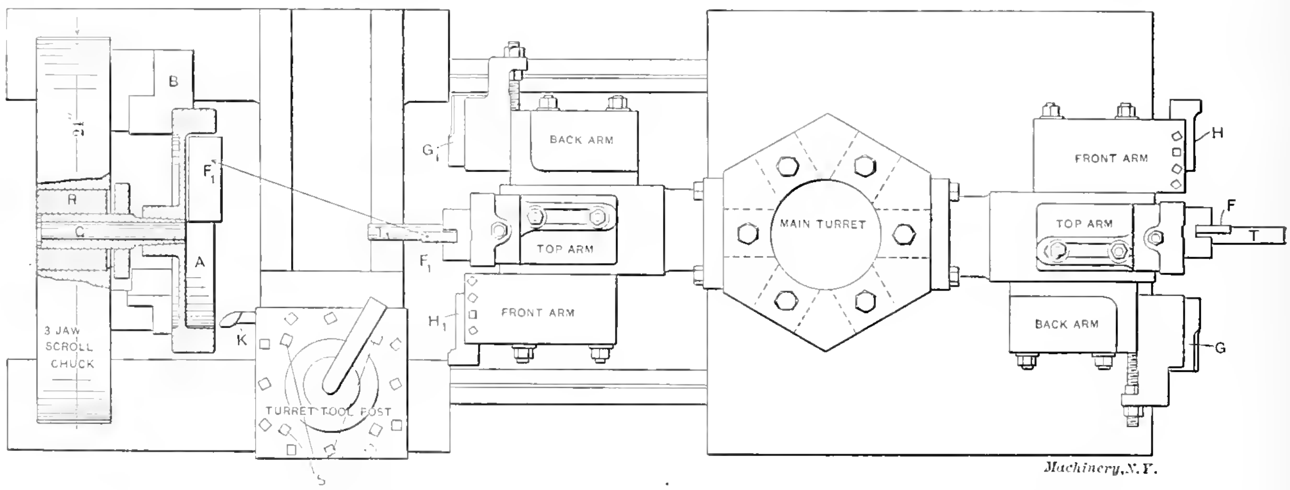

Fig. 3. Finishing the Rear Face of the Work shown in Fig. 2.

hub and faces the web, and blade H faces the rim. A fourth blade E on the under side of the head faces the hub. This brings the piece approximately to size. For finishing, the similar cutters E_1, F_1, G_1, and H_1, in the other facing head are used, this latter being supported by the taper bushing C in the same way. Only a very light cut is taken for finishing. Tool L in the carriage turret is then used to round the outer and inner corners of the rim, this completing the work on this face of the casting.

In the second set of operations, shown in Fig. 3, the same piece, reversed, is shown chucked on the outside diameter

a light cut is taken with blades F_1, G_1, and H_1, in the finishing facing head, which completes the operation.

The tools and operations shown represent the practice of the Gisholt Machine Co., 1316 Washington Ave., Madison, Wis.

* * *

The construction of a lighthouse at the Ar-Gazeck reef near Ushant on the French coast, is being conducted under great difficulties owing to the swiftness of the currents which prevented more than 52 hours' work on the foundation during 1904, more than 206 hours in 1905, and more than 152 hours in 1906, making 51 eight-hour days during three years.

LETTERS UPON PRACTICAL SUBJECTS.

A TOGGLE-JOINT PUNCH.

Punch and die work on sheet metal is done principally upon two kinds of punch presses, namely, the single-acting and the double-acting press. The kind of press to be used depends upon the nature of the work to be done. The single-acting press has one eccentric, or crank, on the shaft, which transmits the required motion to the punch; while the double-acting has two eccentrics, or cranks, set in such a relation to each other that there is produced a follow-up motion. The punch is attached to one eccentric arm, or connecting-rod, and another punch or plunger to the other arm, or connecting-rod. The plunger works on the inside of the punch, and is generally used to form the metal into some desired shape after the blank is cut out. The plunger comes into action just after the punch has cut the blank. By means of the double-acting press, the work is punched and formed in one stroke, and in some classes of work, it is pushed through the die and falls into a box under the press. The single-acting press will do the same work, but the dies are more complicated, and the work comes up on the die by means of springs, and is

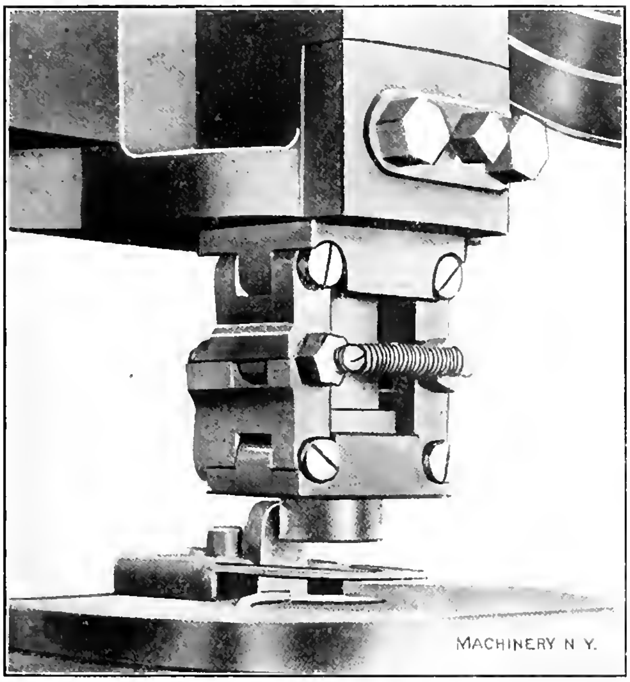

Fig. 1. View showing the Punch in the Up Position.

removed from the die by being brushed off or by sliding off by gravity, since many presses are made so that they can be set in a tilted position. The advantages of the double-acting press are many. The punches and dies are very much more simple and durable than those for the same work on the single-acting press, and the work can be done much more rapidly. Many manufacturers who do their own stamping work purchase the single-acting press, because of lesser first cost over the double-acting press. This is not the most economical method in the long run, if there is a great deal of punching work to do that could best and cheapest be done on a double-acting press.

I shall describe a punch and die which I have designed, which does the work of a double-acting press on a single-acting one. In this design, I have employed the well known toggle-joint. The work of this punch and die is the punching and forming of can bottoms from heavy stock. There are many sizes of cans, and the parts of the punch and die are interchangeable for the different sizes. When the punch is in the up position (Fig. 1), the toggle-joints are in line and are held there rigidly by means of two springs. The punch holder *A* (Fig. 2) is attached to the lower joints of the toggles, and slides up and down on the forming plunger *B*. In operation the punch *C* comes down on the stock and cuts out the circular blank on the die *D*. Just after the blank is cut, the arms *E*, of the lower joints, strike the opening wedge *F* and open the toggle-joints. This causes the punch *C* to slide up on the plunger *B*. Then the plunger *B* continues downward and presses the blank over the rounded shoulder *a*. There is enough clearance between the plunger and the inside of the forming ring, below the shoulder *a*, to allow for the

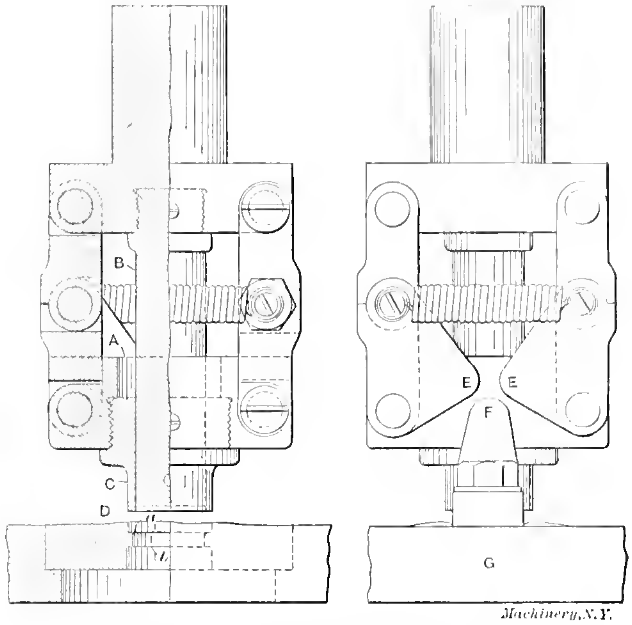

Fig. 2. Front View and Half-section, and Rear View of Punch.

thickness of the metal. After the plunger pushes the formed can bottom through the forming ring at *b*, it starts on the upward stroke. The finished can bottom is stripped off the plunger at the shoulder *b* in the die, and drops into a box under the press. After the arms *E* of the toggle pass above the opening wedge *F*, the toggles close by means of the springs.

It will be noticed that the plunger does not extend flush with the bottom of the punch *C* when the punch is in the

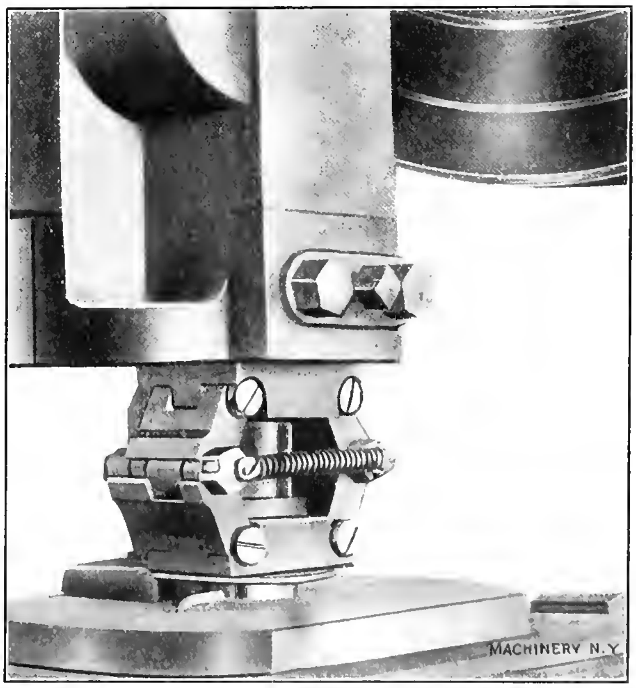

Fig. 3. View showing the Down Position of Punch.

up position. This is for the purpose of allowing the punch to cut the blank before the plunger comes into action. A feature of this punch is that the toggle-joints hold the punch holder perfectly rigid until the blank is cut and the toggles opened. The strain does not come on the bolts, but on the curved shoulders, plainly shown in the isometric views (Fig. 4). If the strain did come on the bolts, there would be a tendency to shear them, especially when cutting heavy stock,

and they would soon be worn enough to throw the whole punch out of true. In this design, there is little wear on the bolts. Figs. 1 and 3 show the up and the down positions of the punch, also the stripper for removing the scrap stock from the punch piece. There is also a stop shown by means of which the holes in the stock are spaced as near together as possible in order to save metal.

This punch will work as fast as the stock can be fed in. There is no trouble caused by bits of metal getting into the die, as there is in dies which throw the finished work up to be brushed off the bolster plate. There is no stopping of the punch to allow the finished work to slide off or be brushed off the bolster plate, as is the case with the old form of punch and die. The opening wedge *F* (Fig. 2) is bolted to the bolster plate *G*, and it is of such a height as to open the toggles just after the blank is cut, and before it is formed. The rubbing surfaces of the wedge and opening arms are case-hardened to prevent wear. The curved shoulders *c* and *d* (Fig. 4) are machined out accurately with an end mill. The punch *C* and the die *D* (Fig. 2) are made of tool steel and hardened. The die is afterwards ground. The cutting edge of the die is waved in order to get a good shearing effect on the stock. The plunger *B* and the punch piece *C* each have a shoulder. These pieces are screwed firmly in their respective holders. There is also a headless set-screw in each holder to prevent any possibility of the piece working loose. When it is desired to change the size of the can bottom, the

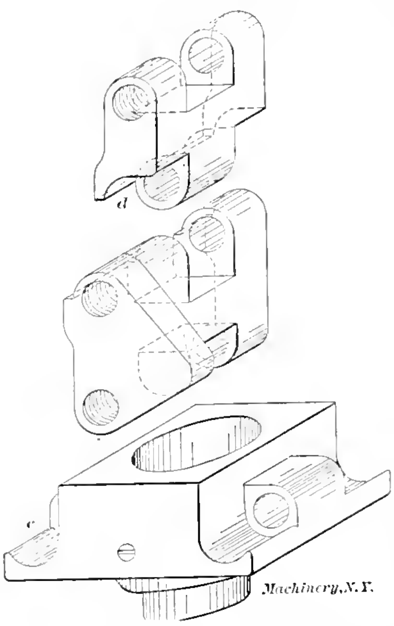

Fig. 4. Isometric View of Toggle-joint and Punch Holder.

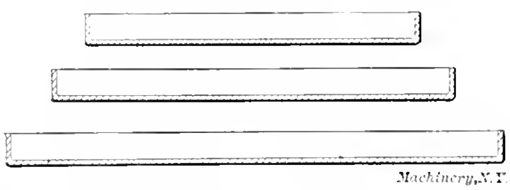

Fig. 5. Can Bottoms which are formed by the Toggle-joint Punch.

only parts to be changed are the plunger *B*, the punch piece *C*, and the die *D*. The plunger and the punch are unscrewed with a spanner wrench. Three different sizes of the can bottoms formed with these punches and dies, are shown in Fig. 5.

This punch and die, after much service, has been found very satisfactory, and has given very little trouble. I have designed a similar punch and die for making square and rectangular can bottoms which has also given satisfaction. Toggle-joint punches can be made for many other purposes, and this type of punch is a time and money saver when used on single-acting presses. J. E. WASHBURN.

Cleveland, O.

SOME GAS ENGINE TROUBLES.

A gas engine had a sparking device arranged as shown in Fig. 1, in which *A* is an insulated point in the sparking plug located in the cylinder head, and *B* a movable point also in the sparking plug but not insulated. This point is driven by a cam on the engine, making and breaking the current to cause the spark. *C* is a spark coil; *D* a battery of four cells; *E* a single-pole double-throw switch, and *F* a small dynamo driven through a friction wheel from the rim of the fly-wheel, and wired up to the other parts as shown. It was customary to throw the switch over to the right and so use the battery current for starting, after which the switch was thrown to the left, and the current taken from the dynamo for the spark. One morning all efforts to start the engine failed, until it was discovered that when the spark plug was held in the hands it would emit a brilliant spark, but if allowed to touch any part of the engine, a very feeble one. A further investigation showed that one of the brush holders

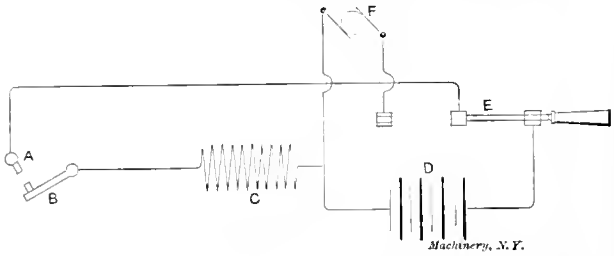

Fig. 1. Diagrammatical View of the Ignition Apparatus.

on the dynamo was grounded, and that the current instead of going through the spark coil *C*, took the easier path up to the dynamo brush, thence to the frame of the dynamo, and then through the gas engine frame to the point *B* as shown by the dotted line in Fig. 2. Hence the spark was very feeble. When the wires were disconnected from the dynamo brushes, the engine was started without difficulty. After putting fresh insulation on the dynamo brush holders, a

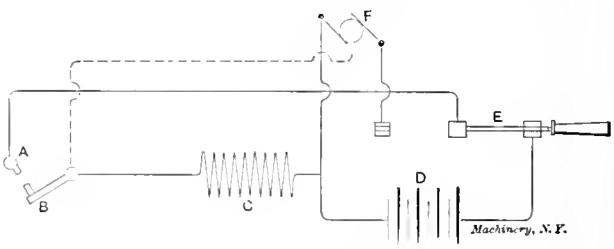

Fig. 2. Diagram showing by the Dotted Line how the Current followed the Path of Least Resistance when the Dynamo Brush was grounded.

change was made in the wiring by substituting a double-pole switch for the one having a single pole, so that the wiring diagram now corresponds to Fig. 3. If the dynamo should get in a bad condition, it would have no effect on the battery current when starting the engine, since both lines are broken by the double-pole switch. The discovery that the spark behaved differently when the sparking plug was in its place in the cylinder than when it was held in the hands, was purely

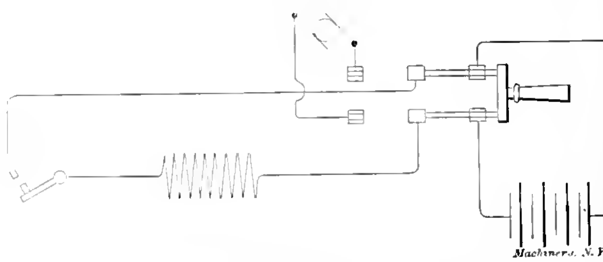

Fig. 3. A Change in the Wiring which prevents the Short Circuit illustrated in Fig 2.

accidental, and the designer of the engine came in for a good share of the blame for not arranging things so that the spark could be inspected under normal conditions. The dynamo is now wiped off clean every morning, and no further trouble has been experienced. L. K. W.

THE GROWING INEFFICIENCY OF WORKMEN.

In the December issue of MACHINERY I noticed an editorial, "The Growing Inefficiency of Workmen," and I can say that it is only too true; but what is the cause of this sad condition to-day?

When the writer and hundreds of others of the old-time mechanics learned their trades twenty-five or thirty years ago, we took pride in doing our work, even if it was only babbitting a journal box. The proprietors of our shops encouraged us in doing work right. What are the circumstances to-day? To-day it is quantity. It is how much work can you turn out? Are you a specialty man? To-day the manufacturers divide their work; they have lathe hands, planer men, milling machine men, bench hands, and floor

men. If you apply for a job as an all-around man they look upon you as a curiosity. In the days when we learned our trades there were no specialty men; they were either all-around mechanics or handy men. A mechanic in those days could fit locomotive links, run a bolt cutter, cut and thread a piece of pipe, or do whatever else the job demanded to make it complete. What is the average so-called mechanic to-day? Is he ever sent out to take charge of a big erecting job or to fit up a complicated piece of work? Not that anyone knows of!

In our day we served three, and sometimes four, years. Our foreman encouraged us not only to think but to put our ideas into execution. He used to say: "Study, boys; learn why you do a piece of work this way or that way. Never take anything for granted on some person's say-so; if you do you only become a machine, you will never become any better than one, and you will always be treated like one." Our old foreman's reasoning holds true to-day. I sometimes think that the average man who passes as a mechanic to-day is more of a machine than a human being. He seemingly has gotten into an automatic way of doing things, and has no conception that circumstances alter cases, or that what might prove effective in one case might be almost disastrous in another. Who is to blame? In the first place, there is a demand for something cheap by a class of people who buy cheap if they buy at all. Then there is a class that manufactures for the cheap trade, and a class of merchants that buys cheap goods and palms them off on unsuspecting people for first-class articles.

In the second place, the unions take in the specialty men, and give them union cards. They go out and represent themselves to be mechanics, whether they know anything or not. They come into competition with men who have learned their trades and who *are* mechanics. The average manufacturer uses the cheap specialty man to hold the real mechanic cheap. What inducement will there be for a man to become a first-class mechanic until manufacturers hire first-class mechanics only, and establish apprenticeship systems that will turn out first-class mechanics?

Let honest manufacturers and mechanics cooperate to put the cheap manufacturer, the dishonest dealer and the cheap mechanic out of business, or, at least, to put them into a recognized position where the general public will know who and what they are. Let honesty be the watchword of both the manufacturer and the mechanic, and let them be satisfied with fair profits and fair wages. Let us leave behind us the present era of bloated dividends, won from the making of dishonest goods—goods in which cheap materials, poor workmanship, plenty of paint and the buffing-wheel create a mockery for the unwary buyer.

When the days of the honest manufacturer and honest workman come—if they ever do—we will have mechanics who are all that the name implies, but not until then. Now, do not think that I believe all manufacturers and workmen of the present time are dishonest; far from it, but anyone who has kept in touch with the manufacturing conditions knows that in the mad rush for wealth they, both high and low, have trampled the good principles of our forefathers under foot to worship at the shrine of Mammon. E. G.

MILLING FIXTURE FOR FINISHING GEAR SEGMENTS.

Some years ago the writer met with a job requiring the finishing of 500 gear segments, of the type shown in Fig. 1. As seen from the cut, these segments were provided with an arm longer than the radius of the gear segment itself, which prevented them from being turned in a lathe, excepting by working the lathe back and forth by hand. As this method was very inconvenient, the following device was designed and put into operation:

A plain milling machine was selected for doing the work, as it would be comparatively easy to mill the face and the sides of the gear segments if a suitable fixture for revolving the work were provided. The pinion for feeding the table of the milling machine was disconnected from the shaft. Then a bracket *B*, as shown in Fig. 2, was made and bolted to the table. This bracket was provided with a projecting lug, which contained a set-screw *F*, for facilitating the setting of the device to the proper position on the table, before being bolted down. The bracket *B* carried an arbor *C* for holding the blank while it was being milled. The arbor *C*, with the blank, was driven from the pinion *D*, which was placed on the end of the feed shaft of the table, which, in this particular machine, came through the frame of the machine, so that one could tap a stud for the gear into it. It was, however, not

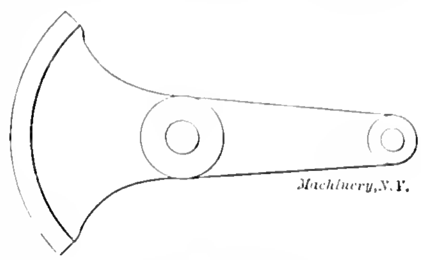

Fig. 1. Gear Segment

possible to use a gear on stud *C* as large as would be required to mesh with the gear *D*, on account of interference with the supporting arm of the milling machine, and therefore the idler *E* was placed between the gear *D* and the gear on arbor *C*.

For finishing the blank, three milling cutters were used, one face and two side or straddle milling cutters, and the work of milling the face and the sides of the gear segments

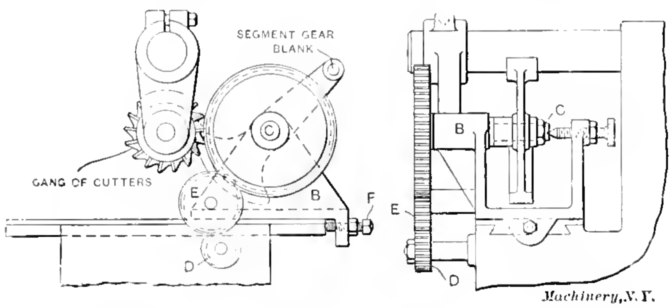

Fig. 2. Attachment for Finishing the Gear Segments on the Milling Machine.

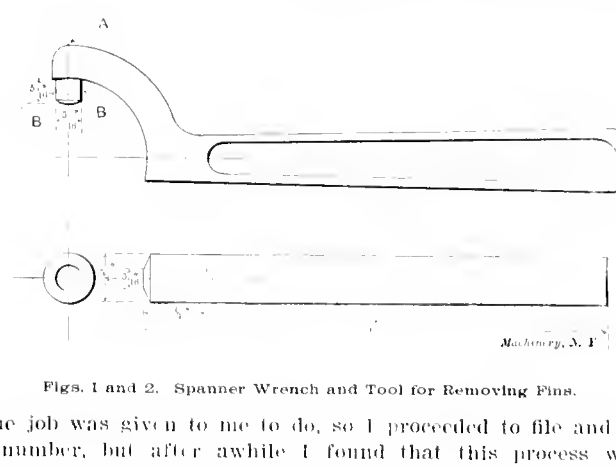
was completed in one cut. The device worked very well, and the blanks were finished at a fraction of the time which had been required by other methods previously employed.

W. ALTEN.

REMOVING FINS FROM THE PINS OF SPANNER WRENCHES.

A manufacturing firm had received a large number of drop-forged spanner wrenches of the type shown in Fig. 1, the pin of which was to fit in a 5/16-inch hole in a packing-nut. The wrenches, it was found on inspection, would not fit the hole, because the pins had a fin projecting about 1/16 inch on each side at *B*. The only remedy for this fault seemed to be to file and fit each of the wrenches to a 5/16-inch gage.



Figs. 1 and 2. Spanner Wrench and Tool for Removing Fins.

The job was given to me to do, so I proceeded to file and fit a number, but after awhile I found that this process was going to take too long, and cost too much, so after some thought I decided upon the following plan, which did the job in about one-tenth of the time it would have taken by the previous method: I took a piece of 5/8-inch tool steel 6 inches long, and drilled a 5/16-inch hole in the center of one end, about 3/4 inch deep; then I filed the stock to a bevel around the hole, as shown in Fig. 2. The drilled end of the

piece was then hardened in the same manner as an ordinary punch or die. The piece was then fastened perpendicular to the bench in a strong, heavy vise, and was ready for service.

The process of removing the fins was performed by holding the wrench so that its pin came directly over the 5/16-inch hole in the tool steel rod. Then one or two blows with a heavy hammer at the point *A*, Fig. 1, removed the fins quickly, so that all the wrenches fitted well, and the work was finished nice and smooth. A little oil on the tip of the wrench kept the stock from tearing. ROY B. DEMMING.

Geneva, N. Y.

A GOOD BOX TRUCK.

For convenience in handling our small brass fittings, both before and after machining, they are put into small wooden boxes and carried wherever wanted by means of a small truck, which is light, and easily handled, and which takes up little space when not in use.

The boxes are made of a good grade of one-inch lumber, and are 16 inches long, 10 inches wide and 9 inches deep, outside measurement. They are bound with heavy strap iron, making them very serviceable and long-lived. One of these boxes is shown in Fig. 1. The figures on the end denote

Figs. 1, 2 and 3. Box Truck for Shop Use.

weight of box. All boxes are marked this way for convenience in weighing, and their weight will vary from six to nine pounds.

The truck shown in Figs. 1, 2, and 3 is made in the factory for our own use only. The frame is made of seasoned oak, bolted together with ¼-inch bolts. The center piece or handle is 4 feet long, 2 inches wide, and 1¼ inch thick. The side pieces are 3 feet long, 1½ inch wide, and 1 inch thick. The frame is 12 inches wide, at top and 11 inches at bottom. The bottom of the frame is 2½ inches square, and through this is run a ½-inch bolt which serves as an axle for the wheels. The wheels are ordinary cast iron wheels, 1¼ inch wide by 4 inches diameter.

The iron work shown on the trucks is all hand-forged. The hook shown fastened to the center piece is also hand-forged, and is so made that it will lie back against the frame as shown in Fig. 2, and when the truck nose is shoved under a box, a quick jerk causes the hook to drop into position shown in Fig. 1.

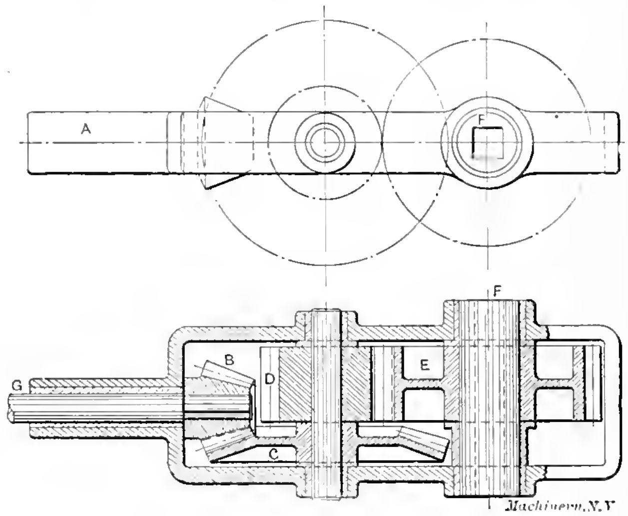
Holes are drilled through the center brace at various heights so that the hook may be placed in proper position for different sized boxes. A small cotter pin is used to keep the hook in whatever hole it is placed.

Reference to Fig. 1 will show that when the hook is in position to hold a box, there is a projection pointing to the rear so placed that the hook can be lifted out of the box with the foot. With very little practice, boys learn to handle boxes full of brass fittings quickly and easily without touching a hand to them. ETHAN VIALL.

Decatur, Ill.

RIGHT-ANGLE POWER HEAD FOR DRILLING AND REAMING HOLES.

The accompanying cut illustrates a right-angle power head which is used principally for drilling and reaming holes in locations where it is impossible to use the regular tools. Especially is the tool found very valuable where traction engines, locomotives, or cars are being repaired. It is often found that the pneumatic drill, or the electric drill, are too



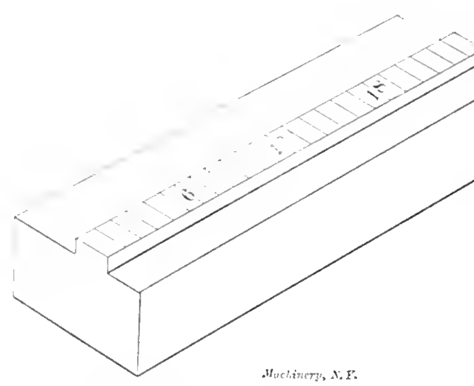
Right-angle Power Head.

large to be used, because of the lack of room, and the only tool that can be used is a ratchet. This power head requires less room than the ratchet. The drill or reamer fits into one end of the square socket *F*, and a small feed screw in the other. This socket is formed in a steel sleeve, which is keyed to the spur gear *E*, having 26 teeth, 5 pitch, and 1¾-inch face. The spur gear *E* is driven by the steel pinion *D*, having 14 teeth. On the same shaft with the pinion *D*, the steel bevel gear *C* is fastened. This gear has 36 teeth, 6 pitch, and 1¼-inch face. The main driving pinion *B* is made of hard brass, and it has 12 teeth. This pinion is keyed to the stub shaft *G*, which is attached to a flexible driving shaft. The shaft *G* can, of course, be driven in other ways if more convenient. The head frame *A* is made of cast iron, and each bearing is bushed with bronze. I believe that most shops will find this power head to be a valuable tool.

Denver, Col. T. B. BURNITE.

GRADUATING ON THE PLANER.

While the planer might not be considered the tool best adapted for graduating, I will describe a case in which I found it both accurate and quick. I had a number of drawn steel bars, from 4 to 12 inches long, to be graduated in sixths of an inch, as shown in the sketch. No miller was available, and the job was marked "rush." The 18-inch planer had a



Steel Bar which was graduated on the Planer.

double threaded cross feed screw with a 1/3-inch lead, and was driven through a 32-tooth ratchet wheel, so I set the feed to move 16 teeth at a time, which gave me a movement of 1/6 inch for every stroke. Putting the vise on the planer, and grinding a V-point tool, completed the preliminary arrangements. The bars were then put in the vise. The tool

was set to the proper depth and brought to the end of the work, after which it was only necessary to throw in the feed pawl and start the machine. The scales were cut at the rate of 5 inches per minute, which is very good time for an odd job. It was, of course, necessary to lift the tool on the return stroke.

DONALD A. HAMPSON.

Middletown, N. Y.

INDICATING FINISHED SURFACES—RECORDING CHANGES ON DRAWINGS.

The article by C. T. in the July, 1907, issue of MACHINERY, entitled Indicating Finished Surfaces, reminds me of a somewhat similar system of finishing marks which, to my mind, is simpler and fully as effective as the system mentioned by C. T., and which has also been in use for several years. In this system the various classes of finish are designated by number, as follows:

Finish No. 1 requires surfaces to be extremely smooth and accurate within a tolerance of ± 0.0005 inch.

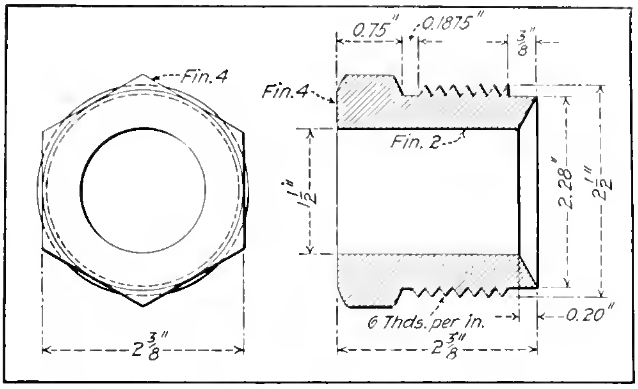


Fig. 1. System of Indicating Finished Surfaces, applied to a Drawing.

Finish No. 2 requires surfaces to be very smooth and accurate within a tolerance of ± 0.001 inch.

Finish No. 3 requires surfaces to be smooth and accurate within a tolerance of ± 0.003 inch.

Finish No. 4 requires surfaces to be accurate within a tolerance of ± 0.005 inch.

Finish No. 5 requires surfaces to be rough machined or filed to within a tolerance of ± 0.025 inch.

Finish No. 6 requires that castings or forgings be cleaned of all sand, scale, risers, fins, etc.; and that no thickness of

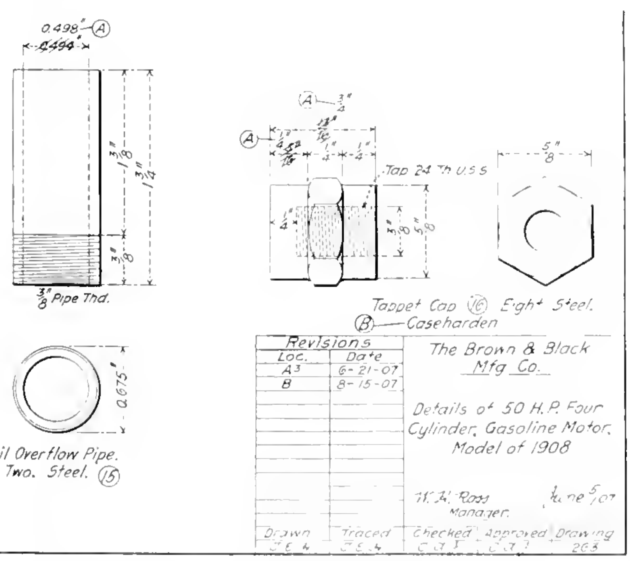

Fig. 2. Method of Recording Changes on a Drawing.

metal when ready to assemble shall differ from drawing dimensions more than ± 5 per cent.

All allowance for fit is to be made on the female parts. Male parts are to be made to the standard size.

With the above system, used on drawings as indicated in Fig. 1, work can be laid out to any degree of accuracy required and the workman readily knows between what limits of accuracy he must make any dimension. In cases where the piece can be made satisfactorily with one grade of finish all over, a note may be added to the name, etc., of the piece on the drawing to that effect. For example, the specification: Washer—Finish No. 4, attached to the drawing of a washer would indicate that no dimension need be worked closer than ± 0.005 inch to the specified sizes.

The recording of changes or revisions made on drawings of any kind is of the greatest importance, and Fig. 2 illustrates

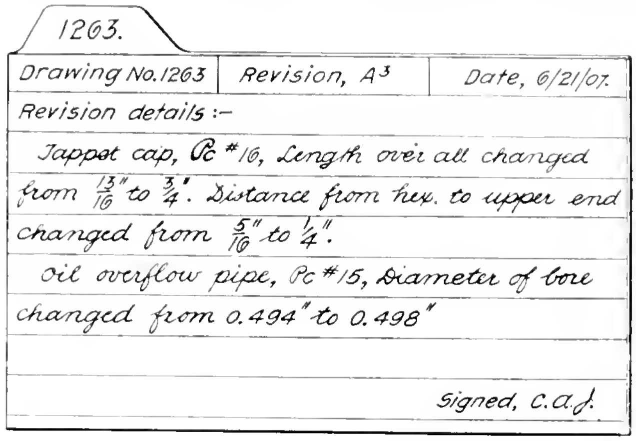

Fig. 3. Card System with Complete Record of all Revisions.

a very satisfactory method of recording changes on a drawing. The columns headed Revisions show the location on the drawing of dimensions revised and also the date when the revisions were made. The small figure at the right of the letter of revision in the column indicates how many places on the drawing the revision affects. For instance, the revision A^3 affects the drawing in three places, while *B* affects it in only one place, as shown. It is a matter of opinion as to how to remove the old dimension and place the new dimension in its place, but, personally, I very much prefer that the old dimension be merely crossed out and the new dimension be shown above it, as in Fig. 2.

It is advisable, on account of its simplicity and the possibility for ready reference, that a separate file of revision records for each type of machine being manufactured be kept. A card system, of some such form as shown in Fig. 3, is preferred by the writer, because its flexibility allows for sufficient expansion to cover all details concerning any revision that may be made in any drawing. The cards in the revision file are indexed by the drawing numbers, and are arranged in their several indexed spaces in the alphabetical order in which the revisions were made. By the above method a complete record of all changes, on any piece, shown on any drawing and belonging to any machine, can be kept in compact form and in condition for immediate reference at any time.

W. E. C.

FORMULAS FOR MILLING END MILLS AND CLUTCHES.

In the following the writer has shown the method by which a formula is arrived at for the correct setting of the index head of a milling machine for milling the teeth on the ends of end mills, on the sides of side or straddle milling cutters, etc. A formula is also deduced for the setting of the index head when milling the teeth of clutches.

Referring first to the question of end mills, let it be assumed that the number of teeth, and the angle of the angular cutter with which the teeth are to be milled are given. The angle sought is the one to which to set the index head of the milling machine. In Fig. 1 the problem is shown diagrammatically, the cutter angle *ADB*, and the number of teeth, *n*, being given, while the angle to which the index head is to be set (which is to be determined) is *BEC*. In order to simplify the calculations, assume the radius of the end mill to equal 1. Evidently, the length of the radius has no influence on the final result, or on our formula, anyway. The angle *BCM* represents the angle of one tooth of the end mill. Now, produce *CM* to *A* and draw *AB*. The line *CE* represents the bottom of the tooth, and the plane in which the angle of

the cutter for milling the teeth must be measured, is at right angles to CE, or in the plane BD (lower view of Fig. 1).

We can now arrive at the following equation:

$$\text{Angle } ACB = \frac{360 \text{ deg.}}{n}$$

$$\tan \frac{360 \text{ deg.}}{n} = \tan ACB = \frac{AB}{BC}$$

But BC = radius of end mill = 1, and consequently

$$\tan \frac{360 \text{ deg.}}{n} = AB \qquad (1)$$

The triangle ABD, shown at the right in Fig. 1, is in a

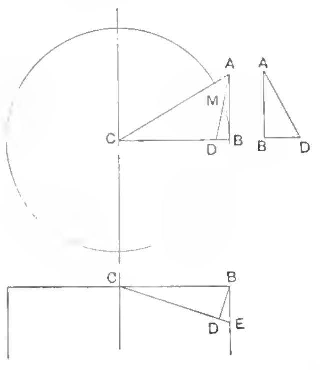

Fig. 1. Deriving Formula for setting Head for cutting End Mills.

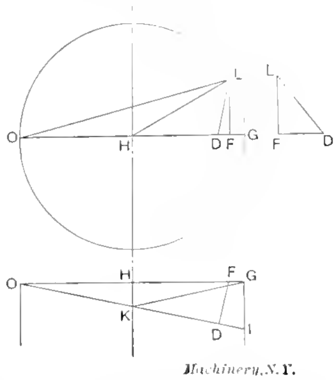

Fig. 2. Deriving Formula for setting Head for cutting Clutches.

plane perpendicular to the bottom CE of the tooth, the angle ADB being the cutter angle, as mentioned. Then

$$BD = AB \times \cot ADB = \tan \frac{360 \text{ deg.}}{n} \times \cot ADB \qquad (2)$$

The line BD, however, also lies in the plane containing the right triangle CDB. We have, therefore,

$$\cos CBD = \frac{BD}{BC} \qquad (3)$$

But BC = radius of end mill = 1, and consequently, from (2) and (3):

$$\cos CBD = BD = \tan \frac{360 \text{ deg.}}{n} \times \cot ADB \qquad (4)$$

The angle CBD equals the angle BEC, or the angle to which to set the index head; therefore,

$$\cos BEC = \tan \frac{360 \text{ deg.}}{n} \times \cot ADB, \text{ or, expressed in words:}$$

The cosine of the angle to which to set the index head equals the tangent of the tooth angle multiplied by the cotangent of the angle of the cutter by which the teeth are cut.

[This formula, expressed in words, was contributed by Mr. George Porter to MACHINERY, April, 1904, but the derivation was not given in Mr. Porter's article. For table see MACHINERY Data Sheet, May, 1904.—EDITOR.]

Clutches, in order to fit into one another, must have the bottom and top of the teeth inclined at corresponding angles, as shown by lines KG and KI in Fig. 2. Assume that the number of teeth n and the cutter angle LDF are given, and that the radius $HG = 1$. The angle LHG = 360 degrees divided by the number of teeth. Draw LF through L perpendicular to OG. The line KI represents the bottom of the tooth. Produce KI to O. The plane in which the angle of the cutter for milling the teeth must be measured, is perpendicular to OI. Assume, therefore, that the angle is measured in a plane FD (see lower view of Fig. 2). Angle $LHG = \frac{360 \text{ deg.}}{n}$.

$$LF = \sin LHG \times HL = \sin \frac{360 \text{ deg.}}{n}$$

The triangle LFD, shown at the right in Fig. 2, is in a plane perpendicular to the bottom KI of the tooth, or perpendicular to OI, the angle LDF being the cutter angle, as mentioned. Then $FD = LF \times \cot LDF = \sin \frac{360 \text{ deg.}}{n} \times \cot LDF$.

But FD also lies in the plane containing the right triangle ODF. Therefore,

$$HF = \cos LHF \times HL = \cos \frac{360 \text{ deg.}}{n}$$

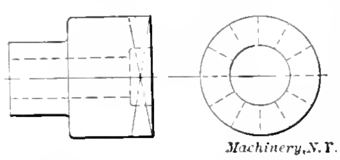
$$OH = 1.$$

$$OF = OH + \cos \frac{360 \text{ deg.}}{n} = 1 + \cos \frac{360 \text{ deg.}}{n}$$

$$\cos OFD = \frac{FD}{1 + \cos \frac{360 \text{ deg.}}{n}} = \frac{\sin \frac{360 \text{ deg.}}{n} \times \cot \text{cutter angle}}{1 + \cos \frac{360 \text{ deg.}}{n}}$$

The angle OFD equals the angle OIG, or the angle to set the index head. Therefore the previous formula expressed

TABLE OF ANGLES TO WHICH TO SET HEAD-STOCK OF MILLING MACHINE WHEN CUTTING CLUTCHES WITH ANGULAR CUTTERS.



The cosine of the angle to which the milling machine index head is set, equals the sine of the tooth angle multiplied by the cotangent of the cutter angle, divided by the cosine of the tooth angle plus 1.

No. of Teeth.	Angle of Cutter. 60°	70°	80°	No. of Teeth.	Angle of Cutter. 60°	70°	80°
5	....	....	82° 12′	18	84° 9′	86° 19′	88° 13′

16	83° 24′	85° 51′	87° 59′	29	86° 24′	87° 44′	88° 54′
17	83° 48′	86° 6′	88° 7′	30	86° 31′	87° 48′	88° 56′

in words, reads: *The cosine of the angle to which to set the index head, when cutting clutches, equals the sine of the tooth angle multiplied by the cotangent of the cutter angle, all divided by the cosine of the tooth angle plus 1.*

The accompanying table gives the angles for setting the index head when cutting clutches, figured from the formula given. IRVING BANWELL.

Belvidere, Ill.

TO CALCULATE THE SIDE OF AN INSCRIBED POLYGON.

Sometimes we do not have our tables handy, and in such a case it is advantageous to know how to construct one, or to calculate a quantity for ourselves. Take, for instance, the length of the side of an inscribed polygon of any number of sides, which increases in geometrical proportion by two, as in the series 4, 8, 16, 32, 64, etc. To solve this problem we can start with the fact that when the radius is unity, the side of the inscribed square will be $\sqrt{2} = 1.4142$. Then the values of the other terms of the series will be as follows:

$$4 = \sqrt{2} = 1.4142$$

$$8 = \sqrt{2 - \sqrt{2}} = \sqrt{2 - 1.4142} = \sqrt{0.5858} = 0.7654$$

$$16 = \sqrt{2 - \sqrt{2 + \sqrt{2}}} = \sqrt{2 - \sqrt{2 + 1.4142}} =$$
$$\sqrt{2 - \sqrt{3.4142}} = \sqrt{2 - 1.8477} = \sqrt{0.1523} = 0.3902$$

and so on, the signs always commencing with minus and then alternating with minus and plus. ROBERT GRIMSHAW.

Hanover, Germany.

IMITATIONS OF AMERICAN MACHINE TOOLS.

The complete and painstaking imitations of American machinery, which a number of German firms are now engaged in manufacturing, is a matter which must sooner or later be considered as a factor having more or less effect on the extent of American foreign trade. It has fallen to the lot of the writer to be in a position where this practice is under his constant and direct observation, and he believes the time has come when a word must be uttered for the benefit, or at least, information, of the people who have spent time, study and money in perfecting and patenting their ideas. Not only is the manufacturer concerned in this subject, but the firms that handle American machinery abroad stand to lose considerable, should there be found no method of checking this piracy.

Almost invariably, before a new machine can be successfully sold in Europe, there must be considerable sums of money spent in advertising and demonstrating, and, as only a short time elapses before one or more of these "Nachahmen" firms has the matter under consideration, it generally happens that about the time the American machine is meeting the approval it deserves, there is quietly insinuated on the market, a "made in Germany" article, which, as far as appearance is concerned, might have been the issue of the same parentage. However, some small amount of comfort can be derived from a consideration of the results.

In one case in which I was personally interested, an American automatic was purchased by a Berlin firm, and a German imitation was installed beside it on the same work. The German machine had the advantage of national prejudice, but I was proud to find that the weekly output was 15 per cent in favor of the American article. The fault in this case was with the spindle, which was not properly scraped in, and in consequence heated frequently.

A friend of mine was once traveling through China. He had a pair of duck trousers which had seen service in the Philippines, and he decided to order a more presentable pair to wear when returning home. So he took them to a Chinese tailor and gave him orders to make another pair exactly like the sample. He received them in due time, and the practical example of the Chinaman's ability to make a perfect copy of a given article, as demonstrated by the work done on those duck trousers, left an impression which nothing could remove. John Lee had faithfully reproduced every detail, the most striking of which was a fair-sized hole, which in the case of both the original and the copy could only be hidden when the wearer assumed a position of rest.

So also is the case here, but I believe the idea in so faithfully copying every detail and not adding any improvements is because of the danger they incur of making something which will not run.

An acquaintance of mine here, a Pennsylvania Dutchman, owner of a small shop, was once in need of a grinding machine. He was visited by one of these "plagiarists" and received an offer of a "made in Germany" grinder at a few dollars reduction in price. A superficial inspection of the machine convinced my friend that it was made in the image of a well-known American design, but a point he almost immediately noticed was that while one center was ground to a 60 degree angle the other was finished at a much blunter angle.

This startled my friend and he pointed out the difference. The maker answered, "Yes, but that is nothing to complain about. Why should a little difference in angle be of any account? The machine is the same as your American grinder." "Yes," answered my friend, "but if you have exercised the same judgment in copying the machine as you have in the centers (which is of the most vital importance), I guess I'll look somewhere else for a grinder. I wouldn't take your machine as a gift."

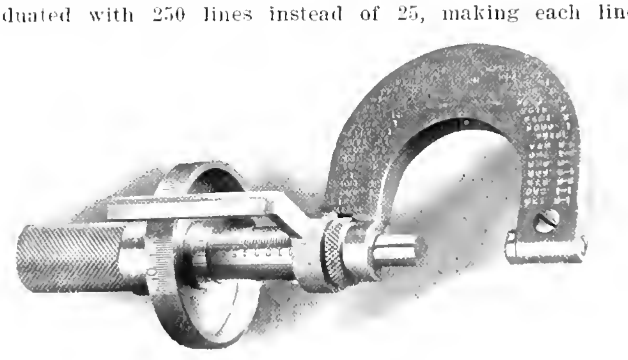
A striking case of so-called improvements was in evidence at the Automobile Show recently held in Berlin. A firm whose business is almost exclusively the copying of the well-known Cleveland automatic, had a machine on exhibition made after the design of the new 3-hole automatic recently brought out in Cleveland. Now, as is well known, the feature of the regular Cleveland automatic is the differential feed through adjustable cams and friction disks.

The 3-hole machine is a special machine designed with a view to cheapness, positive feed and speed, and adaptability for a great range of work. This German concern copied the construction of the machine made necessary because of the changed feed, and then in addition put in the friction feed, etc. The result is a hybrid that is neither ornamental nor useful. The feed is neither regular nor positive, as was demonstrated by the trouble they had in attempting to use a geometric die head. On account of the trouble they had in keeping the feed regular, the die would sometimes open too soon and at other times not at all. However, the natural desire to save a few dollars which actuates most buyers of machinery, often prevents the sale of the original article, and for this reason the writer believes something should be done by American manufacturers, if possible, to correct the evil. DAVID R. MILLINGTON.

Berlin, Germany.

MICROMETER ATTACHMENT FOR READING TEN-THOUSANDTHS.

The accompanying half-tone illustration shows an attachment for micrometers which I designed and made for reading in tenths of thousandths. With very little fitting it is interchangeable for 1, 2 or 3-inch B. & S. micrometers. The idea is simple, as can be seen by the illustration. The diameter of the thimble was increased 3 to 1 by a disk which is graduated with 250 lines instead of 25, making each line



Micrometer with Attachment.

represent 0.0001 inch instead of 0.001 inch. A piece of steel was then turned up and bored and cut away so as to form the index blade and a shell to clasp the micrometer frame, the whole thing being made in one piece. The thimble disk being just a good wringing fit, it can be easily adjusted 0 to 0. The attachment can be removed when fine measuring is not required. P. L. L. YORGENSEN.

Hartford, Conn.

METHOD OF TRUING UP OILSTONES.

There seem to be a great many mechanics who do not know how to true up their oilstones. Every now and then you will see a man spoil a good stone by trying to grind it true on the emery wheel, which usually cracks the stone into several pieces, or checks it with fine cracks which sometimes are almost invisible to the naked eye. My method of truing up an oilstone may not be new to all, but I know from experience that there are many who do not know about it. Take a piece of planed cast iron, and cover the machined surface with loose emery mixed with water. Then place the oilstone upon this surface and grind it true. This can be quickly done if water is used with the emery, as water is much better than oil for this purpose. I have trued up many kinds of stones in this manner, from a coarse India oilstone, to a fine Swaty razor-hone. Stones with special shapes may be formed by planing a groove of the desired shape into a cast iron block, and then drawing the stone back and forth through this groove, using emery and water as before. Those who try this method of truing up an oilstone will find the results satisfactory, and stones which are much worn and useless, can be made almost as good as new. J. J. VOELCKER.

Decatur, Ill.

SHOP KINKS.

A DEPARTMENT OF PRACTICAL IDEAS FOR THE SHOP.

Contributions of kinks, devices and methods of doing work are solicited for this column. Write on one side of the paper only and send sketches when necessary.

DESCRIBING A CIRCLE AROUND A DRILLED HOLE.

Occasionally it is required to describe a circle about a small drilled hole, the method in vogue being to do this with dividers and a ball center. In the absence of the latter, the dividers can be used by putting a sharp prick punch mark in a buckshot, inserting one leg of the dividers firmly in this mark, and proceeding as usual. DONALD A. HAMPSON.

Middletown, N. Y.

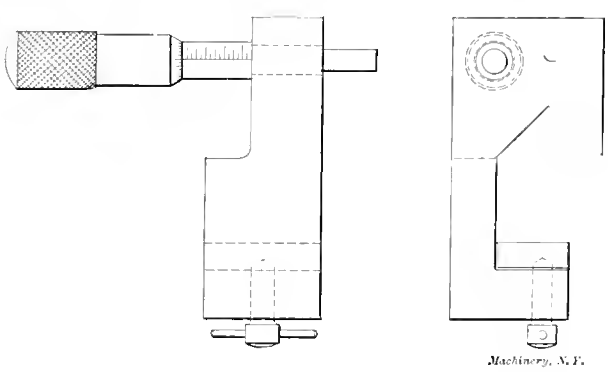
A TIME-SAVING DRAFTING KINK.

A great saving in time, which even well systematized drafting rooms seem to overlook, can be effected by putting one or two tracers to work cutting up a quantity of standard sizes of tracing cloth, drawing the border lines around them, stamping them with the standard marking, simply leaving out the name of the piece, date, and draftsman's initials, which, of course, are filled in when the tracing is made. This saves every man going and cutting up a piece of tracing cloth each time he is to make a tracing. It makes it very convenient for the tracers as they can get the size sheet they want, tack it down, and trace in the drawing right away, without bothering with cutting to size, measuring the outline, and putting on the borders and title stamp. This plan also saves a lot of waste of tracing cloth. F. L. ENGEL.

New Britain, Conn.

MICROMETER STOP FOR THE LATHE.

The micrometer stop shown herewith is used on the engine lathe for obtaining accurate movements of the lathe carrriage. It consists of a micrometer head, which can be purchased from any micrometer manufacturer, and a machine steel

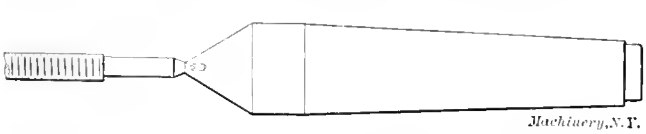


body which is bored to fit the micrometer head. This tool is clamped on the front way of the lathe bed, and when the jaw of the micrometer is against the lathe carrriage, it can easily be adjusted to the thousandth of an inch. Of course, care should be taken not to bump the carriage against the micrometer. J. L. MARSHALL.

Dayton, O.

TURNING AND THREADING NEEDLE POINTS FOR CARBURETERS.

The accompanying cut shows a little kink which saved time and trouble in the shop where I am employed. We were turning and threading needle points for large engine carbureters. These were made from brass rods 5/16 inch in diame-

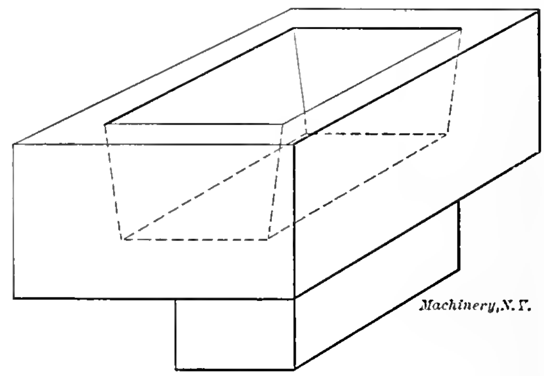


ter, by 4⅞ inches long. The rod was first held in a small chuck and beveled on one end. It was then pulled out a little over 4⅞ inches, and we were then ready for turning and threading the piece. In order to be able to get a support for the pointed end, we drilled a center hole in the tail-stock center of the lathe, and placed the rod with its 60-degree beveled end in the tail center, as shown in the cut. By this means it was possible for us to turn and thread the needle points without much trouble. J. D. COE.

Lansing, Mich.

BABBITT RIVETING BLOCK.

Some time ago one of the boys told me he was tired hunting up new pieces of babbitt or lead to rivet on, so I fixed up a "wrinkle" that helped him out finely. I asked the patternmaker to make a pattern for a little box, as shown in the accompanying cut, and from it got a half dozen castings. The lug on the bottom makes it convenient to hold in the vise. The

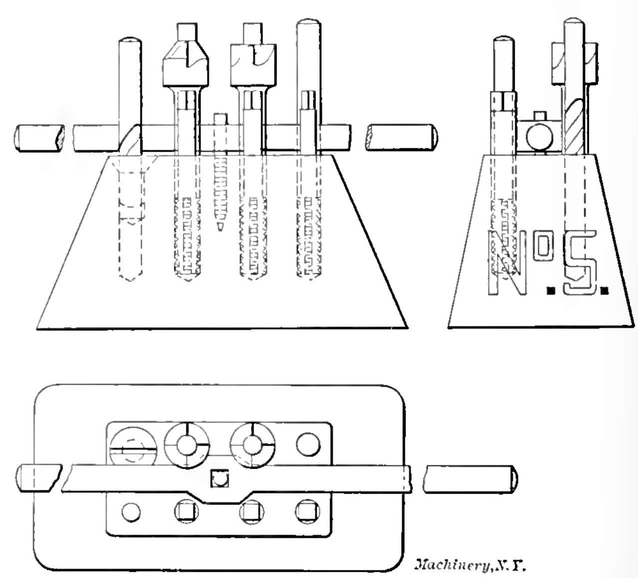


hollow top is poured full of babbitt (or lead), thus forming a soft anvil that lasts much longer than a plain piece of babbitt, as it is supported on all sides by hard metal which prevents the mushroom effect. When the babbitt gets so battered up that it cannot be used longer, we hold the block in the flame a few moments until it melts, and then pour the babbitt over again. The scheme saves time and babbitt, *i. e.*, money. C. H. RAMSEY.

Paterson, N. J.

BLOCK FOR HOLDING TAPS AND TAP DRILLS.

The accompanying cut shows a block which has proved very handy in our shop. It is intended for holding the three taps in the set, one tap drill, one full size diameter drill, one counterbore, one counter-sink, and a tap wrench. By having the tool-room provided with blocks such as these, when a man wants taps and drills or counterbores for a certain job, he simply asks for block number so and so, and he receives then



the block with all the accompanying tools. There is a great deal of time saved as compared with such systems where the man first has to ask for the taps, and then for the tap drill, and finally for the counterbore and counter-sink. Such methods in a shop tool-room ought to be considered obsolete. Tools belonging together should be kept together, and the best way for doing this is undoubtedly by using some kind of a block similar to that shown in the cut. F. RATTEK.

Brighton, Mass.

NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

THE GRIDLEY MULTIPLE SPINDLE AUTOMATIC SCREW MACHINE.

The following paragraphs and the accompanying engravings describe and illustrate a new multiple spindle automatic screw machine, the invention of Mr. G. O. Gridley; it is built by the Windsor Machine Co., of Windsor, Vt., maker of the Gridley automatic turret lathe.

In the principle of its action (see Fig. 4), this tool follows the same plan as other commercially successful machines of its type. It is provided with an indexing head, carrying a number of revolving spindles. Each of these has a chuck and feeding collet for holding and handling the stock, of which there are as many bars as there are spindles—in this case, four. A tool-slide is provided, with a place for a tool opposite each work spindle, with means for feeding the tools simultaneously toward the head. Cross-feeding tool-holders for forming and cutting off are also provided, operating on the bar whose spindle is in position opposite it at the time. The spindle head is indexed periodically to bring each bar of stock in turn opposite each of the tools in the tool-holder, and in position to be formed and cut off as well, these operations all taking place simultaneously on different bars of stock. Thus a completed piece of work—turned, threaded, formed and cut off—is produced for each indexing of the spindle head.

The time required to complete a piece of work is the time required for the longest operation, plus the time consumed in the so-called "idle" movements. Sometimes, as in the turning operation in Fig. 4, a long operation may be split in two, thus materially increasing the output per day. All the other operations, except the longest, are, of course, working at less than the maximum feed of which they are capable, so that conditions are favorable to good work.

Mechanism by which the Machine is Operated.

The mechanism used to accomplish these various movements will be best understood by referring to the rear view of the machine, Fig. 2, in connection with Fig. 1.

The revolving head has a stem or shank solid with it, on which is mounted the "turret" or tool slide. This latter is guided in alignment with the work spindles by a fork having a carefully fitted bearing on the tie-piece D.

Driving pulley E is keyed to a shaft which passes through the hollow shank to the rear of the head, where it carries a gear meshing with the driving gears of the spindles, which are thus rotated continuously in the same direction, without provision for stopping or reversing. (See also Fig. 5.)

The various movements of the machine are all controlled by a cam-shaft F, at the rear of the machine. This cam-shaft may be driven at either of two speeds. One of them, that for feeding the tools, is obtained from spindle driving pulley E, through a double worm reduction and the quick change gear mechanism in the gear box. For the rapid movements, constant speed pulley G is connected by a friction clutch with the worm-shaft J, by which the cam-shaft F is revolved. When this is done, the worm-shaft runs ahead of the slow movement given it by its connection with the spindle, a ratchet mechanism being provided for this purpose. The throwing in of this fast motion is effected by clutch lever K, operated by adjustable dogs on disk L. By adjusting these dogs, the rapid and feeding movements of the cam-shaft may be made to occupy their proper respective portions of the complete cycle.

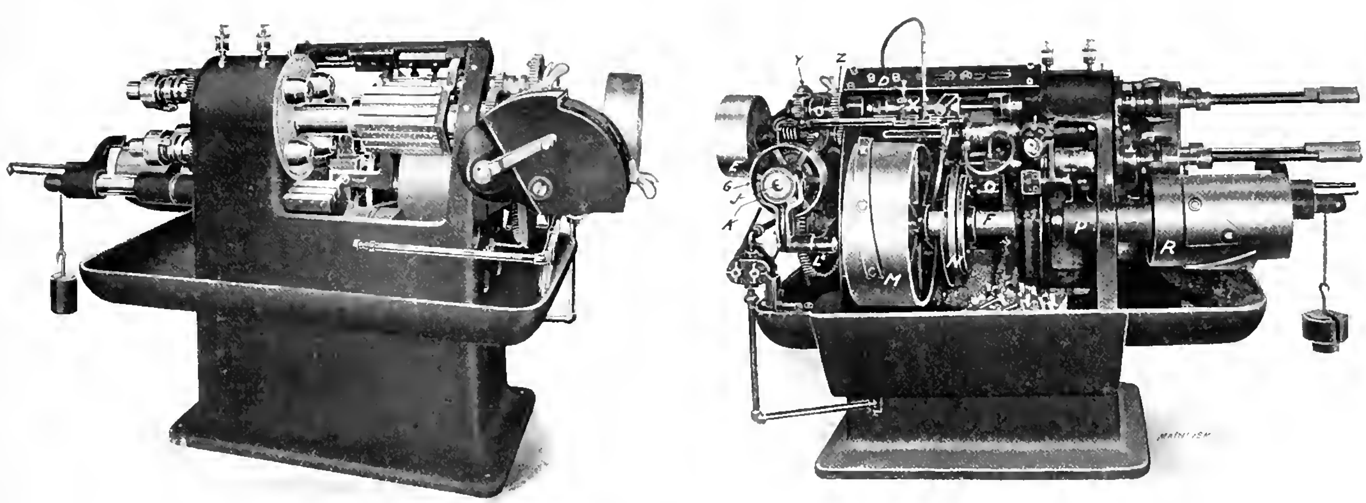
The longitudinal feed cam M acts on a roll at the rear of the tool-slide. Three cam-plates are furnished, having a 2-, 4- and 6-inch throw, respectively, of which the proper one for the length of the work in any given case is used. This cam, of course, advances all the tools on the slide simultaneously. This movement is positive for both advance and return, no springs being used.

The forming and cutting-off tools are mounted on pivoted holders, which are rocked toward and away from the work by positively acting face-cams on either side of disk N. Cutting-off tool-holder O also carries the stock-stop, which is presented to the work spindle opposite it just before feeding commences, after the preceding piece has been cut off.

Indexing arm P is the next member on cam-shaft F. This carries a cam which withdraws the revolving head lock bolt Q. It also carries a roll which engages slots in the inner face of the revolving head, the combination working on the plan of the Geneva stop motion, which is the standard mechanism for indexing heavy parts with a maximum of rapidity and a minimum of shock.

Last in order, at the outer end of the shaft, come the cams for operating the rod feed and chucks. These cams are mounted on drum R. The stock is fed forward by the usual feed tube and gripping collet, operated by a weight to give the required rapidity of action. The feeding movement for each spindle takes place when it is in the lower rear position.

The threading tool, tap or die, is mounted on spindle X, opposite the upper rear position of the work spindle. Spindle X is connected with the main driving shaft by either of gears Y or Z, depending on the position of the clutch between them. In beginning the threading operation, gear Y is clutched to spindle X, which is thus revolved at a slightly slower speed than the work. The threading tool is then pressed against the work by a cam, and the threading proceeds at a suitable surface speed. When the proper length has been threaded, a trip is released which throws the clutch to engage gear Z, which drives the tap or die faster than the work, thus screwing it off.



Figs. 1 and 2. Front and Rear Views of the Gridley Multiple Spindle Automatic Screw Machine.

Cycle of Operations.

The writer saw the machine in operation, making the hexhead cap screw shown at *e* in Fig. 4. The making of this screw will be readily understood, with the preceding description of the mechanism in mind.

We will follow the movements of one of the four bars of stock, starting with it in the front lower position, fed to length, as shown at *a*. When the tool-slide is fed forward, the tool opposite this position (a turner similar to that shown in Fig. 7) takes the cut at the end of the bar as shown at *b*,

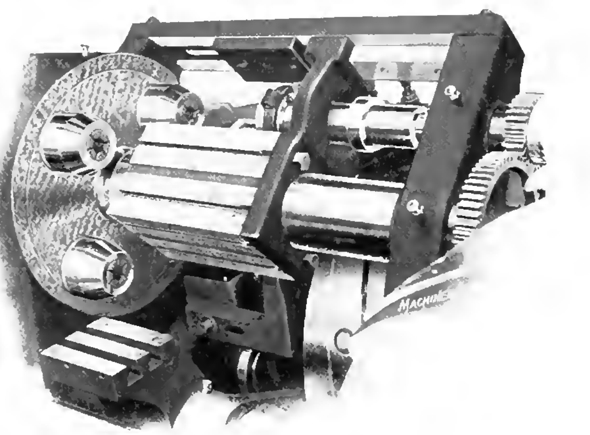


Fig. 3. Detail View of Spindle Head and Tool-slide.

while the forming tool necks the stock. At the completion of this cut the quick movement of the cam-shaft is thrown in, drawing back the tool, revolving the head, and bringing the tools up again. The bar of stock we are following is now in the front upper position where a second tool completes the turning operation, as shown at *c*. Dividing the turning into two operations increases the output, as previously explained. The head is now again indexed, and this spindle is brought opposite the threading die, which is slowly threaded on to the proper length by the mechanism previously described, and then threaded off again, without requiring the reversal of the spindle. The work, now in the condition shown at *d*, is next

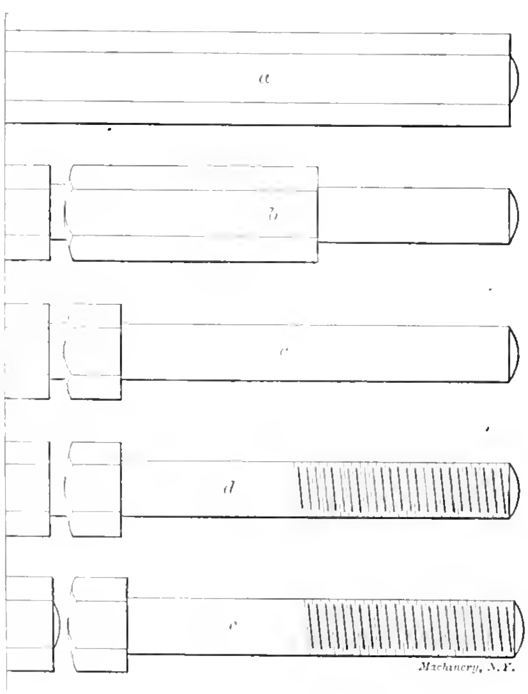

Fig. 4. Cycle of Operations on Hexagon Head Cap Screw.

brought down to the lower rear position, where it is cut off as shown at *e*. Immediately after it is severed from the bar, the cut-off tool recedes, bringing the stop into line, and the stock is fed forward to it while the other tools are being withdrawn from the bars on which they have been operating.

The Central Theme of the Design.

From the preceding description, it will be seen that the mechanism of this machine is simple, ingenious and effective, and therefore worthy of study. The chief interest in the design, however, centers about a definite constructive principle, which is the foundation on which the tool is built. This idea can be best understood by referring to Fig. 5, which shows the machine partly disassembled.

The prime difficulty in practically applying the multiple spindle scheme, is that of indefinitely preserving the alignment of the spindles with the tools. Fine workmanship may have established correct conditions at the start, but a little wear throws the parts out of line, and it is practically impossible to provide adjustments which will return them again to their proper place.

The reason for the existence of this particular multiple spindle automatic screw machine is seen in the construction of the head, shown disassembled on the floor in Fig. 5. It will be seen that this is a rigid casting, solid with the shank which carries the tool-slide. This shank has a bearing in the frame at the right. This is different from the usual construction, in which the comparatively short length of a large diameter head is depended on to preserve the alignment. It will be easily seen that a considerable wear of the bearing surface would have to take place before the head could "wobble" out of line, guided in parallelism as it is by the long shank.

Besides this, the tool-slide is mounted directly on the shank and moves with it, should the head get out of line. This is

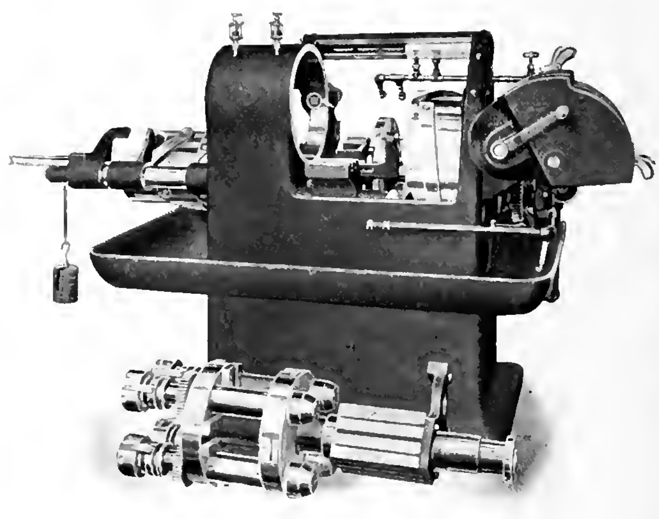

Fig. 5. The Machine Partially Disassembled, showing the General Scheme of the Design.

not the case with the usual construction, in which the head and the slide are separately supported by the base of the machine, each free to wear out of line or be mis-adjusted, without reference to the other. The value of this arrangement will be at once appreciated.

Preserving the Alignment.

Another radical step has been taken by Mr. Gridley to preserve the alignment of the spindles with the tool-slide as long as possible. This will be best understood by referring to Fig. 6, which shows an axial section through the head and one of the spindles. It will be seen that spindle *T* revolves in a bushing *U* of "Lumen" metal—solid and absolutely unadjustable. This is directly opposed to common practice, which provides elaborate adjustable boxes for the work spindles, with means for taking up the wear as fast as it occurs. The plan in this machine is to give the spindle a bearing of unusual area, in the best metal obtainable, with a fit as nearly perfect to begin with as the expert machinist can produce. With the low pressure per square inch to which such a bearing is subjected, and with the high-grade materials used, the expectation is that long continued use will be required to show anything more than negligible wear. The contention is, that where adjustments are furnished, adjustments will be required, for the parts will be continually getting out of their proper position, by working loose or by being tampered with by ignorant operators. We are believers in the correctness of this idea of carefully fitted, non-adjustable bearing of great area, and recommend it to the consideration of machine designers in cases like this, where the unit pressure can be

brought very low. Incidentally, the construction of the machine is greatly simplified, though this is not the purpose of the design.

If the time ever comes that the spindle wears loose, the old bushing *U* is removed and a new one inserted—a simple and satisfactory way of keeping the machine in good condition. There are two or three other points that may be mentioned in connection with this matter of permanency of alignment. The same plan of non-adjustability, careful fitting and large bearing area has been followed in the case of the bearing of the tool-slide on the shank of the spindle head, and the advantages of the construction apply here with equal force. Note also that the spindles are driven by gears *V* (see Fig. 6) flush with the end of the bearing, so that the lateral thrust is not multiplied by a lever action, as is the case when they are located at a considerable distance from the bearing. Being gear driven, the lateral thrust is, of course, less, anyway, than would be the case with belt-driven spindles.

It will be seen that the form of tool-slide used is an important factor in the matter of preserving the alignment. In the first place, the tools do not overhang at all—see the turning tool in Fig. 7, for instance. Besides this, the surface by which the slide is guided (the bearing of the fork on tie-piece *D*) is of a much greater diameter than the circle which contains the axes of the tool spindles, so that even if there were looseness here, it would be diminished instead of multiplied at the tool point. In the same way, the locking of the spindle head takes place on a large diameter.

The form of tool-slide used (identical with that of the Gridley single spindle turret lathe) has also the advantage of allowing the use of multiple tools at the same station to take cuts on different diameters, for instance, or to turn and drill simultaneously.

Points of Interest in the Mechanism.

Referring to the description of the mechanism, it will be remembered that the rapid movement of the cam-shaft is driven from a constant speed pulley, while the feeding movement is derived from the pulley which drives the spindles. This is as it should be. The rapid movements invariably take place at the fastest speed possible, if the speed of pulley *G* is properly selected; and since the feeding movement is con-

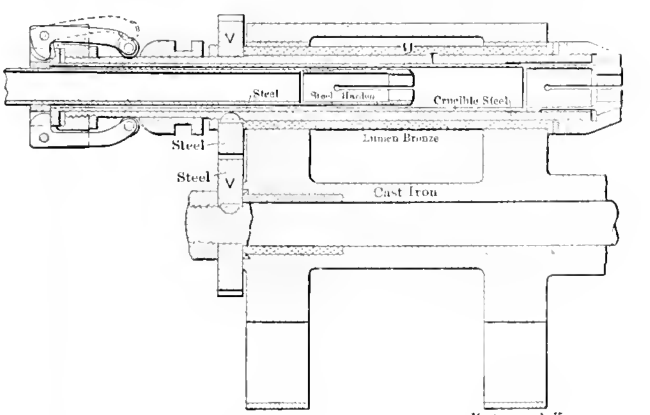

Fig. 6. Axial Section through Spindle Head and Spindle.

nected with the spindle, a given combination of gearing gives a definite feed in turns per inch, no matter what the speed of the spindle. This condition is the same as in the case of the lathe, and is the proper arrangement for any turning machine.

In the five months or more during which this machine has been in use, the value of the quick change mechanism for the feed has been steadily impressing itself on the minds of those who have used it. The machine may be set up with the tools properly adjusted for the work, without reference to the feeds; then, when the machine is started, the operator begins with a fine feed, gradually increasing it until the thickest chip is reached that the tool will stand. If a hard lot of steel is met with, the feed is lowered; if the tool appears to be taking it easy, the feed is increased. These adjustments would seldom be made if it were necessary each time to stop the machine and alter a set of change gears.

As previously noted, there are three cams furnished for the tool slide movement, giving 2, 4 and 6 inches of travel respectively. There are two handles on the feed box. When the lower one of these is set in that one of its three positions which is marked to agree with the cam which is being used, the adjustment of the upper handle will give a certain definite range of feeds, *viz.:* 75, 100, 125, 150, 175 and 200 turns per inch. Other feeds can, of course, be obtained by using other combinations of handle position. These handles operate two shifting idler and gear cone mechanisms, arranged in series.

The threading mechanism is an attractive one. This operation is made entirely independent of the others, by the way

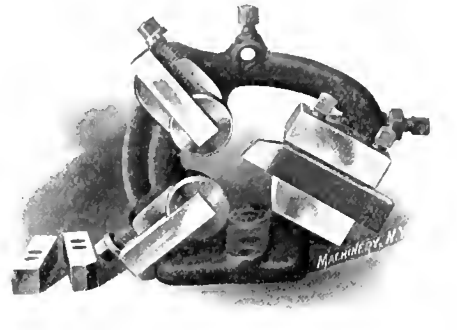

Fig. 7. Type of Turning Tool Used.

in which the die or tap is made to thread on or off by changing its feed relatively to that of the work, which remains unaltered. Left-handed tools are not required for turning and drilling operations, and the die has been threaded off by the time the other operations are completed, it not being necessary to wait for the return motion of the tool-slide to accomplish this.

Rigidity and Simplicity.

It will be seen that the central idea of the design of the head and tool-slide has resulted in a very rigid construction of the frame of the machine. (See Fig. 5.) The frame is all one piece, tied together at the top, so that all the strain of the feeding pressure is taken care of practically in simple tension, no bending action taking place. Above all, it should be noted, in this particular, that the bearing surfaces are free from cramping strains, the action of the feed-cam *M*, directly in back of the tool-slide, being an important item in this respect.

In the details of its mechanism, also, the machine has a noticeable simplicity and ruggedness. This is best seen in the rear view, Fig. 2. The members of the operating mechanism are strong, simple and few. There is nothing to get out of order, and everything is in sight. Strange to say, there are actually fewer parts in the tool than in one of the builders' single spindle machines.

The machine described above will take stock up to 1¼ inch in diameter, and will turn up to 6 inches in length. It weighs about 4,500 pounds.

MOTOR DRIVE MECHANISMS FOR LE BLOND LATHES AND MILLING MACHINES.

We show herewith a series of ten half-tone and line engravings, illustrating the solution of the motor drive problem for lathes and milling machines, arrived at by the R. K. Le Blond Machine Tool Co., 4605 Eastern Ave., Cincinnati, Ohio. These figures are particularly valuable as illustrating a consistent and systematic series of five designs, following the same general principles, but modified to suit the particular conditions under which they are used.

General Features of the Motor Drive Problem.

It is perhaps not necessary to say much about the comparative advantages of motor *versus* belt drive in connection with this line of machines, except as the general excellence of the design in this case enhances the points in which the motor drive appears to an advantage over its competitor. A greater number of speeds for a given range is obtainable with either the constant speed or variable speed motor drives than is ordinarily obtained by the cone pulley and back gear method. The advantage of this is evident. If it is not pos-

sible to run the work within 12 or 20 per cent of the speed at which the chip ought to be taken, it is evident that there is a waste of that amount constantly going on as long as the machine is in operation. There are also the well understood advantages of greater flexibility in arrangement of the machinery owing to the absence of line-shafts and counter-shafts; avoidance of transmission losses due to improperly designed and cared for belt and shaft transmissions; and avoidance of

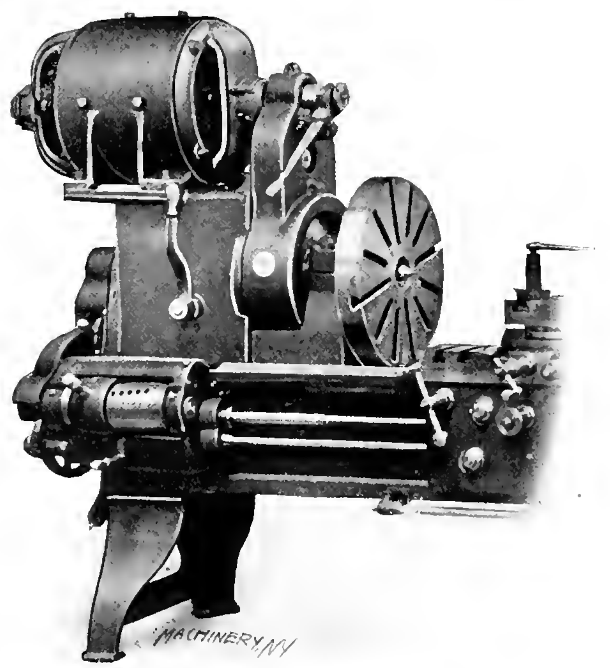

Fig. 1. Variable Speed Motor with Double Back Geared 20-inch Lathe.

the expense of running the whole system of shafts and belts for the sake of a comparatively few tools during slack times or long overtime work.

There are a number of factors entering into the design of motor drives for machine tools. There is, first of all, the question of the electrical system used—whether direct current single voltage, direct current multiple voltage, or alternating

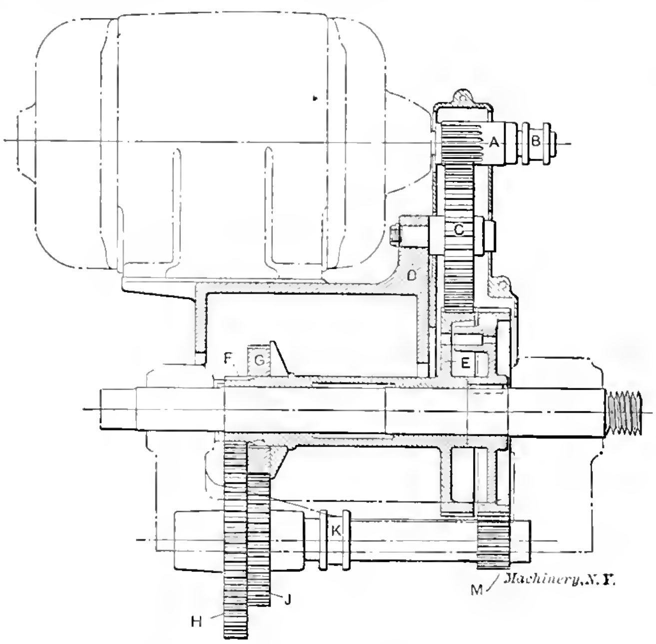

Fig. 2. Diagram of the Drive of the Lathe shown in Fig. 1.

current. With this matter, however, the machine tool designer has nothing to do, except as the system adopted requires the use of a constant speed or multiple speed motor. The arrangement of the gearing is vitally dependent on this question, as many more mechanical speed changes will have to be provided in the first case than in the second. Besides these electrical considerations, there are others which relate to the handiness, durability and efficiency of the mechanism. It should have as few parts as possible, consistent with the number of speeds it is desirable to furnish; changes should be quickly made without stopping the motor; the motion should be positive, and the parts should be strong and durable. In cases where a lot of mechanical changes are to be provided for, it is also an advantage to be able to change from one speed to another without going through all the intermediate steps. In other words, the control should be "selective."

Since provision is made in the Le Blond lathe for threading without reversing the spindle, no mechanical device for this is necessary. On the rare occasions when it might be necessary to run the spindle backward, the motor may be reversed, if electrical provisions are made for this. This simplifies the d sign greatly.

Lathe Driving Mechanism for Variable Speed Motor.

The problem evidently divides itself into two sections—those of providing mechanisms for variable speed, and constant speed motors, respectively. We will first consider the case of the variable speed motor. For lathes, the speed ratio should be from 40 to 1 up, depending on the size, if the lathe is to be used for the ordinary wide range of work. The most useful and satisfactory range of speed obtainable in variable speed motors is seldom much over 3½ to 1; so for small and medium-sized lathes it is evidently necessary to provide three mechanically-obtained speeds, each about three and one-half

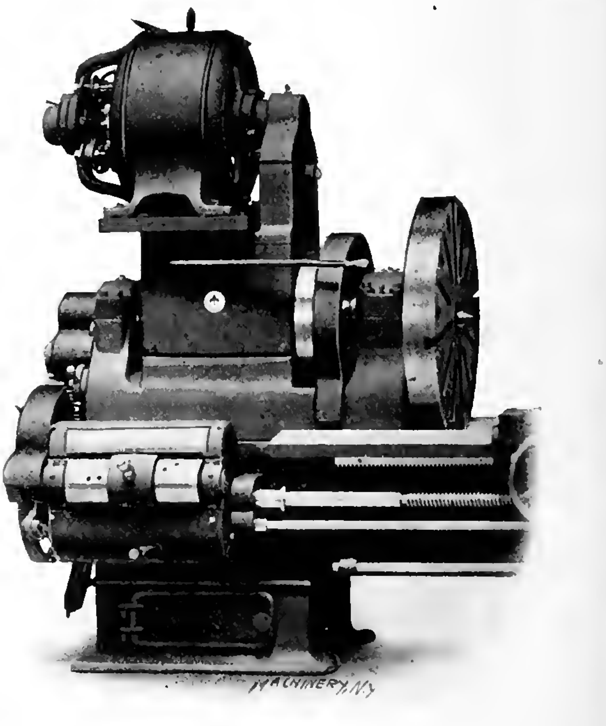

Fig. 3. Variable Speed Motor for 24-inch Lathe requiring Greater Speed Range than in the Case of Fig. 1.

times as rapid as its predecessor. This is done in the case of the 20-inch lathe shown in Fig. 1, by the driving mechanism shown diagrammatically in Fig. 2. The motor is mounted on a casing *D*, which surrounds the head-stock, and is bolted to it on each side. It is so arranged that practically no change has to be made in the head-stock from the form used for the ordinary cone-driven machine. It is only necessary to finish off the pads to which this casing is bolted. The back gear shaft and supports and other mechanism are unchanged, the back gear being shown below the spindle in Fig. 2 merely for clearness. In arranging casing *D* for different makes of motors, the upper part to which the motor is bolted may be readily changed to suit, or an adapter may be used here to connect the motor with the casing, as shown later in Fig. 4. No other alteration is necessary to fit the device to motors of different makes.

On the extended shaft of the motor is carried a driving pinion *A*, which is clutched to the armature shaft or released from it at will, by a clutch mechanism contained with it, operated by the lever shown in Fig. 1. This clutch, though compact, is very powerful, and is self-adjusting. It may be used for stopping the machine independently of the motor, serving the purpose of a belt shifter. Pinion *A* meshes with

a rawhide intermediate gear C, carried by a stud held in casing D. C drives a large gear E which is a part of a sleeve running loosely on the spindle, attachable to it at will through the main spindle driving gear and the usual lock bolt. This

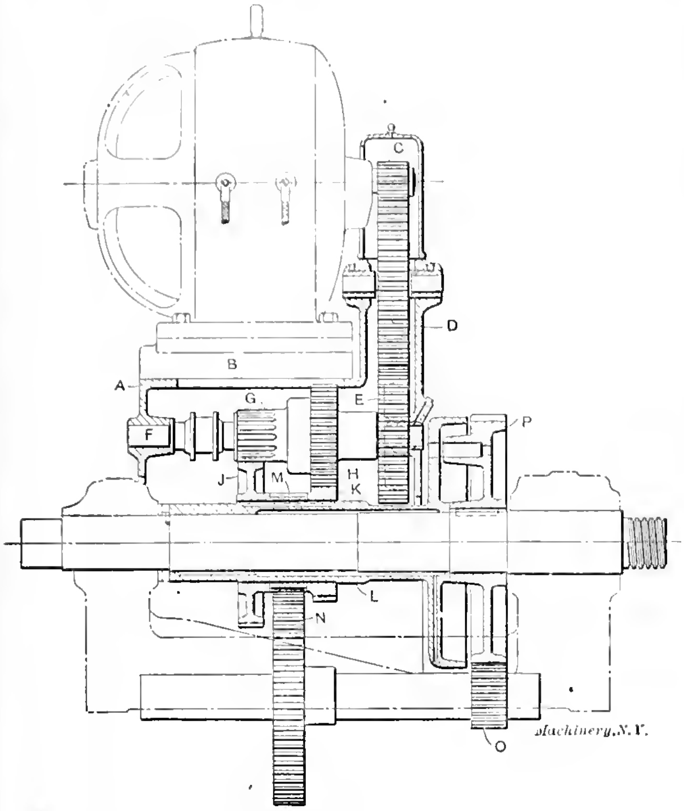

Fig. 4. Diagram of the Drive shown in Fig. 3, showing how the Four Mechanical Changes are obtained.

gives the highest speed. Two slower speeds are obtained through gears F and G, the former integral with the sleeve and the latter keyed to it. These mesh with gears H and J on the back gear quill, to which either one may be clutched by the vertical lever shown at the front of the head-stock.

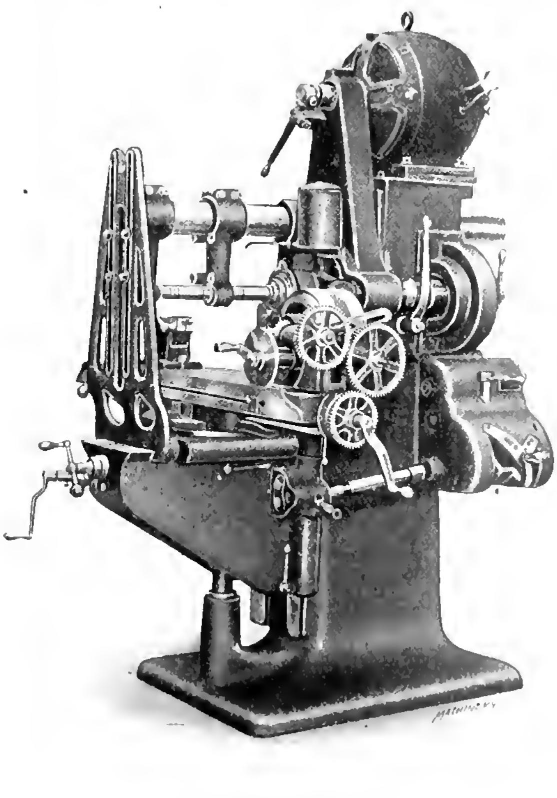

Fig. 5. Variable Speed Motor Drive for Milling Machine

This lever shifts collar K, which operates a double friction of the well-known form used on the builders' double-feed lathe and millers. This design of clutch is simple, durable, strong and compact, and is self-adjusting. Pinion M, at the right of the back gear quill, meshes with the main spindle gear as usual. Three speeds are thus provided for, one direct from E when the bolt lock is engaged, and the other two through gears F or G when the back gears are used.

It will be seen that the mechanism is unusually simple, requires a minimum alteration from the old style belt and cone arrangement, and has the required flexibility in the matter of adapting itself to motors of various makes and sizes.

In Fig. 3 is shown a larger lathe, the 24-inch size in this case, in which the ratio of 40 to 1 is too small to cover the range of speeds desired. Four changes, each in about the ratio of 3.2 to 1 with its predecessor, have to be provided for in this case, giving a total range of 90 to 1 in the speeds, when a 3 to 1 variation is used for the motor.

The arrangement of the gearing will be understood by referring to Fig. 4. In this instance the motor is not directly mounted on the gear casing A, there being an adapting plate B between them whose lower surface fits the casing, and whose upper surface and thickness are altered to agree with the requirements of the motor. The driving pinion C is keyed directly to the motor shaft, since provision is made elsewhere

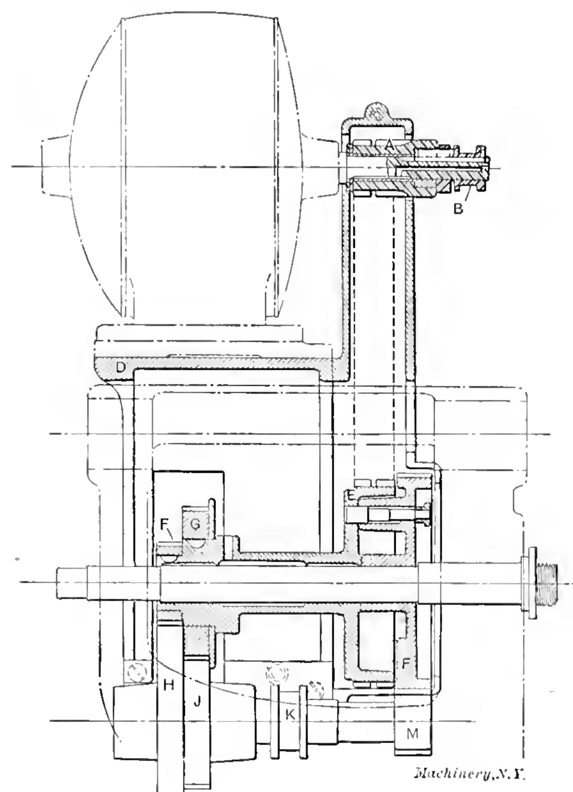

Fig. 6. Diagram of the Arrangement shown in Fig. 5 Compare with Fig. 2.

in the mechanism for disconnecting the drive without stopping the motor. Pinion C meshes with intermediate rawhide gear D as in the previous case, which in turn drives gear E, which is keyed to an intermediate shaft F, journaled at either end of the gear casing above the spindle.

The way in which the four speeds are obtained is readily seen. Sleeve L may be connected directly to the spindle by engaging the lock bolt in spindle gear P with the flange attached to the sleeve. When so connected, two speeds are available by shifting the horizontal clutch lever shown in Fig. 3, which engages either G or H with shaft F as may be desired. When sleeve L is free of spindle gear P and the back gearing is thrown in through M, N, O and P, there are two more speeds available, depending on whether G or H is clutched to shaft F. This gives four speeds in all. When the clutch lever is set on the central position, the motor is disconnected from the spindle. One advantage of this combination of double friction clutch and variable speed motor, is the fact that a total speed range of 9 to 1 can be obtained in 40 gradations, without stopping the lathe or shifting any positively acting connection.

Adapting the Miller to Variable Speed Motor Drive.

The problem of driving the milling machine from a variable speed motor is essentially the same as for the lathe. The only

changes in the conditions of the problem are those introduced by the interference of the over-hanging arm, which prevents the use of direct gearing between the motor and the spindle. The design adopted, shown in Figs. 5 and 6, should be compared with Figs. 1 and 2, the schemes being identical in every way. The change consists in connecting the motor spindle pinion *A* with the spindle sleeve gear *E* by a Morse chain instead of by an intermediate gear, otherwise the mechanism is the same. Similar reference letters refer to similar parts in Figs. 2 and 6. A casing *D* is fastened over the milling machine column in about the same way as it is for the lathe, very little change having to be made from the belt-driven arrangement. In the instance shown, an adapter is used between this casing and the motor. The back gear and motor pinion clutch lever are clearly shown in Fig. 5.

Lathe Driving Mechanism for Constant Speed Motors.

For the constant speed motor a much greater number of mechanical changes has to be provided than in the previous cases. The arrangement adopted for lathes by the builders is that shown in Figs. 7 and 8. The motor used in this particular case is of the alternating current type, though the

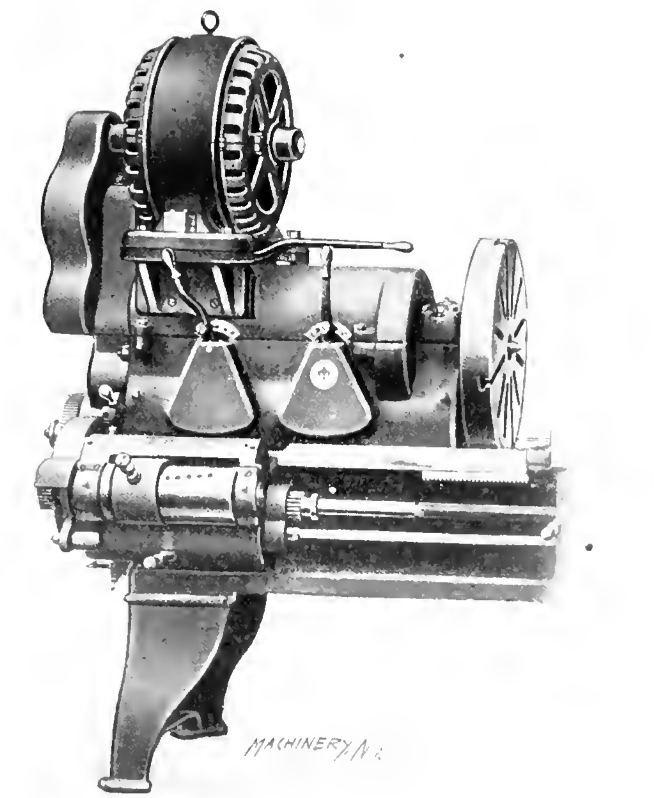

Fig 7. Lathe driven by Constant Speed Motor, with Eighteen Mechanical Speed Changes.

mechanical arrangements would be the same of course with a direct current constant speed machine. The motor pinion *A* is connected to gear *C* on shaft *D* by an intermediate rawhide gear *B* (see Fig. 8). Either one of pinions *E* and *F* may be clutched to shaft *D* as required, so that sleeve *G*, which runs loosely in the spindle, may be driven at either of two speeds, through either *E* to *H*, or through *F* to *J*. Gears *K* and *L*, which form a unit, are keyed to the second intermediate shaft *M*, and may be shifted longitudinally so that *K* engages with *H* as shown, or so that *L* engages with *J*. Gears *Q*, *R* and *S* are all keyed to the lathe spindle. *Q* is permanently in mesh with gear *N*, which runs loosely on shaft *M*. Gears *O* and *P*, which form a unit, are keyed to shaft *M* and may be shifted longitudinally, so that *P* meshes with *S* as shown, or so that *O* meshes with *R*, or so that the clutch teeth on the face of *O* engage those on the face of *N*, thus connecting the spindle of shaft *M* to *N* and *O*.

It will thus be seen that twelve changes are obtained—two by the double clutch between pinions *E* and *F*, multiplied by two depending on the longitudinal position of gears *K* and *L*, multiplied by the three changes depending on the longitudinal position of gears *O* and *P*, giving twelve in all. The various operating levers are shown in Fig. 7. The horizontal lever operates the clutch for pinions *E* and *F*, and is used when in the central position for stopping the machine independently of the motor. The two vertical levers are for shifting the sliding gears, the one on the left operating *K* and *L* and the one on the right, *O* and *P*.

The machine shown in Fig. 7 has 18 changes, instead of the 12 shown in the diagram. This is effected by having a third

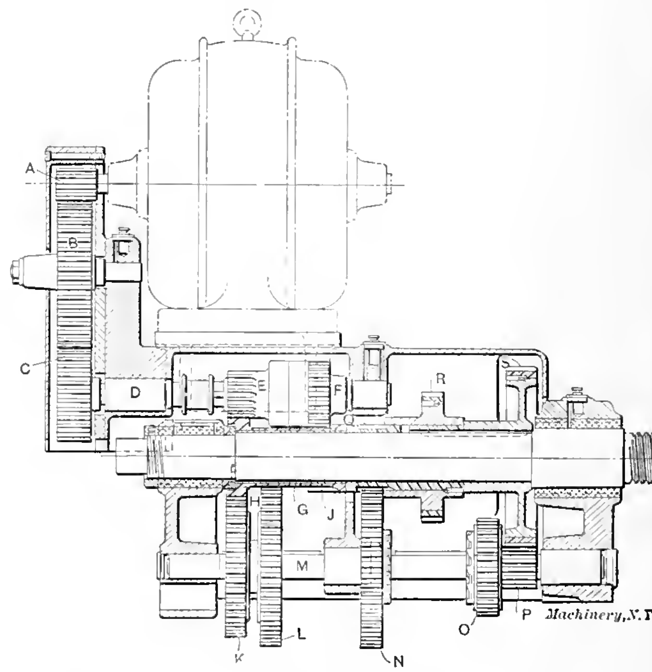

Fig. 8. Diagram of Drive Similar to that of Fig. 7, but giving only Twelve Speed Changes.

gear between *K* and *L* with a corresponding mate for it on sleeve *G*, thus adding six new speeds to the combination. For a 20-inch lathe, these 18 speeds give a total velocity ratio of about 30 to 1, ranging from 9.8 to 300 revolutions per minute in geometrical progression, having a uniform increment of $22\frac{1}{2}$ per cent.

Constant Speed Motor Drive for the Miller.

This arrangement, modified to meet the conditions of the milling machine, is shown in Figs. 9 and 10. The arrange-

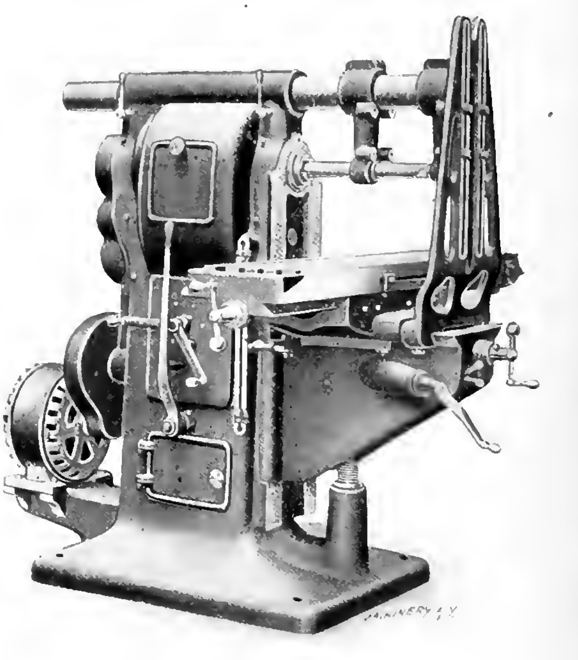

Fig. 9 Constant Speed Motor-driven Miller with Eighteen Speed Changes.

ment of the gearing can be best understood from the line engraving. In this case the column of the machine is designed specially for the mechanism used instead of having it carried by an attached casing. This is necessary, as in Fig. 7, owing to the increased amount of mechanism required.

The motor is mounted on a bracket at the rear of the base of the column, the bracket being designed for the particular motor used, so as to bring the motor pinion A to the right position to mesh with the driving gear C on shaft D.

It will be seen that this arrangement corresponds to the 18-speed modification of the mechanism shown in Fig. 8. Similar gears and parts in Figs. 8 and 10 have the same reference letters.

The 18 speeds are obtained as follows: Two changes depend on the position of clutch fork U, which engages either one of pinions E and F to shaft D. These two speeds are multiplied by the three obtained from the three possible positions of sliding gears, K, L and V, which may be made to engage with either one of gears H, J and W. The six speeds thus obtained are multiplied by three, obtained from the three different positions possible for sliding gears O and P, which may be shifted so that P engages with S, O with R, or so that gear N meshing with Q is clutched to shaft X.

The arrangement shown in Figs. 7, 8, 9 and 10 is applicable to belt drive as well as to motor drive, the only change necessary being the substitution of a single speed pulley in place of the motor. This has the well-known advantages over the cone pulley drive of constant power at all speeds, and practically constant cutting pressure available at the point of the tool within the range of the lathe, whatever the diameter of the work. The ease of obtaining the changes is also

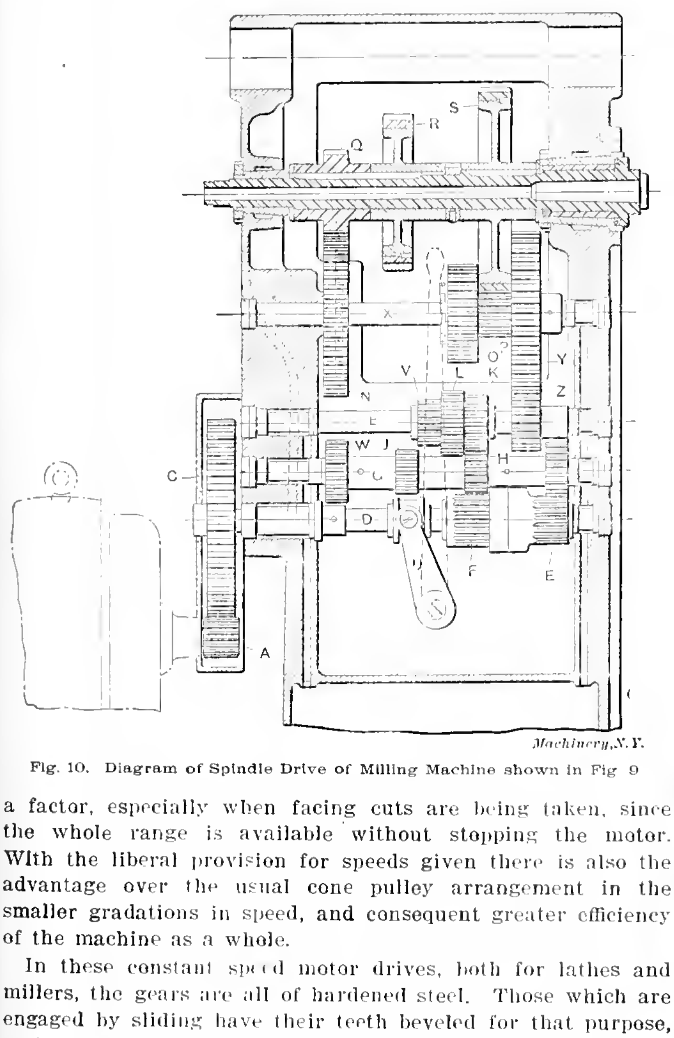

Fig. 10. Diagram of Spindle Drive of Milling Machine shown in Fig 9

a factor, especially when facing cuts are being taken, since the whole range is available without stopping the motor. With the liberal provision for speeds given there is also the advantage over the usual cone pulley arrangement in the smaller gradations in speed, and consequent greater efficiency of the machine as a whole.

In these constant speed motor drives, both for lathes and millers, the gears are all of hardened steel. Those which are engaged by sliding have their teeth beveled for that purpose, as is the practice followed in automobile construction.

Suitable speed plates are provided for each case, with graphical representations of the position of the various levers used, and consecutive tables of the speeds corresponding with those positions. The use of the clutch lever in each of the above designs will be found particularly advantageous in stopping the machine. It avoids the necessity for stopping and starting the heavy, rapidly revolving armature every time it is desired to arrest the motion of the spindle. The whole problem seems to be worked out in a very logical and satisfactory way.

CHICAGO BENCH MILLER WITH COLUMN.

The well-known Chicago hand miller, made by the Chicago Machine Tool Co., of Chicago, Ill., is here shown adapted as a bench machine to the needs of manufacturers of such articles as guns, sewing machines, typewriters, locks, electrical and other work where short milling and slitting cuts are required in pieces of which large quantities are turned out.

The overhanging arm and vertical attachment supplied with the larger machine have been omitted; otherwise the design is about the same. The counter-shaft and the machine itself are equipped with dust-proof, self-oiling boxes, which require filling but once in nine months or thereabouts. This provision adds materially to the life and accuracy of the spindle. The machine may be mounted on the bench or on a special column provided for it, as shown in the engraving. The counter-shaft has two speeds, giving six spindle speeds to the machine.

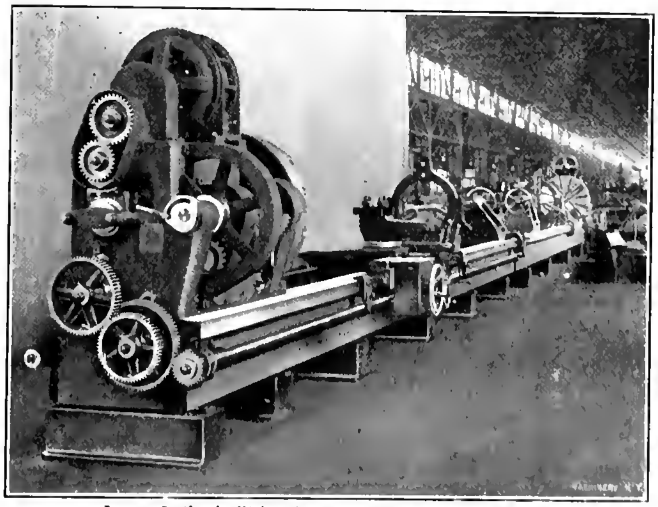
Chicago Bench Miller with Column.

The table feed is 9 inches, with a cross movement of $2\frac{1}{2}$ inches. The vertical movement of the knee is $4\frac{1}{4}$ inches. The spindle is bored to No. 9 B. & S. taper, and is fitted with a sleeve to receive a draw-in collet.

Hill, Clarke & Co., Inc., Boston, Mass., are the agents for these machines.

LARGE SPECIAL POND LATHE.

The lathe shown in the accompanying cut is, as far as length goes, one of the largest ever built in this country. It is intended for turning long propeller shafts, and work of a



Large Lathe built by the Pond Machine Tool Works

similar character, and is to be used at the Mare Island Navy Yard, for which it has been built by the Pond Machine Tool Works, Plainfield, N. J., branch of the Niles-Bement-Pond Co.

This lathe is designated as a 48-inch forge lathe, and is provided with two head-stocks, one mounted at each end of

the bed, and with two carriages and two tail-stocks, the latter normally placed at the middle of the bed, thus making in general two complete lathes. This duplex arrangement is plainly exhibited in the cut, where the heads, steady-rests, carriages and tail-stocks are shown in place. The bed of the machine is 77 feet long, and is made in three sections. The lead-screw on the one side of the machine not shown in the cut, runs for the full length of the bed, and is threaded for a length of 72 feet. On the side of the bed shown is another lead-screw, which, however, only runs half the length of the bed. The long lead-screw presents an interesting example in screw cutting. This screw was cut in an engine lathe. After turning and cutting the thread on a section of shafting, as long as could be handled in the longest lathe in the shop, a second section was welded onto the portion already finished, and then this portion was turned, and the thread cut on same. Several sections were thus welded on until the required length of lead-screw was obtained. The finished portion of the screw, while threading a new portion in this manner, was supported in a steady-rest, instead of being supported on the tail-center, as would have been the case with work that would not have been too long to be held between the centers in the lathe. The machine is driven by alternating-current motors, placed over the head-stocks, as shown in the cut.

THE ROCKFORD ROUTING MACHINE FOR KEY-SLOTS IN SPINDLE.

We show in Figs. 1 and 2 a novel and interesting adaptation of a 20-inch drill press, to the special work of routing the key-slots made in spindles, sleeves, etc., for forcing from their seats the taper shank of the various tools held in them. The drill press shown is one of the line manufactured by the

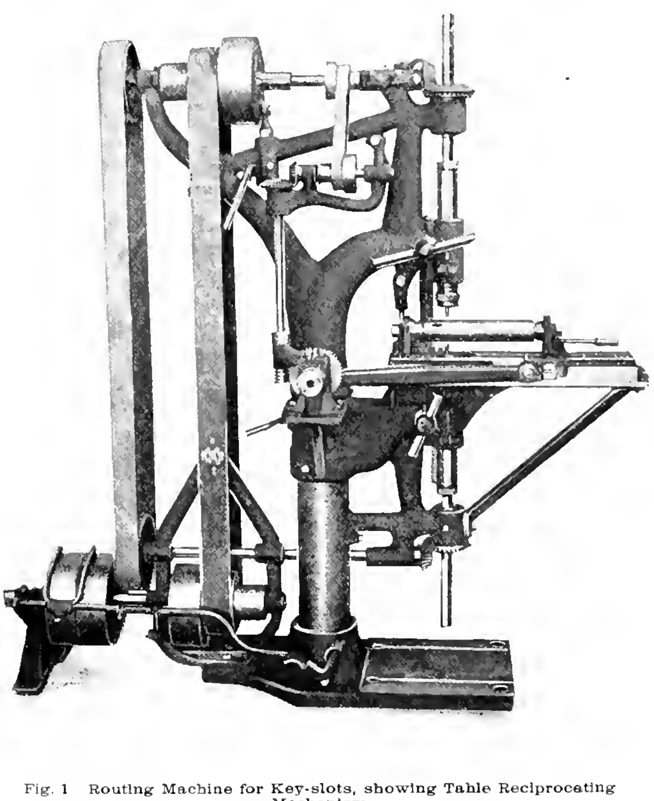


Fig. 1 Routing Machine for Key-slots, showing Table Reciprocating Mechanism.

Rockford Drilling Machine Co., of Rockford, Ill., and the rearrangement of it for this special work was done in the shop of the builders for their own use.

A bed with longitudinal ways, supported by a brace, is used in place of the usual circular table. This bed carries a slide which is attached, as shown in Fig. 1, to a connecting-rod operated by an adjustable crank-pin in the face of a worm gear, carried by a bracket at the side of the column. This worm gear (through suitable belts, cones and bevel gears) is operated from the horizontal shaft at the top of the machine, as shown. By this means a continuous reciprocating movement of suitable length for the length of slot desired is given to the table. The work is held on the table by any suitable means. In the case shown, a pair of stepped centers are used, these being adapted to holding the various sleeves used in the line of drilling machines manufactured by the builders. Spindles and irregular work can be held in any suitable holders or fixtures.

The routing is done by rose or end mills, held in draw-in chucks in both of two spindles, one of which is the regular drill spindle of the machine, while the other is a supplementary one, in line with the main spindle, but below the table. This provision for two spindles and two mills allows the slot to be worked through from two sides at a time, thus increasing the output. The lower spindle is driven by bevel gears from a horizontal shaft, belted as shown to the horizontal shaft at the top, so that both spindles revolve at

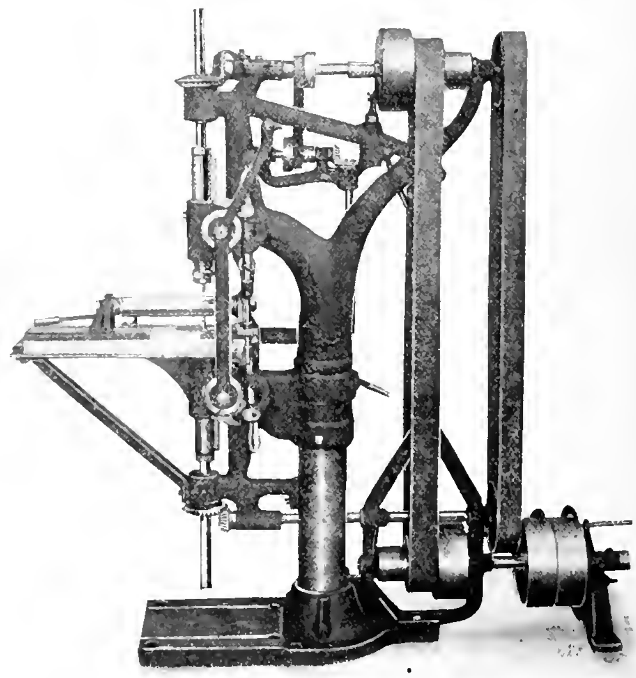

Fig. 2. Right Side of the Routing Mechine, showing Feeding Motion for Mill Spindles.

the same speed, whatever the position of the driving belt on the cone pulleys. The driving mechanism has been strengthened throughout for the use of larger shafts and wider belts and pulley faces.

The feed mechanism is best seen in Fig. 2, which shows the other side of the machine. Each spindle is advanced by a rack and pinion arrangement as usual, operated by worm-wheels. The worm driving each worm-wheel is supported in a pivoted holder, and provided with a knock-out arrangement with automatic stop so that each spindle may be fed to depth and thrown out independently of the other. The vertical shaft which operates the feed worms through the universal joints is rotated by a ratchet mechanism, actuated by the reciprocating motion of the work slide.

The operation of the machine is now clear. The continuous rotation of the worm-driven crank, in Fig. 1, reciprocates the work through a stroke of the required length for the slot desired. At the end of each stroke the ratchet mechanism, in Fig. 2, operates the feed, sinking the mills a little deeper into the work at each reversal. This is continued until the slot has been entirely cut through into the center hole.

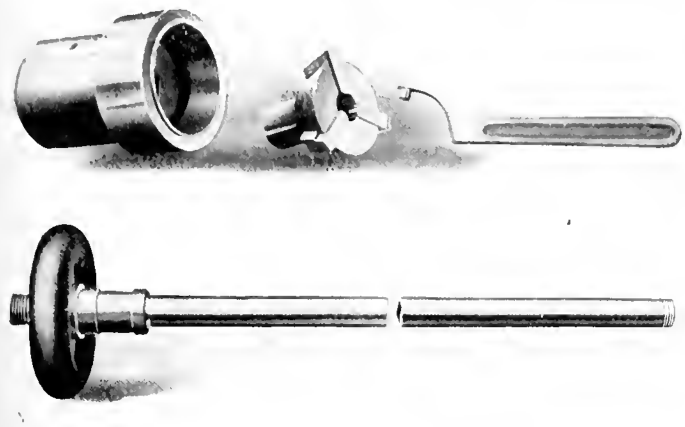
The machine is said to answer the purpose very well, doing the work accurately and quickly. It affords a distinct improvement both in quality and time, as compared to the old method of drilling a number of holes to form the slot, which is finished by chipping or broaching out the stock that is left. The arrangement shown was rather hastily designed for immediate use, but the builders are prepared to furnish it for the market in a more neatly designed form.

ADJUSTABLE COLLET WITH DRAW-IN ATTACHMENT.

In the accompanying cut we show an adaptation of the collet made by the Adjustable Collet Co., of Cleveland, Ohio, to the draw-in arrangement as used for spring chucks of the

usual construction. It consists, as may be seen, of a hood threaded directly to the nose of the lathe spindle, an adjustable collet fitted into the hood, and a threaded tube with hand wheel for tightening the collet on the work, from the rear end of the spindle. The directness of attachment of the device, with the carefulness with which it is fitted, insures the true running of the attachment.

The great advantage of this arrangement is the fact that it does away with the bother of changing from one size to



Adjustable Collet Co.'s Chuck with Draw-in Attachment.

another of the old-style draw-in spring collet, replacing a full set of them; the jaws of the adjustable collet grip any diameter of stock within its range. It may be provided with plain jaws for bar stock, or with step jaws for castings, collars, etc., and for stock that is larger in diameter than the passing capacity of the spindle. These tools are built to fit any size or make of lathe, of the engine, speed or turret design.

VAN NORMAN PLAIN MILLING MACHINE.

The Waltham Watch Tool Company, of Springfield, Mass., has recently added to its line of machine tools two milling machines of the plain manufacturing type. They have been placed on the market to meet the demand for accurately made, small manufacturing millers, such as are required in

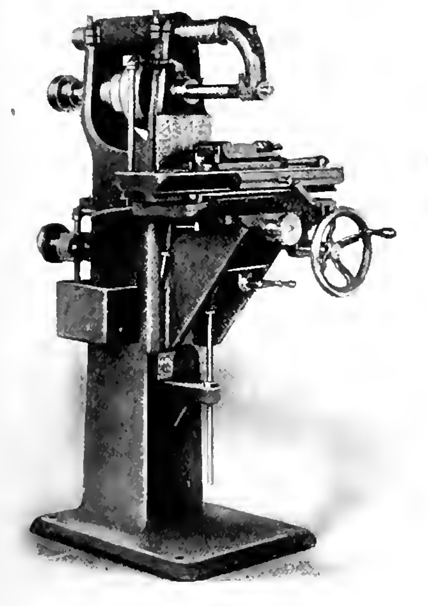


Fig. 1. No. A Van Norman Plain Milling Machine.

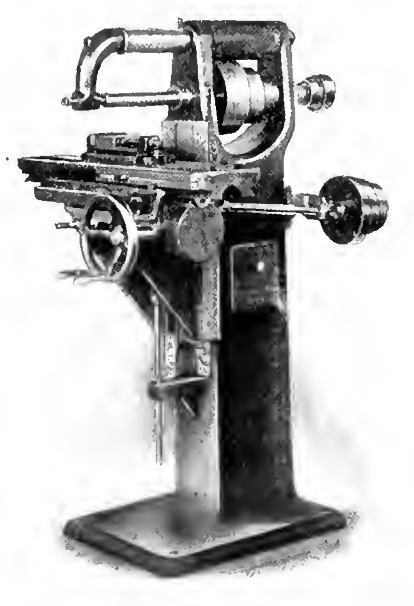

Fig. 2. No. AA Machine of the Same Type.

the interchangeable manufacture of sewing machines, typewriters, electrical apparatus, etc. Proper attention has been paid to the matter of giving them the stiffness required for using cutters of high speed steel, while at the same time sacrificing nothing in the way of ease and handiness in operation.

The No. A machine, shown in Fig. 1, has a table with an automatic feed by means of a vertical rack and pinion, with a quick return operated by a conveniently placed hand wheel; this gives 3 inches table movement to a revolution of the wheel. The table of the No. AA machine (see Fig. 2) which is somewhat similar to that designed for No. A, but is of somewhat larger dimensions, is operated by means of a revolving nut and stationary screw. While feeding automatically, the screw is locked; when it is desired to stop it, the locking device on the screw can be instantly released, when the latter may be operated by hand. A quick return is furnished, as in the case of the smaller machine.

Attention is called to the design and fitting of the spindle. The bearings, both front and rear, are of cone form, and adjustment for wear is accomplished by one pair of take-up nuts at the rear. The spindle pulley is of ample diameter and width for the required driving power. The carriage and table are made with wide and long bearing surfaces, carefully fitted to insure rigidity. Ample provision is made for the use of oil in cutting operations, an oil tank with pump being attached at the side of the machine, while suitable channels in both table and carriage are furnished to return the oil after it has been applied to the cutter.

The feed of the table in the No. A machine is 13 inches. The table is 24 inches long by 7 inches wide. The spindle cone has three steps for a 2½-inch belt, the largest diameter being 7½ inches. The machine weighs about 850 pounds.

In the No. AA machine, the length of the feed is 18 inches, the area of the table 28 by 8 inches, the width of the belt 2¾ inches, and the largest diameter 8 inches. The weight of this machine is 950 pounds. In both cases the cross feed is 5 inches, and the vertical movement of the knee 14 inches.

NO. 3 WALKER SURFACE GRINDER.

We herewith show half-tones and line engravings descriptive of a surface grinder recently placed on the market by the Walker Grinder Co., of Worcester, Mass. The machine is intended for commercial work in the grinding of hardened steel, and soft stock as well, and can be used for roughing and finishing flat surfaces on castings and forgings of all kinds. It will thus be seen that it has a range of usefulness beyond the ordinary tool-room sphere to which the surface grinding machine is generally restricted. It is rigid enough to take cuts varying from 0.0005 inch or less up to 0.015 or 0.020 inch in depth, with a cross feed ranging from zero to 1/10 inch wide. The machine has three especially notable features—an adjustable tension belt drive, an improved method of guiding and supporting the sliding wheel column, and a new noiseless friction clutch reversing mechanism. These and other interesting details will be understood after a study of the accompanying engravings and descriptive matter.

The base of the grinder is of the usual T form; one section of it supports the bed for the work table, while the rearward extension carries a base on which the wheel housing slides. These two parts of the bed are made separate in order to provide for the extended bearing of the wheel housing, which is a feature of the machine. The wheel column bed *B* (see Figs. 2 and 3) has projecting horns, carrying the guiding surfaces on its top in through an opening in the side of the work table bed *C*. The wheel column *E* also has its ways extended on the front of projecting horns, which enter the same opening in bed *C* and bear on the extended guides of *B*. It will thus be seen that the wheel *D* has a support directly under it throughout practically the whole range of its cross travel. The two parts, *B* and *C*, of the bed are tied together by a bolt *G* as shown, which thus makes the base one solid casting, so far as vibration is concerned.

Column *E*, wheel slide *F*, and the wheel with the attached parts, together weigh something over 300 pounds, which is much more than sufficient for the heaviest feed that could possibly be borne by the wheel. Since it is thus possible to depend on the weight of the column, the ways provided for

it on base B are of the V type, commonly used for lathe carriages.

The movement of the column is controlled by cross feed screw T, operated by a hand-wheel at the front of the bed. The gear driving the table rack, and some parts of the reversing mechanisms are pivoted about the axis of the screw T, but they are entirely separate from it. The wheel slide F is guided on sliding surfaces within the double column. It is adjusted vertically by the hand-wheel H, which may be

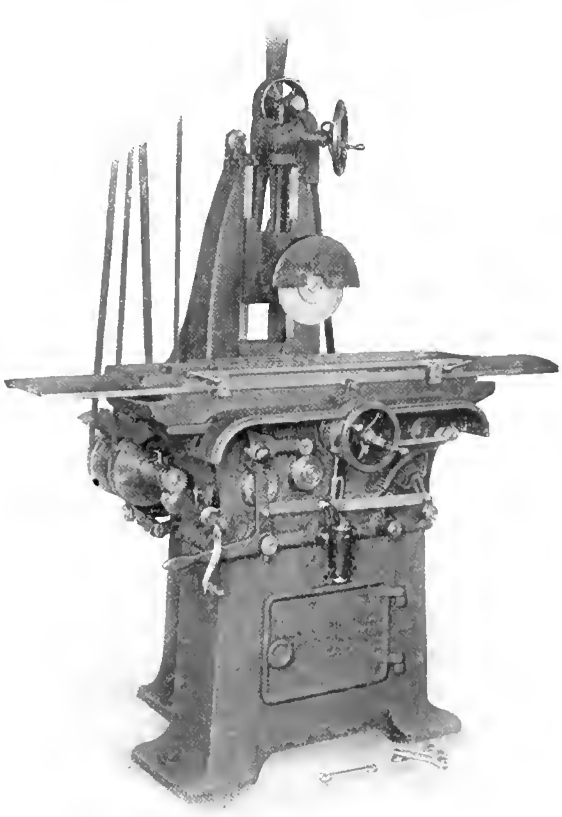

Fig. 1. The Walker Surface Grinder.

swiveled to any convenient angle to suit the position of the operator. Being counterweighted, there is no danger of its dropping down against the slack of the vertical adjusting screw. This also makes it as easy to raise the slide as to lower it, the motion being equally free in each direction. The wheel spindle is hardened and ground, and runs in hard bronze ring-oiling boxes, adjustable for wear. The end play is taken up by an adjustable cap at the rear of the spindle.

The arrangement of the belt drive can be followed from line drawing Fig. 3, and the rear view of the machine, Fig. 2. Drum A at the base of the machine is connected with the counter-shaft by the pulley and belt shown, and drives a belt J, which passes up over a pulley at the top of the wheel column and down around the driving pulley K on the spindle. (See the small detail at the left of Fig. 3.) From here the belt passes up over an idler L in the wheel slide, and back down to the drum again. It will be noted that the belt enters and leaves pulleys K and L vertically, so that there is no disturbance in the tension of the belt as the slide is moved up or down. Pulley M at the top of the column is carried by a slide, adjustable vertically by a screw and slide for maintaining the proper tension of the belt. As about 5 or 6 inches of stretch are provided for, an endless belt may be used, which will not need re-cementing until after long continued use.

The work table N is provided with liberal guiding surfaces, and has a roll oiling device which is identical with the standard arrangement applied to planer ways. The table receives its reciprocating movement from a rack and gear in the same way as does a planer. This gearing is connected to a pair of friction clutches, contained within the forward and reverse driving pulleys seen at the left of the machine in Fig. 1. The friction clutches contained within these pulleys are of durable construction, with a large area of contact surface, and are very simply constructed as well. By the use of a screw driver and wrench, they may be easily adjusted when adjustment is required, yet not so easily that they will be constantly tampered with by an unskilled operator. The use of friction clutches in place of the usual positive toothed clutches for driving the table, is considered by the builder to be a great improvement. The reversal is effected accurately, but with an entire absence of the shock noticeable with the older arrangment.

Reversing dogs O and O (see Fig. 4) are clamped in a T slot on the front of the table. These dogs engage the upper end of reversing lever P, whose lower end carries a roller operating the spring plunger Q, of the usual design in such mechanisms, whose function is to prevent the reversing lever from stopping on dead center. As lever P is thrown over alternately in each direction, it strikes contact screws on swinging bar R which operates clutch lever S. This latter is directly connected with the clutch mechanism. The table movement may be manually operated by the crank and pinion shaft at the left side of the base. The pinions are slipped out of engagement when the hand movement is not in use. Reversing dogs O may be thrown out of the way when desired, to allow the tool to run beyond its regular movement without altering their adjustment.

An automatic cross feed is provided, acting on screw T. Reversing lever P is connected by a link as shown to toothed sector U. This link may be adjusted in the slots of both P and U (as shown only in Fig. 1) to vary the amount of swinging movement given to the latter as each reverse movement takes place. This adjustment serves to vary the automatic cross feed. Sector U meshes with a pinion rotating the feed crank V, which thus receives a movement of con-

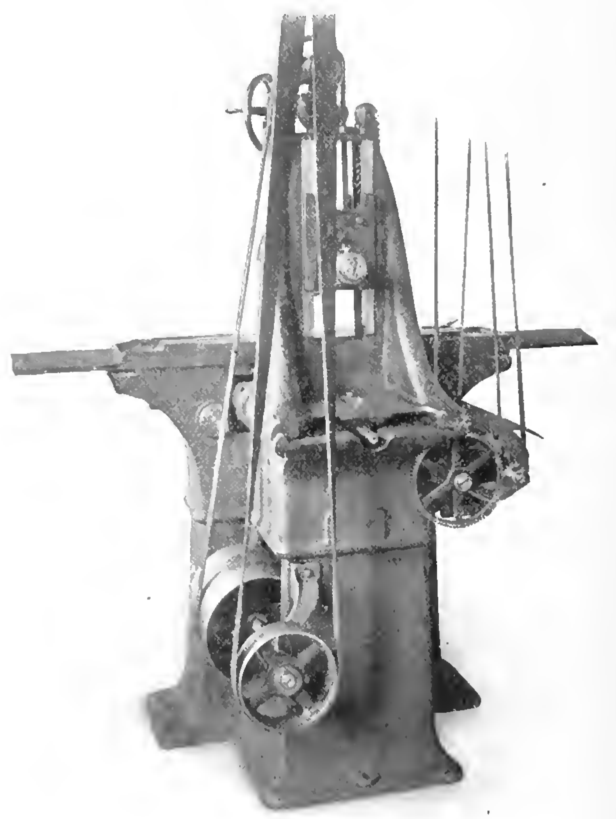

Fig. 2. Rear View of the Grinder, showing Extension of Wheel Column Ways under Work Table.

siderable amplitude on either side of the dead center, so that the connecting-rod W, to which it is attached, is given a forward and backward movement at each reversal. This connecting-rod has rack teeth cut in it, engaging with a pinion X (see Fig. 3) operating the ratchet feed mechanism of the cross feed screw. The ratchet may be made to feed either in or out, by shifting the operating pawl in the same way as is customary for planer feed mechanisms.

Means are provided for stopping the reciprocating movement of the work table at any point in the automatic cross

feed. The upper end of clutch lever S carries a projecting arm, so shaped as to engage with an abutment on stop lever Y. This lever is normally held in its upward position by the support of a collar on stop rod Z; this stop rod can be operated by adjustable dogs on the wheel column E. When the column has reached the desired point in the cross movement, given by the automatic cross feed, the adjustable

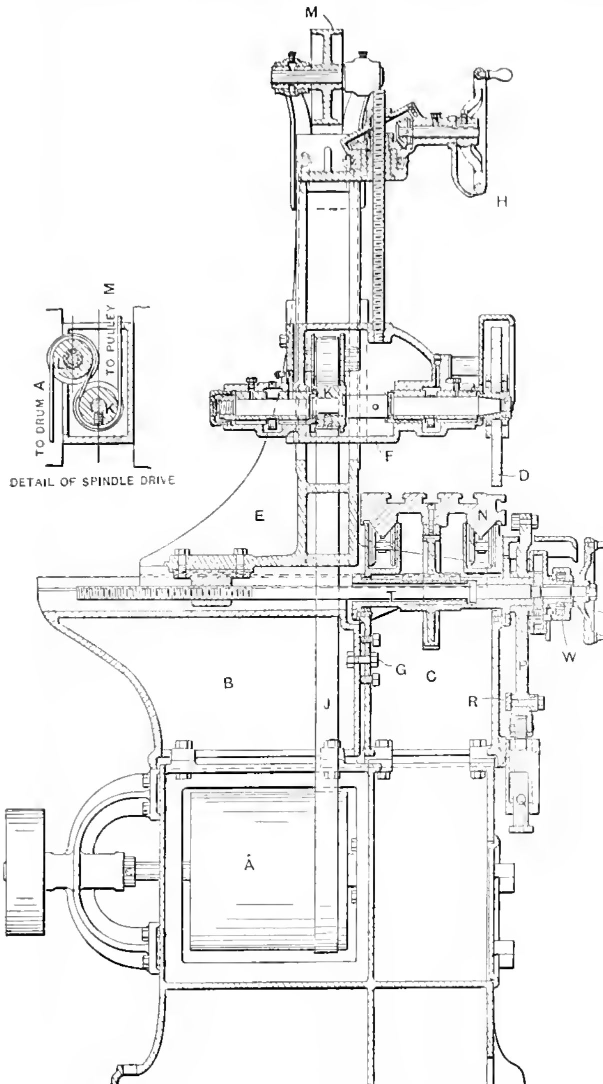

Fig. 3. Vertical Section showing General Design of Walker Grinder

dog shifts stop rod Z, allowing stop lever Y to drop from its position on the collar until its abutment rests on the upper end of reversing lever S. As the next reversal takes place, the two engaging surfaces of Y and S strike, stopping the movement of S in mid-position where both of the friction clutches are disengaged, so that the movement of the table is arrested. The adjustable dogs on the wheel column which

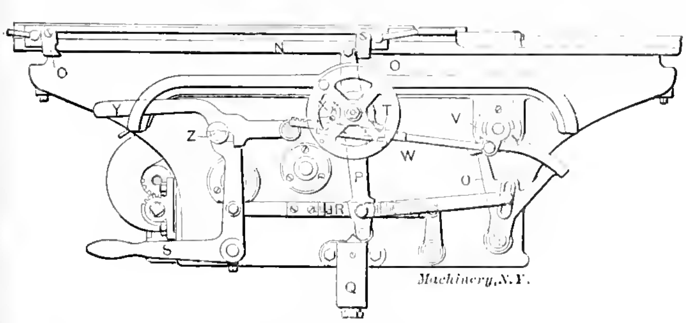

Fig. 4. The Reversing and Automatic Cross-feeding Mechanism

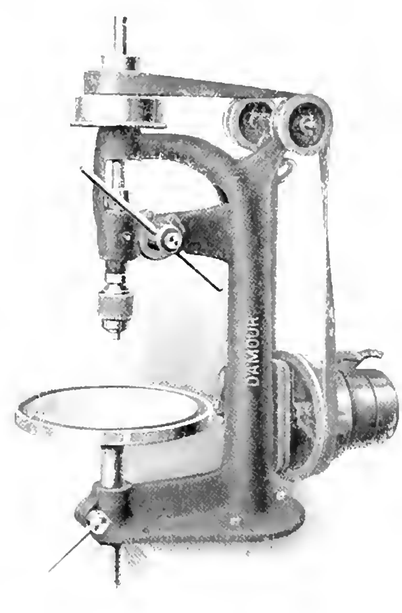
govern this movement are so arranged as to be positively operative, at the extremes of travel of the cross movement, so that there is no danger of the power feed being forced beyond the range of movement provided. This avoids the possibility of damage to the mechanism from this cause.

Three speeds are provided for the grinding wheel, obtained from a pair of cones in the overhead works. It is thought best to place the speed change here, since the only reason for altering it is to accommodate the change in diameter of the wheels as they wear down. If the speed change is made too easy, there would be danger of the operators experimenting with it after it had been set for the proper rate. It can still be easily changed when there is really need for it.

The machine is arranged to carry grinding wheels 10 inches in diameter and 5/8 inch wide. The grinder can be furnished with a magnetic chuck built integrally with the platen, or if desired, a special magnetic chuck 26½ inches long can be used. The grinder can also be provided with an individual exhausting system for the dust, and can be arranged for motor drive if the purchaser desires. The length of the stroke of the table is 30 inches, the cross feed is 8 inches, and the vertical adjustment is 10½ inches. The net weight of the tool is about 1,700 pounds.

D'AMOUR SENSITIVE DRILL PRESS.

This little tool, shown in the accompanying half-tone as a bench machine, may also be furnished with a column for use on the floor. It is built by the Charles Ramsey Company, 135th Street and Willow Avenue, New York. The spindle is of open hearth steel and is entirely relieved of belting strain, besides being counterbalanced by a weight inside of the frame, making it extremely sensitive to the touch. It is also provided with means for taking up wear and lost motion. The feed is by rack and pinion. The adjustable stop is of new design, applied directly to the pinion instead of to the top of the spindle, thus doing away with the tendency to spring the frame of the machine, making it possible to drill or counterbore more nearly to exact depth.



D'Amour Drill Press arranged as a Bench Machine.

The spindle is driven by either of two speeds, obtained from the cone pulleys shown. The counter-shaft pulleys are carried by a bracket which has vertical adjustment, and acts as a belt tightener. An endless belt is provided for the machine. The fact that the counter-shaft is attached to the machine makes the trouble and expense of properly installing it very small. The spindle and counter-shaft pulleys are of unusually large diameter, giving greater belt speed and a more powerful drive than is usual with drills of this size and type.

The greatest distance from the spindle to the table is 8 inches, and from the center of the spindle to the frame, 6 inches. The table has a vertical adjustment of 5 inches, that of the spindle is 2 inches. The drill capacity of the machine is from zero to 5/16 inch diameter. The weight without column is 60 pounds; with column, 120 pounds.

MANVILLE CAM CUTTING MACHINE.

It has always seemed strange that no machine tool has been placed on the market, carefully and consistently designed for the purpose of making cams, one of the commonest and most vital machine parts used in a wide range of automatic machinery. The various forms of cams have almost invariably been cut on attachments to the lathe or milling machine. Many of these attachments are very ingenious, and work in a way that is quite satisfactory, but they have the lack of convenience and productive power that almost invariably at-

tends the use of such special contrivances. Barring a machine for cylindrical cams which was built some years ago and had a comparatively limited sale, the one we illustrate in Figs. 1 to 4 is, so far as we know, the first distinctive cam cutting machine to be placed on the market. Its construction is rigid and convenient, and ingenious enough to repay a study of the half-tones and line engravings we show herewith.

As may be seen, the machine consists essentially of a bed on which are mounted two heads—one for the cam and one for the former—while between them is mounted a spindle on a swinging frame, one end of which carries the former roll, while the other carries the cutter which does the milling. It will be seen that the machine is for the variety of cams known as plate cams, in which the guiding surface is formed on the outer periphery of the disk. It will also, of course, form what are known as face cams, in which a cam slot is milled in the face of a disk. These two forms constitute by far the larger part of the cams in common use. The only other type frequently met with being the barrel or cylindrical variety.

Head-stock *A* (see Figs. 3 and 4) carries a heavy face-plate to which the work is clamped. This face-plate is cast solid with a rugged, large diameter spindle, which carries the driving head at its rear end. Similarly, foot-stock *C*, which has also a limited adjustment on the bed, has a face-plate for the former or master cam, and is driven by gear *D*. Both *B* and *D* mesh with pinions on driving shaft *E*, which runs the length of the bed and rotates the two face-plates in unison. It receives its motion through the quick change gear mechanism shown, giving a suitable range of feeds, which can be quickly altered to suit the changed conditions as the mill approaches the center or recedes from it. This feed may be thrown out instantly, or reversed as well, all the controlling handles being within easy reach. It may be manually operated by hand-wheel *F*. Driving gears *B* and *D* are split, and may be adjusted to take up all back lash, so that assurance is given that the work and the former revolve in absolute unison.

The swinging frame *G*, which carries the mill *H* and the forming roll *J*, is pivoted at the back of the machine near the base, and is normally under the influence of weight *K*, acting through rock shaft *L* and arm *M*, so that the former roll *J* is pressed firmly down against the periphery of the forming cam on the face-plate of tail-stock *C*. As this forming cam revolves, it is evident that frame *G* will swing in and out, giving mill *H* the proper motion to duplicate in the work the contour of the former. The mill is driven from cone pulley *N* through the bevel gears and the vertical shaft *O*, contained within the swinging frame *G*. The various speeds provided by the cone pulley, and the provision for reversing the movement, gives a wide range of adaptability to different sizes and designs of milling cutters.

Hand-wheel *P*, mounted on the back of the swinging frame, acts through the worm and worm sector *Q* on a pivoted bar *T*, which is notched to bear against a pin in *Q*. When this pin is in the notch and the hand-wheel is rotated in the direction shown, the pressure of *Q* against *T* forces the frame *G* back, lifting the weight and raising the roller *J* from the former. This provision is made for changing the work, removing the cutter and for similar adjustments. When hand-wheel *P* is rotated in the other direction and the roll is again brought back to the former, the continued movement of the hand-wheel withdraws the pin in *Q* from the notch in *T*, allowing the latter to drop to the position shown by the dotted lines. The frame is then absolutely free to follow the contour of the forming cam under the influence of the weight.

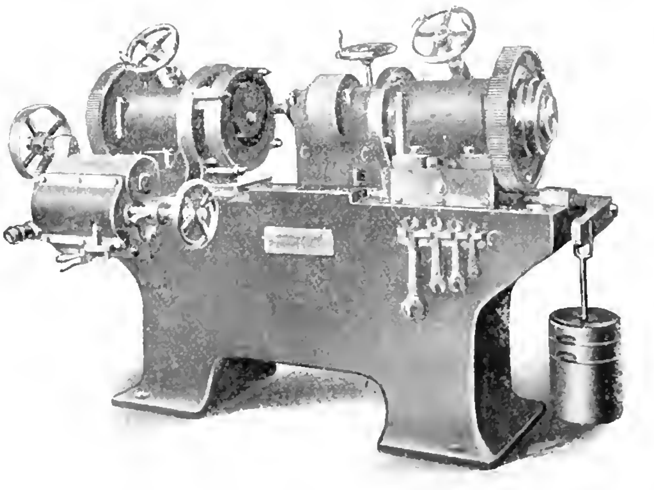


Fig. 1. The Manville Machine for cutting Plate and Face Cams.

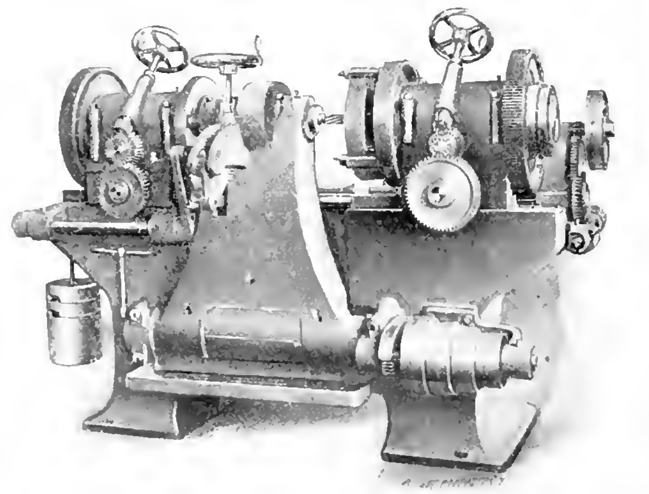

Fig 2. Rear View of Cam Cutting Machine, showing Spindle and Forming Roll Support.

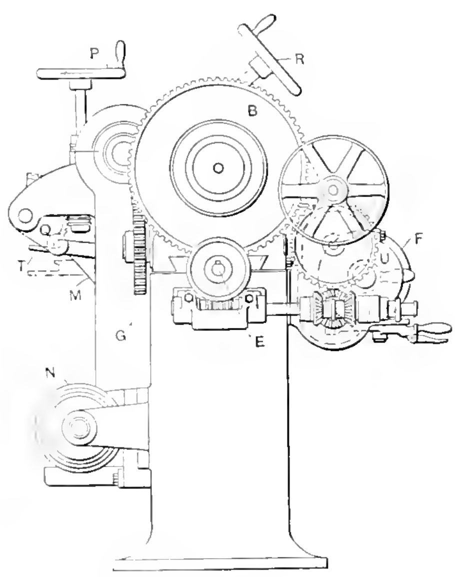

Fig. 3. End View of Machine.

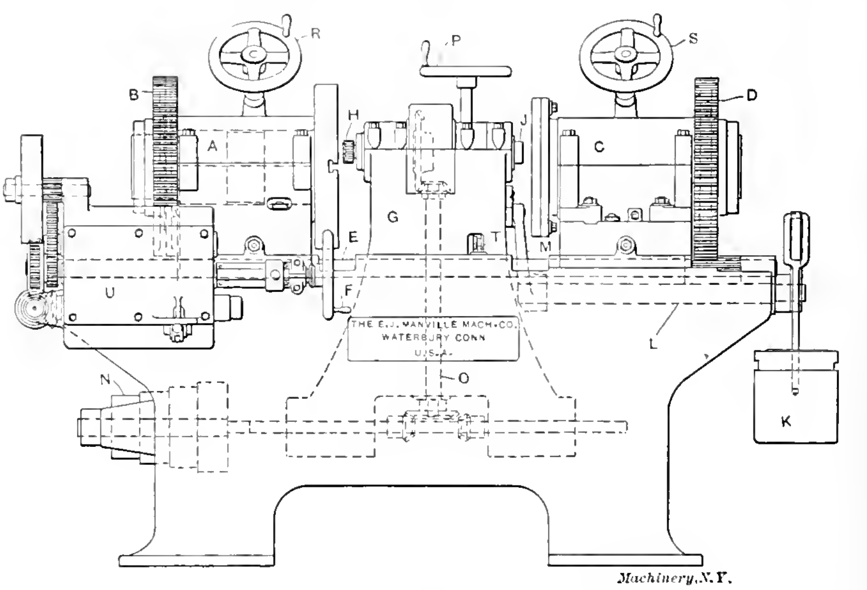

Fig. 4. Front View, showing Driving Connections for Spindle and Rotary Feed Motion.

When it is desired again to raise it from the work, bar T is brought into position by hand, easily done from the front of the machine, while the hand-wheel is operated as before.

The convenience of the arrangement of the machine will at once be appreciated. The longitudinal adjustment of heads A and C can be effected from the front by hand-wheels R and S. These heads are firmly clamped in their position by handles projecting from the front of the machine. Hand-wheel R is used, of course, in feeding the mill H to depth when cutting face cams. If desired, it is possible to follow an outline scribed on a cam without using a former at all. Under such conditions, swinging bar T is thrown into engagement with the pin in Q, and hand-wheel P is used to feed the mill out or in, in following the contour, while the work is revolved by the left hand, controlling hand-wheel F. Provision thus seems to have been made for about all the requirements likely to be met with in a machine for this work. The stiffness and cutting power of the machine should evidently be considerable, to judge from the general design, and the swinging member is so rugged, and supported so firmly, that all rocking and twisting strains are avoided. This stiffness and rigidity result from the use of separate spindles for the work and former, and the placing of the milling cutter and forming roll between them.

The machine is built by the E. J. Manville Machine Co., of Waterbury, Conn. It is the result of the requirements of their own business, which includes the designing and building of automatic machinery of all kinds, particularly that for bending wire into intricate shapes. Such machinery is largely dependent on the use of cams. To indicate the applicability of cam driving mechanism for such machinery, mention may be made of that used in making the well-known De Long hook and eye, built by this firm. The cams of this machine are run at the rate of 250 revolutions per minute, producing 250 perfect hooks per minute. These same machines were operated at a speed above 300 per minute, but at this rate it was found necessary to use an air blast to assist the finished product in dropping from the machine fast enough to prevent it from clogging up.

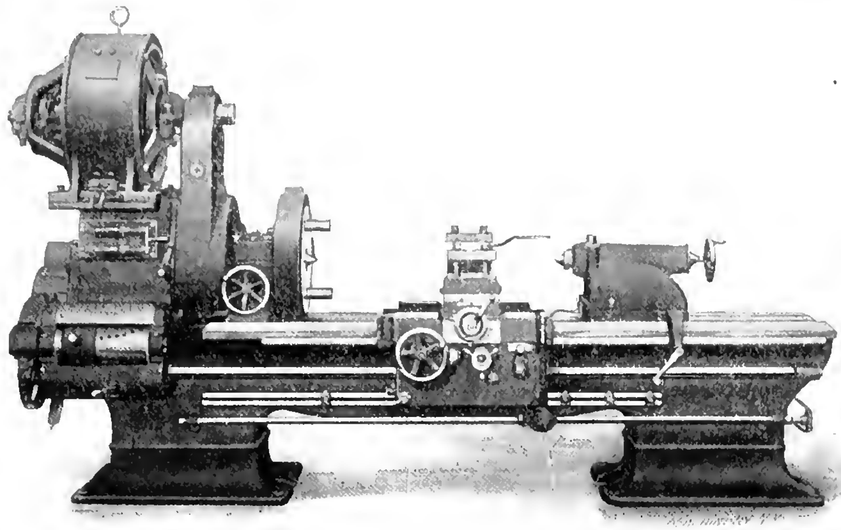
LE BLOND HIGH-SPEED ENGINE AND REDUCING LATHE.

Two new modifications of their regular design of engine lathes have been developed by the R. K. LeBlond Machine Tool Co., 4605 Eastern Avenue, Cincinnati, Ohio. The change consists in re-designing the bed, head-stock, foot-stock, and carriage to withstand the greater strains they are expected to carry, and involves a corresponding re-designing of the spindle drive and feed mechanism.

For the belt-driven, high-speed engine lathe, a 3-step cone pulley is provided for a 5½-inch belt. This cone may be connected directly with the spindle, or geared to it through quadruple back gearing, from which two changes are obtained by the regular LeBlond double friction back gear, while the other two changes are obtained by the endwise shifting of a double pinion on the back gear shaft, which may be made to engage with either the spindle gear or with teeth on the periphery of the face-plate. When a double speed counter-shaft is used, 30 speeds are thus provided for, ranging from 7.6 to 250 revolutions per minute. With the reducing lathe, the drive is practically the same, except that the machine is always back-geared, and the double-speed counter-shaft is not required. This gives 12 speeds, ranging from 11.2 to 143 revolutions per minute. The reducing lathe is especially designed for heavy cuts in steel castings and forgings.

When the machine is motor driven, a variable speed motor is used, mounted as shown in the illustration, which represents the reducing lathe. The controller is operated from a handle on the carriage, connected by gearing, chain and sprocket with the controller shaft at the back of the machine. The motor may be stopped and started by this handle, or the machine may be stopped and started independently of the heavy, rapidly revolving armature shaft by the friction clutch provided between the armature shaft and the driving pinion mounted on it.

The apron on this lathe has steel gears throughout, is of a semi-box construction in which all the shafts and studs are supported at both ends. The rear bearing acts as a rib, to connect the ends of the apron. The tail-stock is of improved design, reinforced to withstand heavy strains, with improved and effective methods of clamping the spindle to the body, and the body to the bed. The turning and screw cutting feeds are obtained by the standard Le Blond quick change device, giving 33 threads and feeds, including the 11½ pipe thread, without removing a gear. The range of threads is from 1 to 24, and the feeds are four times the threads. A series of stops are provided in the T-slot at the front of the bed behind the apron. These may be set for the shoulders on the work, so they will stop the carriage successively as each point is reached.



Le Blond Motor-driven High speed Reducing Lathe.

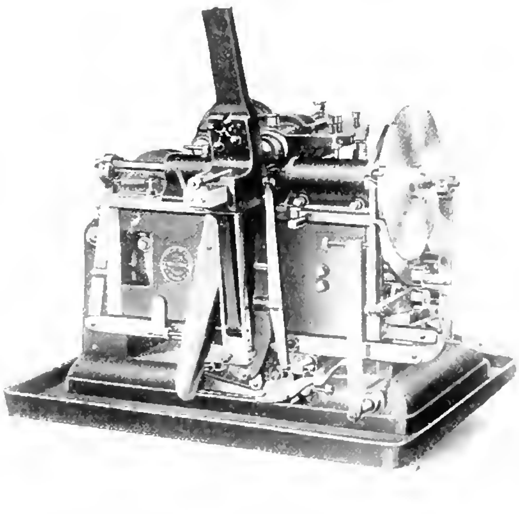
The engine lathe is provided with compound rest and power angular feed. The reducing lathe is ordinarily provided with a carriage of special construction, in which the lead-screw and threading mechanism are omitted, and double tool-posts are provided, one in front of the work and one in back, so that a double chip may be used for great reductions in diameter. The strong spindle drive and feed connections permit the removal of great quantities of chips by this method.

WALTHAM AUTOMATIC PRECISION GEAR AND PINION CUTTER.

We illustrate in the accompanying half-tone a highly developed form of automatic gear and pinion cutter, intended for small work on gears such as are used in instruments, typewriters, clocks, recording devices, etc. An especially interesting feature of the machine is the magazine feed provided for pinion blanks. When this is used, the machine is entirely automatic in all its movements. At the conclusion of the last cut on the work the holding centers are separated, the cut pinion ejected, a new blank is brought by the carrier from the magazine to the centers, the centers are clamped to the blank, and the cutter is again brought into position to take its first cut on the new work.

Provision is made in this machine for taking either one, two or three cuts through each tooth space. The cutter spindle is lifted while the return stroke of the work slide is being made, thus allowing the indexing to be done without loss of time, and preventing damage to the work by the cutter dragging back through it. The stroke of the work slide is adjustable, and the head- and foot-stocks can be shifted so that either long or short work can be accommodated. When

used as a hand-fed machine, the magazine is removed. The machine is then adapted to the cutting of small gears in stacks, as well as to the cutting of pinions.

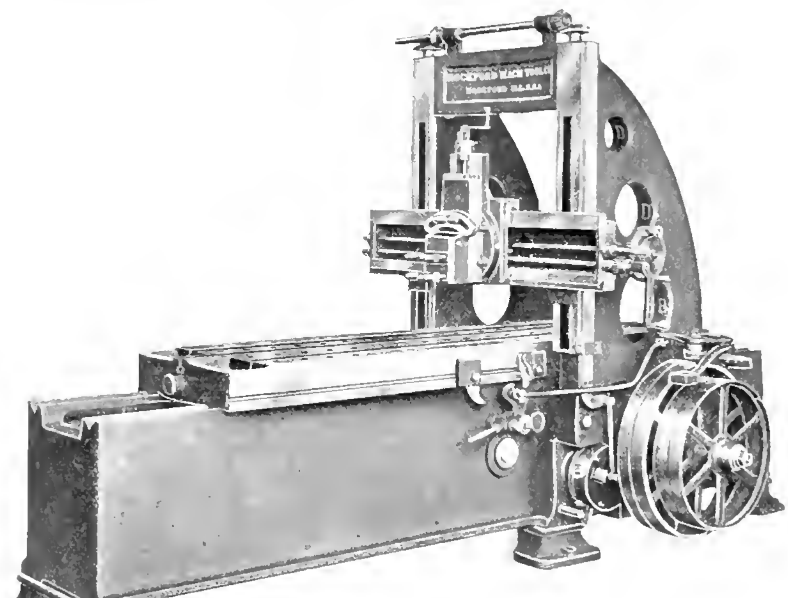


A Precision Gear or Pinion Cutter in which the Work may be automatically fed to the Machine.

This tool is built by the Waltham Machine Works, Waltham, Mass., and is similar to the smaller size shown on page 361, (Engineering edition) of this same issue, that one being also a three-cut machine.

ROCKFORD HEAVY PATTERN PLANER.

The accompanying half-tone shows the first of a new line of heavy pattern planers which the Rockford Machine Tool Co., of Rockford, Ill., is bringing out. The machine shown has a capacity for work 24 inches wide by 24 inches high, and has a 6-foot bed. Among the salient features of the machine is double gearing inside of the bed for transmitting the motion from the pulley shaft (which carries two pinions) through two intermediate gears, one each side of the bull wheel, to the large pinion which drives the latter. This feature ensures long life, and gives great power to the machine. All the gears in the drive are inside the bed, between the bearings, so they are protected from accident and falling

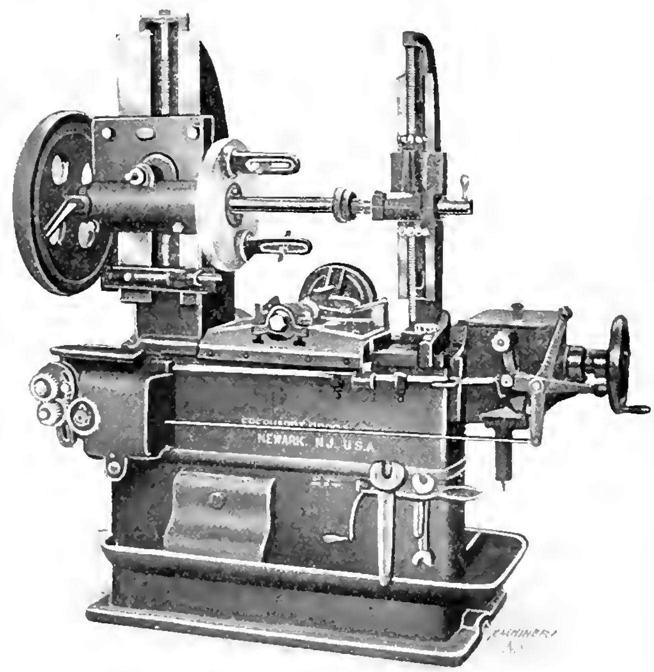


The Rockford Heavy Pattern Planer.

chips. All the bearings in the bed are bored and bushed and fitted with efficient self-oiling devices. The feed friction is of the double releasing type, and will not heat even when on short stroke, though furnishing a powerful feed to the tool when taking heavy cuts. The feed range is from 0.016 inch to 0.750 inch per stroke. At a cutting speed of 30 feet per minute, the drive is so proportioned that the return of the platen is 95 feet per minute. The machine weighs 7,100 pounds.

EBERHARDT BROS. NO. 3 AUTOMATIC GEAR-CUTTER.

The accompanying half-tone shows the new No. 3 size of the line of automatic gear-cutting machines built by Eberhardt Bros. Machine Co., 66 Union St., Newark, N. J. This new size has a capacity for work 36 inches in diameter and



A New Member of the Eberhardt Bros.' Line of Automatic Spur Gear Cutters.

10 inches face. It will cut 4 diametral pitch in cast iron (or 5 diametral pitch in steel) in one cut at a fast rate of feed. It will, of course, cut larger teeth if a stocking cut is taken first.

The mechanism of this machine, which is designed for cutting spur gears only, is similar to the rest of the line brought out by this firm, embodying the positive indexing mechanism, the spur gear drive for the cutting spindle, the long cutter carriage with the spindle in the center of its length, and the provision for putting the feed screw under tension instead of under compression during the cutting action. It will be noticed that the 10-inch width of face which is within the capacity of the machine, is unusually long, allowing several gears to be cut at a time. This is made possible by the design of the machine, which permits the cutter slide to run past the column to some extent, thus adding considerable to the effective feed of the cutter.

A convenient feature is the arrangement of the controlling handles. These are all on the front side, or near the hand-wheel at the end of the machine, so that the operator, in setting, has control of all the movements without changing his position. The hand-wheel has a clutch and spring to keep it automatically disengaged during the running of the machine.

The equipment regularly furnished includes an indicator for setting the cutter central, change gears for cutting all numbers of teeth from 10 to 100, and all from 100 to 400, excepting prime numbers, and many higher numbers, change gears for feed and speed changes, face-plate with jacks and drivers for fastening and driving the work, a work arbor with collars and stepped flanges, a cutter arbor of the removable type, oil cup and fittings, and counter-shaft. The counter-shaft is of the tight and loose pulley pattern, and is

ring oiling, special provision being made for lubricating the loose pulley bushing. Other members of this line of gear cutters were illustrated in the November, 1906, and the June, 1907, issues of MACHINERY.

NEW LINE OF HEAVY NEW HAVEN LATHES.

In Fig. 1 is shown an example of one of a line of heavy pattern engine lathes which the New Haven Mfg. Co., of New Haven, Conn., is placing on the market. Aside from the general strength of the design, of which considerable may be understood from a study of the engraving, there are a number of interesting points connected with the details of the mechanism, particularly with reference to the feed changing device and the taper turning attachment.

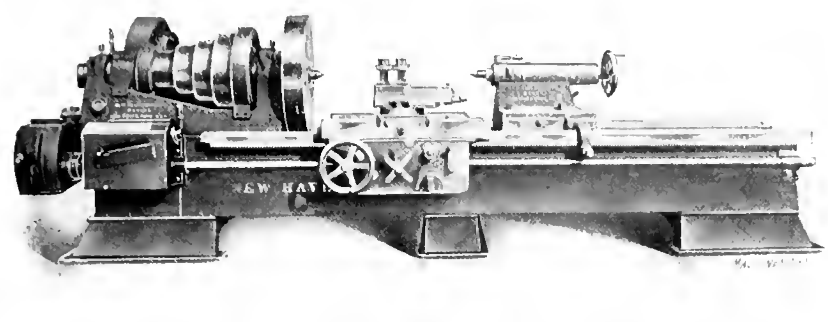


Fig. 1. Heavy 28-inch New Haven Lathe.

The speed changing box at the front of the head-stock is of the design which we have described before (see the New Tools of the Month in the August, 1904, issue of MACHINERY), giving seven changes of speed. This number is quadrupled by the supplementary feed box at the end of the head-stock, whose mechanism is shown in Fig. 3, removed from the casing which encloses it when in place on the machine. Stud *A* carries the gear which receives the motion from the lathe spindle. About it is pivoted a rocking frame *B*, carrying pivots *C* and *C*, which each carry a pair of gears driven by the central pinion on *A*. Gear *D* is mounted on an extension of the shaft of the main feed box *E*. This gear may be made to engage with either one of the two gears on each of the two pivots *C* and *C* by the operation of handle *F*. Shifting *F* longitudinally brings gear *D* opposite the outer or inner gear

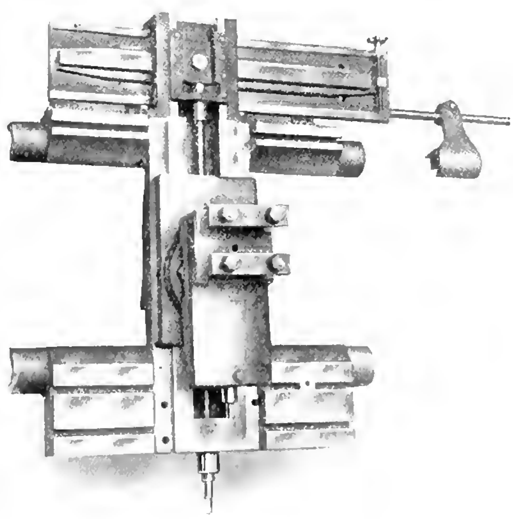

Fig. 2. Plan View of Taper Attachment.

on stud *C*. Shifting it vertically, by means of the connecting links *G*, rocks frame *B* to bring either the upper or lower gears on *C* into mesh with *D*. Four changes are thus provided for.

The design of the taper attachment is shown in Fig. 2. The taper bar is carried by a table, sliding in brackets attached to the back side of the carriage, and always in place. When it is desired to turn tapers, a clamp, which is fastened to the bed of the lathe, is tightened down on the rod which connects it with the table. The cross feed screw is connected by a tapered pin with the sleeve at the front of the slide which locates it so far as endwise movement is concerned. When this tapered pin is removed, and the clamp is tightened down on the rod, the attachment is ready for action. The tapered swivel bar is graduated at one end to read in degrees, and the other in inches per foot. A fine adjustment is provided for it by the screw and hand nut shown.

STURTEVANT HIGH-SPEED LARGE VOLUME FAN.

The original Sturtevant fan, invented over half a century ago by B. F. Sturtevant, was for high pressures and small

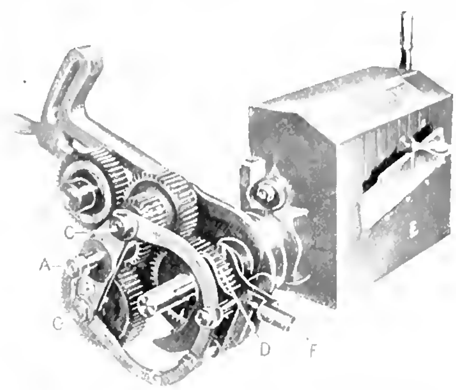

Fig. 3. Detail of Mechanism for Quadrupling the Number of Feeds obtained in the Feed Box.

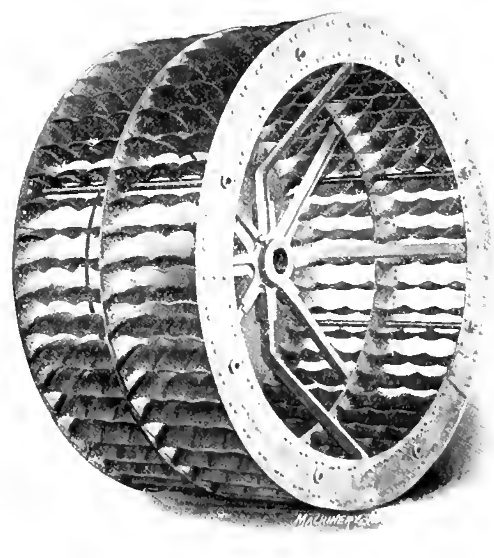
volumes. It was intended particularly for exhausting the dust produced by the buffing wheel, in smoothing the soles of shoes. At that time it was thought necessary to use small pipes and maintain a high velocity throughout an exhausting system, and as the inventor naturally designed this fan for a pulley drive at the high rotative speeds existing in shoe factories, planing mills, etc., where the device was used, the



Design of Runner for Sturtevant High-speed, Large Volume Fan.

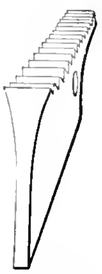
form of fan he developed had 24 or more blades, curved, and with a depth equal to about 1/8 the diameter of the wheel, which was very narrow. This was, and still is, the proper form for such service, where the volume required is small as compared with the velocity. Further study of the problem showed that there was a wide field for fans giving a large volume of air at low velocity. In many cases it is desirable to connect steam engines directly to the shaft, making the speed of the fan much lower than had previously been used. These and other considerations necessitated wider and fewer blades, giving the larger volume at lower velocity. At the same time the proportion of blade area to the volume was practically the same as in the type of wheel originally designed.

The B. F. Sturtevant Co., of Hyde Park, Mass., has recently added to these types a form intended for high speed and large volumes. Requirements of this kind have only been met with

in the past few years, with the growing use of the steam turbine and the electric motor. Still keeping the proportion of blade area to volume the same as in the previous types, the natural way to attain the desired result under the new conditions was to widen the wheel to give the increased volume, at the same time making the blades more numerous and considerably shallower, thus providing a large inlet area. In practice, slight changes in construction were found advisable to increase the efficiency and to reduce eddy currents and other obnoxious features. One of these improvements consists in making the floats for the high speed, large volume wheels with several cup-shaped cavities or spoons, as shown in the illustration. This prevents the air which enters the pockets from slipping along the length of the float, constraining it to enter and leave in a radial plane. The form of runner shown in the illustration is being regularly furnished by the makers for high speed, large volume service.

SIMONDS SCREW SLOTTING HACK-SAWS.

The Simonds File Co. of Fitchburg, Mass., is manufacturing extra thick, concaved hack-saw blades in sets of four, for the special purpose of slotting odd screw heads for tool and repair work. The general outline of one of these blades is shown in the accompanying line cut. The thickening of the width at the toothed edge gives the blade a clearance which allows it to be easily worked by hand, even on the widest size of the set, which is 0.109 inch thick. The other three saws are 0.083, 0.065 and 0.049 inch thick, respectively. These screw slotting blades, though they have been in the market but a short time, have already met with cordial appreciation on the part of tool makers, repair men and others, who have occasional jobs of screw slotting to do, which have hitherto been done in a patched up way with thin hack-saw blades, or on the milling machine with a milling cutter, at a considerable expense of time and labor.



Machinery,N.Y.

Wide-face Hack-saw Blade.

HENDERSHOT SHAFT COUPLING.

This device, which is being placed on the market by Manning, Maxwell & Moore, Inc., 85-87-89 Liberty Street, New York, embodies novel features of construction which gives it great usefulness and effectiveness. The design can be easily understood from Figs. 1 and 2, of which the first shows it assembled, and the second separated into its component parts.

It is made in two complete halves, each half consisting of a body and a split tapered bushing, the latter bored to fit the shaft and turned to fit the tapered hole in the body of the coupling. The two bodies, which form the flanges of the coupling, are provided with interlocking lugs on their faces, which take the torsional strain of the transmission, the bolts being required only for compressing the sleeve on the shaft. A turned ledge on the face of one flange fits a turned recess on the face of the other, thus serving to keep the shafts concentric with each other and in correct alignment.

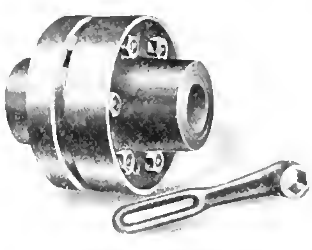


Fig. 1. Hendershot Shaft Coupling, Assembled.

Among the advantages of this construction are the following: The two parts of the coupling may each be assembled on its own shaft while they are on the floor, before being hoisted into place, thus facilitating the work of erection. Owing to the fact that two taper bushings are used instead of one, differences in diameter of the two shafts are taken care of without the slightest difficulty. The transmission of the turning moment by interlocking lugs instead of by the bolts, relieves them of a large share of the strain; though, in accordance with the plan of making this coupling unusually strong, even greater bolt area than usual is provided. The tapered bushings are made quite thin, while the hubs are proportionally large, thus obtaining great strength and holding power with the application of comparatively little force in clamping.

It will be seen that this device is, in use, simply two positive interlocking couplings of the old style, presenting, with the improved design, the advantages of not requiring to be accurately fitted to the shafts, driven on them, or have key-

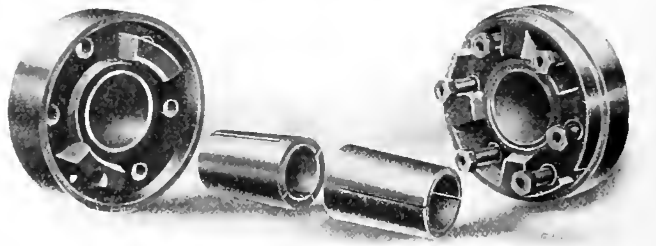

Fig 2. The Construction of the Coupling, as shown by the Component Parts.

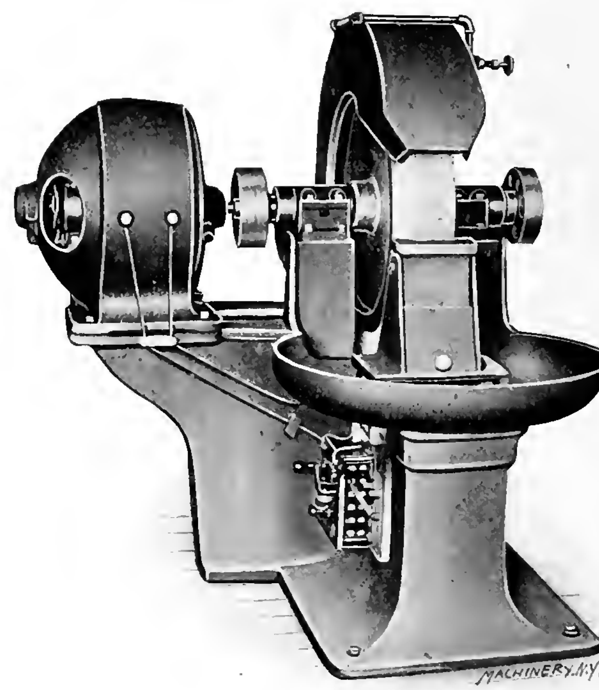
ways cut in the latter. The coupling is easily taken apart by screwing two bolts into holes tapped in the shell for that purpose. Each complete set is put together on a test bar and inspected before it leaves the factory.

BRIDGEPORT DROP APRON TOOL GRINDER.

The principal peculiarity of the tool grinder shown in the engraving is the fact that the rim of the bowl which surrounds the wheel stand has been made considerably lower than is usually the case. The reason for this construction is to be found in the necessity for grinding tools much larger and



Tool Grinder with Low Bowl or Apron, for Grinding Long-shanked Lathe or Planer Tools.

longer than was the case when the original designs of wet tool grinders were first brought out. The great size and length of these tools makes it almost impossible to grind them at the proper angles on grinding machines as ordinarily made with the high bowl or apron, it being impossible to lower the shank to an angle sufficient to give the proper bevel.

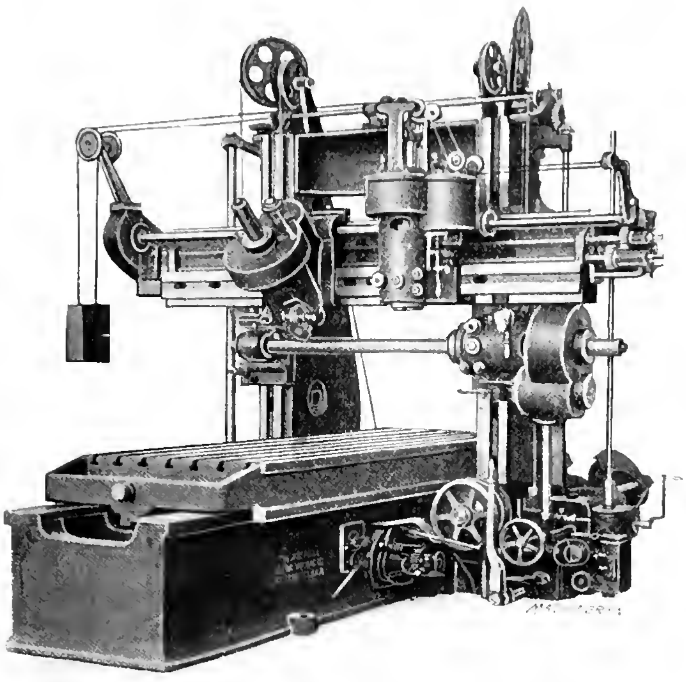
In its general construction, the tool is similar to other machines the builders brought out. The base forms a large water tank supplying the centrifugal pump, which forces a full stream of water to the wheel. The tool may be either belt or motor driven. When belt driven, it is equipped with tight and loose pulleys on the emery wheel spindle, with a self-locking belt shifter to hold the belt on the desired pulley. This shifter is within easy reach of the operator. When driven by a direct-current motor the motor is mounted on a substantial bracket, cast integrally with the base, as shown in the engraving. The armature spindle is then directly coupled to the wheel spindle. When arranged for an alternating-current motor, the motor is back geared to the wheel spindle, being mounted on a bracket similar to the one shown.

The device is made for a 36-inch wheel, with a 4-inch face, 20 by 21½ inches. The emery wheel should run about 425 or

450 revolutions per minute. The weight of the machine with motor is 2,600 pounds. It is built by the Bridgeport Safety Emery Wheel Co., Inc., Bridgeport, Conn.

INGERSOLL MILLING MACHINE WITH HORIZONTAL, VERTICAL, AND ANGULAR SPINDLES.

The milling machine shown in the accompanying half-tone was designed by its builders, the Ingersoll Milling Machine Co., Rockford, Ill., for milling the general run of work requiring the finishing of plane surfaces on the top, sides and ends. The angular spindle, shown in the cross rail, is a special provision for finishing the surfaces of inclined pillow blocks for gas engine frames.



An Ingersoll Miller with a Special Head for Facing Gas Engine Pillow Blocks.

Each of the two heads on the cross rail has an automatic reversible feed across the machine in either direction, each taking in the full width between the housings. The angular head may be readily removed, if it is not required for a considerable period of time, though it is not in the way of ordinary work when moved to the extreme end of the cross rail. When using the vertical heads, the horizontal arbor shown in place on the machine is removed. It can be seen that in finishing horizontal surfaces, either slabbing cuts or end mill cuts can be used.

It will be noticed that the horizontal head is at the operator's side of the machine instead of being mounted on the further cross-rail, as is common in machines of this kind. This makes it much more convenient for the operator in setting to proper depth of cut when using face mills. The horizontal spindle head, the cross-rail, and the spindle of the vertical head, are all counterbalanced to make the adjusting of the machine as easy as possible. The spindles are driven by spur gears cut from solid forgings, and are encased so that they can be packed in grease.

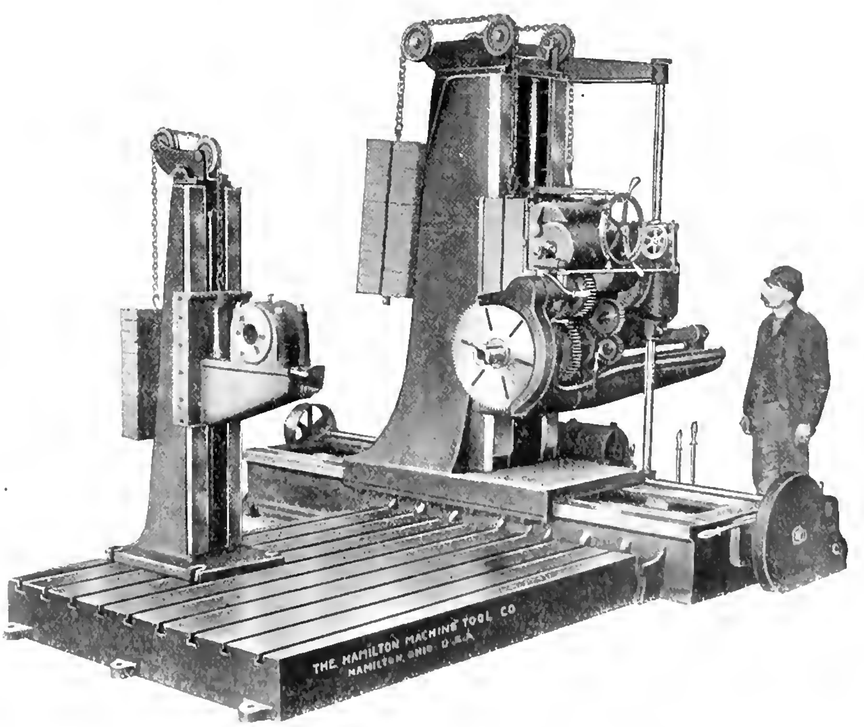
This machine is made in two standard sizes, 36 inches and 46 inches width, with any desired length of table. The positive table feed has eight changes for each cutter speed, giving a range of from ½ inch per minute up to 15 inches per minute. The quick power adjustment in either direction is about 30 feet per minute. The axial adjustment of the vertical spindle is 8 inches, that of the horizontal spindle being the same.

HAMILTON NO. 3 HORIZONTAL DRILLING, BORING, AND MILLING MACHINE.

The tool shown in the engraving is built by the Hamilton Machine Tool Co., Hamilton, Ohio. It is a drilling, boring and milling machine of heavy and rigid construction, characterized by a facility of adjustment and operation unusual in a machine of this size. It is particularly adapted to the handling of unwieldy pieces which are difficult or inconvenient to move. After these are once placed on the floor-plate, the spindle can be adjusted horizontally and vertically to perform different operations within its range, resulting in a saving of time and the obtaining of greater accuracy than by less improved methods of doing the work. The operations of drilling, boring and tapping, together with milling of slides, bearing surfaces and T-slots, can all be performed at one setting of the work.

In its general construction, the machine consists essentially of a floor-plate to which the work is fastened, combined withh a transverse bed along which a column may be adjusted or fed to any desired position within its range. The column carries the boring spindle in a slide on its face. An outboard support for the boring bar is also furnished, which is clamped in a suitable location on the floor-plate.

Power feeds and quick traverse movements in both directions are provided for the column on the bed, for the slide up and down the face of the column, and for the spindle in and out of its bearings in the slide. Graduations are provided for reading the various adjustments used for column slide and spindle, as well as for the adjustments of the outboard bearing, so that the matter of setting the machine for a given operation is a simple one. The spindle slide on the column is counterweighted, as also is the supplementary slide on the outboard bearing.



A Drilling, Boring, and Milling Machine of Rigid and Convenient Design.

The various spindle speeds and feeds are obtained from a single pulley running at constant speed, the changes being made by positive quick change mechanisms controlled by suitably placed levers. All the changes can be made while

the machine is in motion. There are eight changes for the feed of the column, slide and spindle, ranging between 0.0196 and 0.66 inch per revolution of the spindle for the column and slide, and from 0.001 to 0.033 inch per revolution for the longitudinal feed of the spindle. Positive quick change gearing with suitable levers provide for 16 spindle speeds in geometrical progression, ranging from 2 to 180 revolutions per minute. The mechanism for these changes is suitably enclosed and guarded, and the controlling handles are located within easy reach of the operator, as are those for the quick power movements. The single pulley drive makes the use of the motor drive a simple matter, it being merely necessary to replace the driving pulley with a constant speed motor.

The floor-plate, shown in the engraving, is 8 feet long by 6 feet wide and 10 inches thick. The area of this plate may be altered to suit the requirements of the purchaser. The traverse of the column on the bed is 72 inches; of the spindle slide on the column, 40 inches; and the longitudinal traverse of the spindle is 36 inches. The distance from the center of the spindle to the top of the floor-plate may be adjusted within the limits of 24 inches and 64 inches. The machine, as shown, weighs about 30,000 pounds.

HILBERT UNIVERSAL DRILLING TABLE.

The accompanying half-tone shows a device made by the Hilbert Machine Co., Cincinnati, Ohio, for increasing the range of usefulness of the ordinary drill press or radial drill. It is a universal attachment, permitting holes to be drilled at any angle in either of two planes, giving access to all sides of the work except the face upon which it is clamped.

The attachment consists of a circular table, pivoted at the center and capable of being swung to any angle about the axis perpendicular to its face, with provision for clamping to any desired position when it is obtained. The holder to

A Device for Presenting Work to the Drill Press at any Desired Angle.

which the table is pivoted is mounted on trunnions, carried by standards integral with the base, so that the work fastened to the table may also be adjusted about a horizontal axis. A worm-wheel sector with adjusting worm is provided for this motion, making it easy to handle heavy work with delicacy and certainty. When desired, for rapid adjustment the worm may be dropped out of mesh with the sector, and the table swung over by hand. Clamping mechanism is provided for this adjustment also. When used in connection with an ordinary drill press it will be seen that this device will perform many of the functions of the universal drill.

The base of the table is 14 x 14 inches, and the height from the horizontal clamping surface to the base is 22 inches. The table is 25 inch in diameter.

LANDIS STAY-BOLT CUTTER.

The Landis Machine Co., of Waynesboro, Pa., is building the stay-bolt cutter, illustrated in Fig. 1. The principal feature of this machine is the avoidance of the lead-screw, which has hitherto been considered necessary in stay-bolt threading machines to bring the thread of the stay-bolt to exactly the right pitch, so that it will match up with the holes in he boiler plates as tapped by the stay-bolt tap. If the pitch of the stay-bolt is not exactly proper, contiguous bolts in the boiler being of different pitches, the continuous threads produced by the tap will force the plates apart at different distances, thus straining both the plates and the bolts.

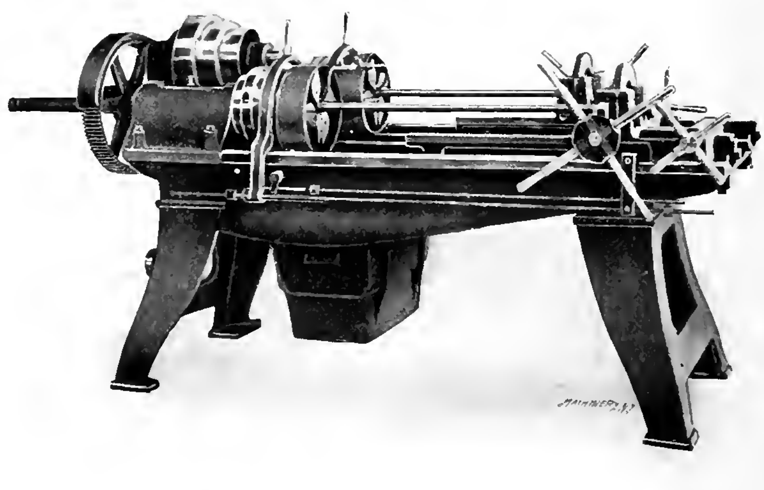


Fig. 1. Double Head Landis Stay-bolt Cutter.

The builders have adopted their regular form of chaser for this purpose, obtaining with its use, a high degree of accuracy without requiring the incorporation of a lead-screw in the machine. One of the chasers is shown in Fig. 2. As may be seen, the teeth are not hobbed, but milled. They are set in the head, tangent to the work, with the front ground at an angle so that the work only bears on the cutting edges for the first few teeth. The finished threads bear on the back of the cutting edge on the milled surface of the threads of the chaser. The work and the chaser together, thus furnish the lead-screw and nut for the machine. These chasers are carefully made, and very accurate results are secured. When a lead-screw and die are used, if they are not exactly the same pitch, the two work against each other, producing rough and torn threads.

Another advantage of the type of chasers shown is the fact that they are ground on the end only, and so may be sharpened repeatedly until the full length is used up. The end may also be ground at any angle to suit the material being worked on, it being possible to produce a curling chip, as with a lathe tool. The die never requires to be annealed, hobbed or retempered, consequently it is not subject to the changes which occur in rehobbing dies, and has a life far in excess of the old style type. The head in which it is mounted is arranged to swing the cutters apart or bring them together, so as to cover a wide range of diameters.

Fig. 2. Type of Chaser used in Landis Bolt Cutter.

The carriage of this machine has an adjustment vertically and sideways. The cutting strain is exactly central. The rack is provided with recesses between the teeth, so that it is impossible to clog them up with chips or scale, which are allowed to fall through into the base without interfering. The machine is built in single and double head arrangement in sizes up to 1½ inch diameter.

BRITISH INDUSTRIAL NOTES.

The previously mentioned downward tendency in British industrial returns continues, though not apparently at such a rate as to justify unduly pessimistic views. Here and there, slackness is pronounced; for instance, in Sunderland considerable distress prevails, as a consequence of the abnormal scarcity of ship-building orders, due to a number of causes, one being the high prices of ship-building material, another the high price of coal acting unfavorably on the shipping trade. In the Midlands, Wolverhampton has experienced several set-backs within recent years, due to the removal of large works to more favorable positions near the seaboard, the railway companies appearing unable, or unwilling, to assist—by reduced rates of carriage—in the retention of these businesses. Two works engaged in the manufacture of puddled iron, have just been sold, ostensibly on account of inability to meet competition, though an impression prevails in some quarters, that it is more in consequence of the pooling of financial interests. At the same time it is reported that the size of the large works formerly occupied by Daniel Lysaght & Co., who removed to Newport, South Wales, has been purchased by a London syndicate which will probably build new works, and Sir Alfred Hickman will entirely reorganize and equip the large steel smelting and rolling mill plant at the neighboring town of Bilston, electrical driving being adopted on a considerable scale.

Banks and Banking.

Though the subject of banking methods is not too often included in reports on engineering industry, the present financial troubles in the United States—sympathetically felt in other countries—may justify reference to an important paper on "A Decade of Bank Amalgamation," prominent points raised including the fact that since 1897 no fewer than eighty-five British banks have ceased to exist through amalgamations, a chief feature being the continued disappearance of the once powerful private banker. Tables given in relation to British joint stock banks, their assets and liabilities, show their great solidity. For every £100 of deposit liability the banks hold £30 in liquid assets, £17 in A1 investments, £62 is employed in making advances and discounting bills for the trading community, leaving only £9 in bank premises and cover for acceptances. In addition there is the guarantee of the uncalled capital which is equal to £24, or a total security of £142 for every £100 of deposit liability.

Franco-British Exhibition in 1908.

Considerable interest is being evinced in the Franco-British Exhibition to be held at Shepherd's Bush, London, in 1908. There appears some probability of a representative show of British and French machines and products. The buildings, etc., will cover forty acres.

Ship-building.

In ship-building, recent developments include the complete removal of Messrs. Yarrow from the Thames to the Clyde, which will take place immediately the last torpedo boat, now under construction, is completed. Operations, more particularly boiler-making, are now in progress at the new works. Messrs. Thorneycroft have practically removed all their naval works from Chiswick to Southampton, their latest production, which has just gone through its trials, being the turbine-driven destroyer *Tartar*, which in three runs, with and against the tide, attained the record speed of 35.95 knots. The *Ghurka*, another ocean-going turbine destroyer, built by Hawthorn, Leslie & Co., in her official six hours' trial attained an average speed of 33.91 knots. She proved her ability to steam a distance of 1,715 knots at a speed of 13½ knots without replenishing her fuel supply, which is considerably better than the Admiralty requirements. If supplementary oil tanks were fitted, she could steam 2,500 knots without taking on board more fuel.

Interesting Foundry Practice Development.

In foundry practice, a method, developed by Dr. Szekely, Sr., of 113 Clements Inn, London, of producing iron castings in metal molds shows interesting and suggestive results, there being practically no shrinkage. The molds are treated by a wash, and all castings produced are soft. We understand that Alfred Herbert, Ltd., Coventry, produces a number of its castings on these, or somewhat similar lines. Speaking broadly, more consistent attention than formerly is being devoted to the layout, equipment, and management of foundries, the British Foundrymen's Association being an active agent in the dissemination of information and suggestions calculated to improve the general status of the foundry, which, though essential to engineering, has never been as well recognized as its importance would naturally suggest.

Lifting and Conveying Machinery Sugar Machinery.

The manufacture of cranes and lifting and conveying appliances in general, has made substantial though unobtrusive progress of late years in this country. One of the most prominent concerns in Great Britain is that of Appleby's, Ltd., of Leicester and London, which by amalgamation with a Glasgow firm, and, more recently, with the Temperley Transporter Co., is now particularly well equipped for dealing with practically all branches of this important section. The building of the heavier traveling cranes, especially since the general adoption of electric driving, has often been dealt with by machine tool makers in conjunction with their regular output, but where such is still the case, the work is to all intents and purposes produced in a distinct shop or department. Iron and steel foundries, as well as ship-building yards, have contributed largely to the increased demand for powerful lifting appliances, while the general run of industries are increasingly alert as to the advantages obtainable from rapid internal transit of material. All the same, the number of plants concerned in this branch of work seems, to say the least, fully adequate to the demands made on their output.

In addition to other considerable orders, The Mirrlees-Watson Co. of Glasgow, has recently had placed in its hands the contract for the whole of the buildings and plant for a large sugar refining works in the State of Morelos, Mexico, the layout being such as will admit of easy extension. In the Glasgow district generally, things in the engineering and tool-making line are decidedly less brisk than for some time past.

Milling Machine Development—Yorkshire Tools.

In the way of milling machines, considerable advances have, within the last few years, been made by British manufacturers both as regards power provided—with proportionate stability—and ease of manipulation. This has taken place in all the branches of this class of tool from the heaviest and more simple forms, to those in which comprehensiveness of function for small and medium work is the leading characteristic. About eleven years ago (March, 1897) the writer contributed a short article to this journal, on Yorkshire tools, dealing with the phenomena of the extremely low priced tools which then formed the staple product of a number of makers in several districts. A number of Yorkshire friends obtained the impression that undue severity towards Yorkshire practice was evinced in the paper, though nothing was mentioned that could not easily be upheld, and full allowance was made for ruling conditions, and due credit given for wonderful value for price paid. However, the change in absolute value and accuracy of machine tools easily obtainable in Yorkshire during the last seven years or so, cannot be over emphasized. The amount spent in the most approved plant, organization, and design, must be enormous, and the result has more than justified the expenditure. Since the Paris Exposition of 1900, one firm alone—Dean, Smith & Grace, Ltd., Keighley, has at least trebled its turnover, having, since then, specialized on one form of machine tool only—lathes. On Japanese account alone, they have supplied over 250 lathes. The only tools built outside of lathes are special machines for their own use which cannot conveniently be obtained from other makers. The great majority of the lathes turned out are cone-driven and specially adapted for high-speed work, though all-gear-head machines are built to special order or to meet certain conditions. A line now being produced very successfully is that of four-jaw independent chucks, it very early being seen that the then commercially obtainable chucks were far from equal to the duty imposed by high-speed steel.

JAMES VOSE.

Manchester, Eng., December 31, 1907.

OPENING OF THE NEW ENGINEERS' CLUB BUILDING.

On the evening of January 11, more than 600 men of prominence in the engineering, architectural, and industrial world, met at the new Engineers' Club house in Philadelphia for a house-warming and reception. It probably was the largest and most representative gathering of engineers ever held in Philadelphia. The event marked the thirtieth anniversary of the club, which has had a long and creditable career.

The new club house, which is situated at No. 1317 Spruce Street, was formerly the residence of Mr. Charles Potts, a wealthy iron manufacturer. It was designed by Mr. Lewis Hickman on such broad lines that when the Engineers' Club purchased it, it was found to need little alteration to convert it into an ideal club house. The purchase price was $55,000, and $15,000 additional was spent in changes and furnishings.

Fig. 1. New Engineers' Club of Philadelphia

The building, which is of brownstone and four stories in height, has a frontage of 25 feet and a depth of 140 feet. At the right of a wide hall is a lounging and reception room 17x48 feet, fitted with two costly mantel pieces, one of solid onyx and the other of mahogany. In this room is a chandelier valued at several thousand dollars, which was imported by Mr. Potts from Turkey. Handsome mahogany tables and leather upholstered chairs make this room most comfortable and inviting.

The meeting hall is on the second floor in the front. This was two rooms which are now converted into one large room 24x48 feet. Here can be seated 200 persons, and it is the intention of the club to hold not only semi-monthly meetings of the club here, but also all business meetings. In the rear of the meeting room is a closet wherein can be installed the stereopticon apparatus when it is not in use. The room is lighted by electric lights hung close to the ceiling in front of the ceiling beams so that the rays of light do not dazzle the eyes of those seated in the auditorium.

The library, a room 17x34 feet, filled with books and periodicals, is on the second floor, at the rear of the meeting hall. The floor of this room is covered with cork carpet. Back of the library is a small room used temporarily by the officers, but which will eventually be used as a conversational corner. On the third floor are six comfortably furnished bedrooms for convenience of out-of-town members. On the fourth floor a room 17x67 feet is given over to a playroom, being equipped with pool tables, shuffle board, etc. There are also two bedrooms, a bath and committee room on this floor.

The Engineers' Club was founded December 17, 1877, at a gathering of twenty-one engineers at the home of Dr. Coleman Sellers. Fifty members were quickly enrolled, and the growth of the club has been going on steadily since. Some very notable papers have been contributed by its members. Of the original members who organized the club, there are only three surviving, these being Mr. Wilfred Lewis, Mr. Chas. A. Billin, and Mr. M. R. Muckle, Jr. The present membership is about 590. The recent growth has been rapid, about 124 new members having been enrolled within the past few months.

Fig. 2 Lounging Roome, Engineers' Club

Fig. 3. Meeting Hall, Second Floor, Engineers' Club.

The following are the officers: President, H. W. Spangler; vice-presidents, Washington Devereux, W. P. Dallett, Wm. Easby; secretary, Francis Head; treasurer, George T. Gwilliam.

* * *

THE MACHINERY CLUB, NEW YORK.

Plans for the new Machinery Club are practically mature at the present writing, and all the contracts for furnishing, equipment and decoration have been made. The Fulton Building, whose two upper floors, the twenty-first and twenty-second, the club is to occupy, is to be ready April 15, while the contracts are all called for completion on April 1, so there should be no delay in geting into the quarters as soon as the building is completed.

The architect's plans show a very elaborate and serviceable lay-out. The twenty-first floor will be occupied by the offices, hall, coat room, reception room, etc., and the main dining-room. This latter will be of sufficient size to accommodate 500 guests during the luncheon period, between 12:30 and 2 or 3 in the afternoon. In addition to this, there is, on this floor, a large grill-room and a bar. The top floor of the build-

ing, the twenty-second, is provided with a ladies' dining-room, a smoking-room and a number of private dining-rooms. Only a part of this story is housed in, the remainder being fitted up as a roof garden, to be used in pleasant weather. This should be an especially attractive feature, as the building is a lofty one near the water's edge, on the outskirts of the high building district, with unobstructed view in almost every direction. The kitchens are also on this floor, in the rear of the building.

As we have previously explained, the membership of this club is divided into three classes; resident members, suburban members and non-resident members. We are informed that over 500 membership applications have been accepted by the committee on membership, these being about equally divided between resident and non-resident members.

* * *

PERSONAL.

Walter B. Snow, publicity engineer, Boston, Mass., has been elected president of the alumni association of the Massachusetts Institute of Technology.

A. L. Roberts has entered the employ of Pawling & Harnischfeger, Milwaukee, as mechanical and designing engineer. Mr. Roberts was for eighteen years with the Morgan Engineering Company.

T. D. W. Moore, general manager of the Remington Arms Co., Ilion, N. Y., has resigned his position, and will be succeeded by Mr. Jerome Orcott, general manager of the Union Metallic Cartridge Co., Bridgeport, Conn., as general manager and superintendent.

Gorham C. Parker, formerly head of the selling department, Jacobs Mfg. Co., Hartford, Conn., has been made sales manager of the Wm. J. Smith Co., New Haven, Conn., manufacturer of adjustable reamers, automatic tools and special machinery.

George A. Gauthier, formerly chief draftsman and designer of the Universal Screw Machine Co., Hartford, Conn., has taken a position in Toronto, Canada, to design machinery for the Caldwell double-thread wood screw, which is being developed by Worth & Martin of that city.

D. G. Baker, who has been superintendent of the Remington Arms Co., Ilion, N. Y., for the last three years, has resigned that position, and will become one of the engineering firm of S. M. Green, Inc., Holyoke, Mass. Mr. Baker will remain in Ilion with the Remington Arms Co. as consulting engineer for some time.

H. F. Sanville, who has been for the past two years with Dodge & Day, engineers, of Philadelphia, joined the organization of Frank B. Gilbreth, general contractor, on the first of the year. Since completing his engineering education at Columbia University, in 1892, Mr. Sanville has had a very wide experience in engineering and construction, as well as in commercial lines. For the past four years he has been secretary of the Philadelphia section of the American Institute of Electrical Engineers.

A dinner was given by the American Museum of Safety Devices and Social Hygiene at the rooms of the Aldine Association, January 15, in honor of the decorations conferred by the French Republic upon Mr. Charles Kirchhoff, editor the *Iron Age*, Mr. T. Commerford Martin, editor *Electrical World*, and Rev. Percy Stickney Grant, rector Church of the Ascension. Mr. Elbert H. Gary, chairman of the U. S. Steel Corporation presided, and John La Farge, the eminent painter, conferred the decorations of Officier de L'Instruction Publique.

MEMORIAL SERVICE FOR LORD KELVIN.

An impressive memorial service in honor of Lord Kelvin, who died December 23, was held in the Engineering Societies Building, New York, Sunday, January 12, under the auspices of the American Institute of Electrical Engineers, assisted by representatives of the American Society of Mechanical Engineers, American Society of Civil Engineers, and other leading engineering societies of United States and Great Britain. The program included the reading of memorial resolutions by the secretary. These were adopted by a rising vote. President Stott of the American Institute of Electrical Engineers made appropriate introductory remarks, and introduced Prof. Elihu Thompson, whose subject was: "Lord Kelvin as an Electrical Engineer." He was followed by Prof. E. L. Nichols with the subject, "Lord Kelvin as a Scientist." Mr. G. G. Ward, vice-president of the Commercial Cables Co., spoke on the subject, "Lord Kelvin's Work in Submarine Telegraphy," and Rear Admiral Geo. W. Melville, U. S. N., treated of his work in naval engineering. To T. C. Martin was given the subject of Lord Kelvin's relation to the American Institute of Electrical Engineers. Mr. Ward's remarks were of much interest because of his intimate connection with submarine telegraphy, in which Lord Kelvin's most notable commercial success and widest fame were won. The mirror galvanometer, which was followed by his equally sensitive and more practical siphon recorder, are rated among the most remarkable instruments ever devised. The effects of inductance, reactance and capacity in very long submarine cables prohibits the use of strong electrical currents. The first cable laid in 1858 was ruined by disregard of Lord Kelvin's advice, the insulation being broken down by using too great battery power. The mirror galvanometer responds to impulses so feeble as to be almost inconceivable. It is asserted that a battery contained in the bowl of an ordinary clay pipe is sufficient to operate an ordinary ocean cable of 2,000 or 3,000 miles length.

* * *

OBITUARY.

George V. Cresson, president of the George V. Cresson Co., Philadelphia, Pa., died at his country home near Philadelphia, January 18, at the age of 71.

Charles W. Martin, Jr., assistant general manager of Jenkins Bros., New York, died at his home in Bay Ridge, South Brooklyn, December 31, of pneumonia, following an attack of the grippe. Although Mr. Martin was only thirty-seven, he had been in the employ of Jenkins Bros. twenty-one years, having entered their employ when a boy of sixteen. He was one of the best known men in the power plant and railway supply fields and had a wide circle of friends. He leaves a wife and two children.

Matthias N. Forney, a well-known retired engineer, author, editor and publisher, died of paralysis January 14. He was born March 28, 1835, in Hanover, Pa. Mr. Forney displayed a marked taste for mechanics at an early age, and in 1852 entered the shop of Ross Winans as an apprentice to learn the building of locomotives. Following his apprenticeship in the shop and drafting-room was a period of varied mechanical and mercantile experience during which he was granted a patent in 1866 for the celebrated "Forney" tank locomotive, which was used for years on the elevated railways of New York City, and in large numbers by contractors, etc. In 1870 he became associate editor of the *Railroad Gazette*, and in 1873 brought out his celebrated Catechism of the Locomotive, which has had a large sale. He was later the editor and part owner of that Journal, severing his connection in 1883. In 1886 he bought the *American Railroad Journal* and Van Nostrand's *Engineering Magazine*, which were consolidated under the name *The Railroad and Engineering Journal*, later being changed to *American Engineer and Railroad Journal*, under which name it is still published. Mr. Forney was very active in the Master Mechanics' and Master Car Builders' Associations. He was married for the first time about one year ago.

DR. COLEMAN SELLERS.

The death of Dr. Coleman Sellers, at his home in Philadelphia, Pa., December 28, removed one whose ingenuity and taste did more, perhaps, than any of his contemporaries to make American machine tools the standard of excellence and efficiency the world over. He was born in Philadelphia, January 28, 1827. His early education included a course in the academy of Anthony Bolman, West Chester, Pa., from which he graduated at sixteen. To possibly benefit his health, which was not robust, he was advised to engage in agricultural pursuits for a year or so after graduation, but his tastes were too scientific and mechanical to long permit him to follow this prosaic occupation, but during this period his inventive

Dr. Coleman Sellers.

genius was displayed in the invention of a metal tooth hay-rake on wheels that anticipated by many years the modern implement.

At nineteen his brothers in Cincinnati gave him a position as draftsman in the Globe Rolling Mills in that city, and before he was twenty-one he was made superintendent and general manager of the mills. This fact of having gained a thorough insight into the manufacture of iron in less than two years, coupled with evident executive ability, early developed, speaks eloquently for his extraordinary talents. In 1851 at the age of twenty-four he was made foreman of Niles & Co., locomotive builders of Cincinnati, the founders of the present Niles Tool Works branch of the Niles-Bement Pond Co., at Hamilton, Ohio. Five years later he returned to his home city, Philadelphia, and became chief engineer of Wm. Sellers & Co., and later was made a member of the firm.

His inventive genius and skill as a designer soon put the Sellers machine tools, already well-known, in advance of competitors. Those were the days of piano legs, beading, fluting, scroll work and other *outré* architectural ornaments in machine design, now regarded as ridiculous, but then considered to be quite the proper thing. Young Sellers discarded the clumsy and inappropriate designs, and made shapely and well-proportioned forms which coupled with superior mechanical design throughout, easily made Sellers tools the best produced. He was the first to devise the scheme of rational design in proportioning shafting, hangers and pulleys for power transmission, thus revolutionizing the power transmission business which had grown up under the totally unsound and ungainly system of selling by the pound. The obvious effect of this practice, of course, was to make the power transmission parts as heavy as possible without particular regard to the stresses transmitted. In these days of copious half-tone illustration, it is interesting to know that Mr. Sellers was an "amateur" photographer who materially advanced the art by his experiments and practice. He took it up in 1858, having recognized its value for advertising machine tools.

Dr. Sellers was associated with Wm. Sellers & Co. for thirty years, resigning in 1886 to enter consulting engineering practice. In 1889 he was retained to assist in the power development of Niagara. It is of melancholy interest that Dr. Sellers and Lord Kelvin, both having been connected with the pioneer development of this great water-power, died only five days apart. Lord Kelvin, then Sir William Thompson, was chairman of the International Commission of five members appointed to develop the plan of power development, and Dr. Sellers was consulting engineer. He acted both as consulting engineer of the Cataract Construction Co. and as chief engineer and president of the Niagara Falls Power Co.; also as chief mechanical engineer of the Canadian Niagara Power Co. His work in the pioneer development of these great water powers would alone establish his standing as a great mechanical engineer of international renown. Besides the mechanical features of the dynamos, improvements in the shaft bearings and other details of the installation, his advice guided the company safely through the whole of the initial development, both as to the mechanical as well as the electrical features involved.

Dr. Sellers was a member of the leading engineering societies of the United States and Great Britain; he was a charter member of the American Society of Mechanical Engineers. At the time of his death he was associated in consulting work with S. Howard Rippey and H. W. Sellers, of Philadelphia, under the firm name of Sellers & Rippey, the practice being now continued by the junior partners.

* * *

NEW BOOKS AND PAMPHLETS.

PROCEEDINGS OF THE TRAVELING ENGINEERS' ASSOCIATION; FIFTEENTH ANNUAL MEETING, CHICAGO, ILL., September 3-6, 1907. 340 pages, 6 x 9 inches. W. O. Thompson, secretary, Buffalo, N. Y.

PROCEEDINGS of the Twenty-seventh Annual Convention of the American Water Works Association, held at Toronto, Ontario, Canada, June 17-21, 1907. 527 pages, 6 x 9 inches. Published by the Secretary, J. M. Diven, 14 George St., Charleston, S. C.

COAL MINE ACCIDENTS, THEIR CAUSES AND PREVENTION. By Clarence Hall and Walter O. Snelling, with introduction by James A. Holmes. 22 pages, 6 x 9 inches. Published by the Department of the Interior, U. S. Geological Survey, Washington, D. C.

REPORT of the Proceedings of the Fifteenth Annual Convention of the International Railroad Master Blacksmiths' Association for 1907. 244 pages, 5¾ x 8¼ inches. Published by the association. A. L. Woodworth, Lima, Ohio, secretary.

AMERICAN SOCIETY OF TESTING MATERIALS; PROCEEDINGS OF THE 10TH ANNUAL MEETING, held at Atlantic City, N. J., June 20-22, 1907. 759 pages, 6 x 9 inches. Published by the society, Edgar Marburg, secretary-treasurer, University of Pennsylvania, Philadelphia, Pa.

Technical Literature, published by the Technical Literature Co., 220 Broadway, New York, has been changed in name to the *Engineering Digest*. This publication, as many of our readers doubtless know, is a review of the general engineering press, and is intended to give its busy readers a comprehensive idea of the best and most important current articles without the drudgery and time-consuming process of reading all the technical and trade publications.

BANKER'S MATURITY GUIDE AND HOLIDAY CALENDAR. 32 pages 5x6¾ inches, with thumb index. Compiled and published by Sperry & Morgan, Hartford, Conn. Price, 50 cents.

This convenient little work is a summary of the laws and customs in the United States and possessions, Canada, Cuba, and Mexico, governing days of grace, Saturday half-holidays, maturities of negotiable paper, legal rates of interest, etc. It should be of value to manufacturers and others generally doing business in the various states and countries represented.

THE STUB TOOTH GEAR. 24 pages, 6 x 9 inches, illustrated. Published by the Fellows Gear Shaper Co., Springfield, Vt., for free distribution to those interested.

This pamphlet describes in a very convincing fashion the merits of the involute gear tooth of shortened addendum and increased pressure angle, as exemplified in the "stub tooth" system introduced by the Fellows Gear Shaper Co. The subject is discussed very plainly, with a profusion of explanatory diagrams. It is stated that fully one-third of the cutters ordered from this firm, are now required by customers to be of the stub tooth form.

MACHINE DESIGN. By Charles L. Griffin. 186 pages, 6 x 9 inches. 82 line illustrations. Published by the American School of Correspondence, Chicago, Ill. Price $1.50.

This work is substantially the same as the well-known work on machine design published by Mr. Griffin some years ago. It is bound in red cloth binding, uniform with the edition of books on various mechanical and electrical subjects now being issued by the American School of Correspondence. As a simple and comprehensive work on machine design on the subjects treated it is one of the most clear and logical that we have ever examined. It is deservedly popular.

WM. DAWSON & SONS, LTD., Cannon House, Bream's Buildings, London, E. C., England, have sent us their little "red book" listing annual subscriptions to English and foreign magazines, newspapers, etc. This list of the principal daily, weekly, and monthly papers and magazines is arranged alphabetically, with subscription prices for a year, both for England and abroad. A classification follows enabling one to find at a glance all papers on a certain subject or science. The little book also includes a full list of the principal American, Canadian, Australian, Chinese, Japanese, French, German, Indian, etc., newspapers, there being in all 5,000 listed. Copies are sent to any address on application.

SPECIFICATIONS AND CONTRACTS. By J. A. S. Waddell, with Note on the Law of Contracts by John C. Wait. 174 pages, 6 x 9 inches. Published by the Engineering News Publishing Co., New York. Price $1.00.

This work is compiled from a series of lectures delivered by Dr. Waddell. It treats of specifications and gives examples for practice in specification writing, engineering contracts, examples for practice in contract writing, notes on the law of contracts. The work is one that will be highly appreciated by contractors, manufacturers and others having to execute contracts for engineering work. A study of its pages would often save some very costly mistakes. The book is one that we can recommend to all engaged in contract work.

ELECTRICAL POCKETBOOK FOR 1908. 247 pages, 4 x 6 inches, illustrated. Published by Emmott & Co., Ltd., 65 King St., Manchester, England. Price sixpence, net.

This pocketbook is compiled on lines similar to the *Mechanical World* pocket diary, published by the same concern. It treats of the electrical units by the C. G. S. system, specific resistance, table of horse-power equivalents in volts and amperes, mechanical and electrical unit equivalents, electrical transmission of power, dynamos and motors, methods of distributing electrical energy, alternating and polyphase motors, alternating current generators, machine driving by electric motors, and in general contains a large amount of useful electrical data. Mathematical tables are also included, and about sixty blank pages for diary and memoranda.

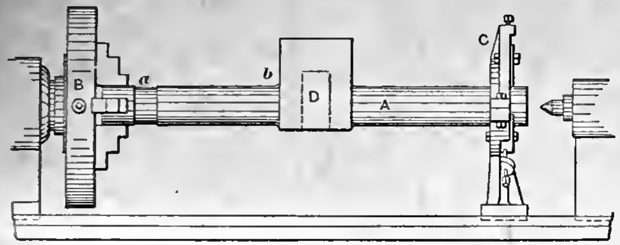
NEW BASIS OF CIVILIZATION. By Prof. Patten. Macmillan Co., New York. Price $1.00.

This book may seem at first thought to be a little out of our line, but it really treats of subjects in which every mechanic should be vitally interested. The author's idea is that the tremendous improvements in the production of wealth that have taken place in the past decades, are resulting in an economic change which is destined to

PUNCH PUNCH

SHOP OPERATION SHEET NO. 55.

Stanley Gould. MACHINERY, March, 1908.



To Rough Turn a Single-throw Crank-shaft Forging.

1. Place on the lathe spindle an independent four-jaw chuck *B*. Clamp center-rest *C* to the lathe bed at a point nearly the length of the forging *A* from the chuck.

2. Place the end of forging *A* in the jaws of the chuck *B* and clamp it, supporting the opposite end in the center-rest *C*. Lubricate the inner ends of the jaws. Prick punch center of forging. Adjust center rest jaws to bring this mark opposite tail center. Start the lathe. Hold a piece of chalk against the forging at *a*, and adjust chuck jaws until forging runs true.

3. Turn the space *a* long enough to take center-rest jaws.

4. Reverse the forging *A*, placing opposite end in chuck jaws, and space *a* in center-rest jaws. Adjust the chuck jaws as in Step 2.

5. Face end of forging to length. Drill and ream center. Bring up tail-stock center. Remove center-rest *C*. Turn a bearing for center-rest between chuck and crank, and close up to crank as at *b*, and adjust center-rest here.

6. Rough turn the end next to tail-stock, leaving from 1/16 to 1/8 inch, according to size of shaft, for finishing.

7. Change center-rest *C* to opposite side of crank. Rough turn shaft from crank to chuck.

8. Face both outsides of crank nearly to finish dimensions.

9. Change forging end for end, supporting tail-stock end in center-rest *C* jaws on turned part. Turn part previously held in chuck, face end to length, and drill and ream center. Remove forging from lathe.

10. Lay off that portion of the crank which is to be removed, as shown by the dotted lines at *D*. The vertical dotted lines should be equidistant from the sides of the crank, and the horizontal dotted line located so as to leave plenty of stock for the pin. Lay out rows of holes, inside these dotted lines, spaced so as to touch each other.

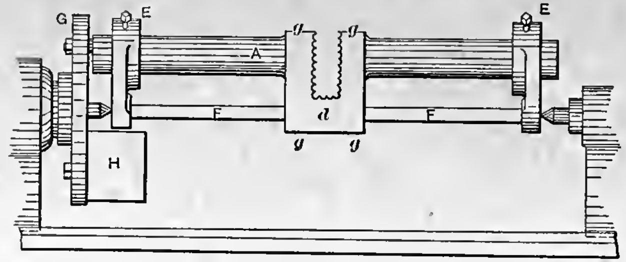
11. First drill each alternate hole, and then the remaining holes, the holes being drilled through the forging in both instances. Alternate holes are drilled first to prevent the drill from running into the hole next to it, as it would be apt to do if the holes were drilled in succession. After the holes have been drilled, remove the center piece with a hammer and chisel.

NOTE.—When the crank-shaft is large, the center piece can be removed with less trouble by drilling one row of holes along the horizontal dotted line, and then removing the center piece on the slotter, one cut being taken along each vertical dotted line.

PUNCH PUNCH

SHOP OPERATION SHEET NO. 56.

Stanley Gould. MACHINERY, March, 1908.



To Turn the Crank-pin of a Single-throw Crank-shaft Forging.

NOTE.—The crank-shaft is supposed to have been centered, the ends faced to the required length, and the shaft rough turned.

1. Select a pair of crank dogs or carriers *E* which are bored slightly smaller than the rough-turned shaft. Each of these dogs must be provided with a center upon which the work rotates when turning the crank-pin. The distance from these crank-pin centers to the center of the hole in the dog must equal the throw of the crank. Midway between each crank-pin center and the center of the crank dog hole, there is another center. These intermediate centers are used when turning the ends *g* of the crank.

2. Turn the ends of the shaft to fit the holes in the crank dogs *E*, and then place the dogs on the shaft as shown in the cut, allowing the ends of the shaft to project through the dogs as far as possible to make the work more rigid.

3. Put the crank-shaft in the lathe, using the crank-shaft centers. Locate the center of the crank-pin on one side of the crank. The distance from this center to the shaft will equal the throw of the crank, minus one-half the diameter of the shaft. Place the crank in a horizontal position, with the crank-pin center the same height from the lathe bed as the lathe centers. Measure the distance from the crank-pin center to the lathe bed, and then adjust each crank dog until the distance from the crank-pin center in the dog to the lathe bed is equal to this measurement. Fasten the crank dogs securely in place by tightening their set-screws.

4. Fit braces *F* between the crank dogs and the crank, to take the thrust of the lathe centers, and then shift the crank-shaft in the lathe, supporting it by the crank-pin centers. Move the crank-shaft until its centers are about the same height as the lathe centers, then caliper from the shaft to the lathe bed and see if the shaft is parallel with the bed. If it is not, one of the dogs must be readjusted.

5. Fasten a driver to the face-plate *G*, and a counterbalancing weight *H* opposite the crank-shaft.

6. Rough turn the inside faces of the crank to nearly finish dimensions. Rough turn crank-pin *d* until it is cylindrical.

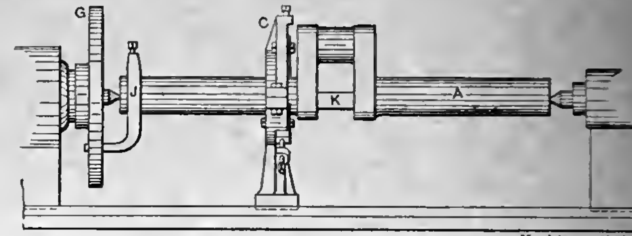
7. Finish inside faces of crank to dimensions, leaving fillets next to crank-pin. Finish crank-pin to finish dimensions.

8. Put the work on the intermediate centers in crank dogs *E*, and finish the ends *g* of the crank.

PUNCH PUNCH

SHOP OPERATION SHEET NO. 57.

Stanley Gould. MACHINERY, March, 1908.



To Turn the Main Bearings of a Single-throw Crank-shaft.

NOTE.—It is assumed that the main bearings and the outside faces of the crank have been rough turned, and the inside faces of the crank, and the crank-pin, have been finished. The work is supposed to have been left in the lathe on completion of the last operation, with the crank dogs and the braces, shown in the preceding operation, in place.

1. Remove the work from the lathe. Take off the crank dogs *E* and the braces. Put in place the block *K*, carefully fitted, so as to prevent springing the crank-shaft. Put the lathe dog *J* on the crank-shaft and clamp it. Put the shaft between the lathe centers, and the tail of the lathe dog in the slot in the face-plate *G*.

NOTE.—When turning a crank-shaft, unless it be one of very small size, a counterbalancing weight should be fastened to the face-plate. This weight should be placed on the face-plate near the point indicated in the illustration by the tail of the dog *J*. If the dog *J* fits loosely into the slot in the face-plate, the play should be taken up by inserting a wooden wedge.

2. Turn a space on the crank-shaft between the face-plate and the crank, and near the latter, removing as little stock as possible to true it. Clamp the center-rest *C* at this point, oil the jaws and adjust them.

3. Take a roughing cut over the part of the shaft between the crank and the tail-stock center 1/32 inch larger than the finish diameter. If the shaft runs considerably out of true, take two or more cuts, as may be necessary.

4. Take a finishing cut, using a broad, keen-edged tool and a coarse feed. The width of the tool's cutting edge, and the feed, will depend upon the rigidity of the work. Soda water used on the finishing cut will produce a smooth surface.

5. Take a finishing facing cut on the outside face of the crank, making the side of the crank the required width. As the inside face of the crank has been finished it will be necessary to work from this face.

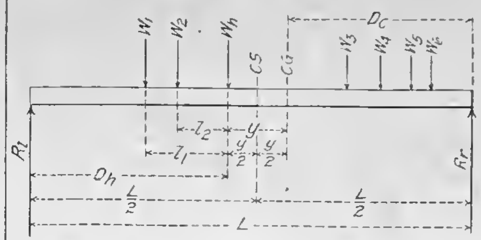
6. Turn the shaft end for end in the lathe, changing the lathe dog to the opposite end, putting a piece of copper under the set-screw to protect the finished surface. Adjust the center-rest jaws and oil their inner ends.

7. Repeat upon the rough-turned end of the crank-shaft the operations of turning described in steps 4 and 5.

NOTE.—As the stock between the sides of the crank was removed after the shaft was rough-turned, the shaft will very likely run somewhat out of true. Because of this, the turning operation described in step 2 is usually necessary.

I.—FORMULAS FOR MOVING LOADS.

Location for Maximum Moment.



CS denotes center of span.
CG denotes center of gravity of loads.
W_h denotes heaviest load adjacent to CG.
Let W = total load and M = moment.
For M a maximum place CS midway between W_h and CG and find M under W_h. For reactions, $R_l = \frac{WD_c}{L}$ and $R_r = W - R_l$. For maximum moment $M = R_l D_h - (W_1 l_1 + W_2 l_2)$, or since $D_c = D_h$, $M = \frac{WD_c^2}{L} - (W_1 l_1 + W_2 l_2)$.

Two Wheels Equally Loaded.

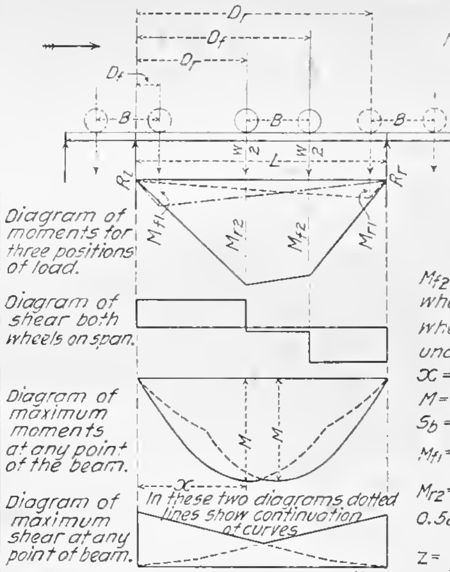


Diagram of moments for three positions of load.

Diagram of shear both wheels on span.

Diagram of maximum moments at any point of the beam.

Diagram of maximum shear at any point of beam.

For B = or exceeds 0.5858 L, $M = \frac{WL}{8}$ and $R_r = \frac{W}{L}(D_r + \frac{B}{2})$.

Notation: All values in inches and pounds. W = total load. $W/2$ = load on one wheel. L = length of span. B = wheel base. R_l = left reaction. R_r = right reaction. V = vertical shear = reaction nearest to the point under consideration. D_f = distance to front wheel, D_r = distance to rear wheel } the load coming on from the left. M_{f1} = moment under front wheel, one wheel on the span. M_{f2} = moment under front wheel with both wheels on the span. M_{r1} = moment under rear wheel, one wheel on the span. M_{r2} = moment under rear wheel, both wheels on the span. x = value of D_r for M_{r2} a maximum. M = maximum moment. Z = section modulus. S_b = stress due to bending.

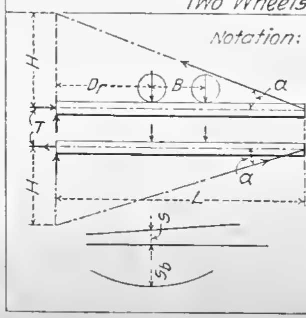
$M_{f1} = \frac{WD_f}{2L}(L - D_f)$. $M_{r1} = \frac{WD_r}{2L}(L - D_r)$. $M_{f2} = \frac{W}{L}(D_f - \frac{B}{2})(L - D_f)$.

$M_{r2} = \frac{WD_r}{L}(L - D_r - \frac{B}{2})$. For values of B less than 0.5858 L, $x = \frac{L}{2} - \frac{B}{4}$ and $M = \frac{WL}{4}(1 - \frac{B}{2L})^2$.

$Z = \frac{M}{S_b}$ or $S_b = \frac{M}{Z}$.

For both wheels on the span, $R_l = \frac{W}{L}(L - D_r - \frac{B}{2})$

Two Wheels Equally Loaded, Oblique Reaction.



Notation: Same as above with addition of; α = angle of the reaction with beam. A = cross sectional area of beam. T = thrust or pull due to oblique reaction. S = direct stress due to T (tension or compression).

$T = \frac{W}{H}(D_r + \frac{B}{2})$, or $T = \frac{W}{L}(D_r + \frac{B}{2}) \cot \alpha$.

$S = \frac{T}{A} = \frac{W}{HA}(D_r + \frac{B}{2})$, or $S = \frac{W}{LA}(D_r + \frac{B}{2}) \cot \alpha$.

M_{f2}, M_{r2}, x, M and S_b = same as above.

$S + S_b = W(\frac{D_r + \frac{1}{2}B}{HA} + \frac{D_r(L - D_r - \frac{1}{2}B)}{LZ})$, or

$S + S_b = \frac{W}{L}(\frac{(D_r + \frac{1}{2}B)\cot \alpha}{A} + \frac{D_r(L - D_r - \frac{1}{2}B)}{Z})$.

$S + S_b$ = a maximum when $D_r = \frac{LZ}{2HA} + \frac{L}{2} - \frac{B}{4} = \frac{Z}{2A}\cot \alpha + \frac{L}{2} - \frac{B}{4}$.

For light weight I-beams $\frac{Z}{A}$ = about $\frac{1}{3}$ depth of beam.

Contributed by John S. Myers.

II.—TABLES FOR SHEAR OR MOMENT. MOVING LOADS; TWO WHEELS EQUALLY LOADED.

Notation: W = total load on wheels. $\frac{1}{2}W$ = load on one wheel. L = length of span. B = wheel base. D = distance from support to point at which moment or shear is required. R = ratio of B to L = B/L. x = ratio of D to L = D/L. M = bending moment. S = vertical shear on beam which is also the reaction of the support nearest to the point under consideration. V_m and V_s are variables to be taken from tables.

Table giving values of V_m in formula $M = WLV_m$.

In both the above tables R = 0 indicates one wheel instead of two. When B = 0.5858 L the moment with one wheel in the center of span is equal to the maximum moment with both wheels on.

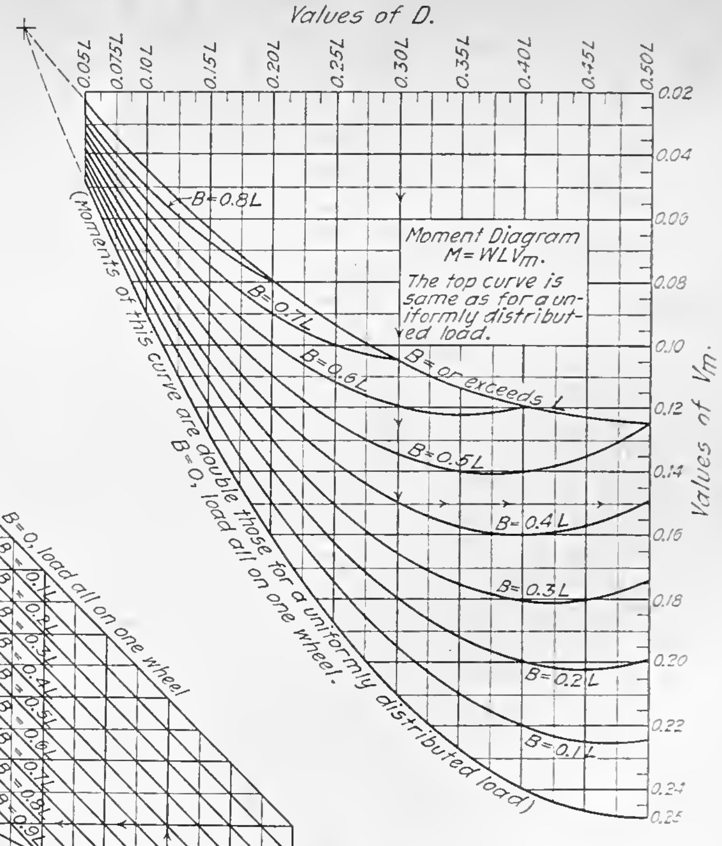
Contributed by John S. Myers.

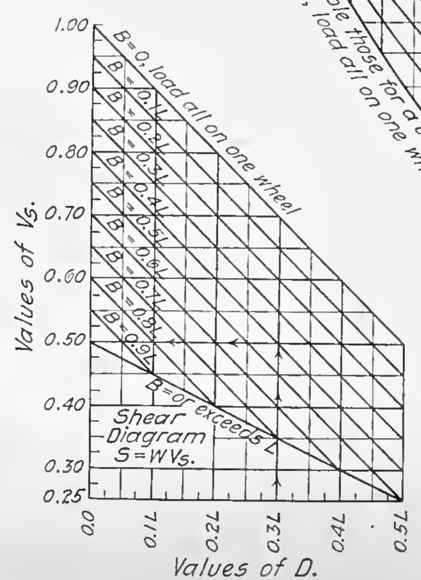
Payment will be made for all accepted matter.

This data sheet is made up so as to be readily bound. It may be cut into four sections, 6x9 inches in size, and bound into note-book form for convenient reference, by means of staples inserted into holes punched at points indicated.

III.—DIAGRAMS OF MOMENT AND SHEAR. MOVING LOADS; TWO WHEELS EQUALLY LOADED.

Notation: W = total load $\frac{1}{2}W$ = load on one wheel. B = wheel base. L = length of span. M = bending moment. S = vertical shear. D = distance from nearest support to point where moment or shear is required. V_m and V_s are variables to be taken from the diagrams. The shear is also the reaction at the nearest support.





Example: W = 2000 lbs. B = 8′0″ = 0.4L. L = 20′0″.
When D = 6′0″ = 0.3L, what is the bending moment and shear?
By the diagrams V_m = 0.15 and V_s = 0.5, then by formula, M = 2000 x 20 x 0.15 = 6000 ft. lbs. S = 2000 x 0.5 = 1000 lbs.

IV.—SAFE STRESS FOR BEAMS UNSUPPORTED LATERALLY.

In order to provide the same security in both flanges of a beam the compression flange should either be supported against lateral flexure at distances not greater than 20 times the flange width, or a lower stress should be used for the compression flange than is permissible for the tension flange.

The formula given in the Cambria Steel Co's. hand-book corresponding to 16000 lbs. per sq inch safe tensile stress is:

$$S_c = \frac{18000}{1 + \frac{L^2}{3000 b^2}},$$

where the letters have the following values; S_c = safe compressive stress. L = length unsupported in inches. b = breadth of flange in inches.

The curve marked 16000 was plotted according to the above formula.

The curves for 14000, 12500 and 10000 corresponding tensile stresses were plotted from proportionally lower values.

Values of S_c read from the 10000 curve, if considered as a decimal, give the ratio of safe compressive to safe tensile stress.

Values read from the dotted line in the same manner, give this ratio according to Pencoyd and Carnegie Co's hand-book.

Examples:

$\frac{L}{b}$ = 55, safe tension = 12500. What is the safe compression?

Following as indicated by arrows, the 12500 curve gives 7000; answer.

Following from A to B then to C indicates that for $\frac{L}{b}$ = 90 S_c = 0.3 S_t.

MAXIMUM STRESSES.—1.*

JOHN S. MYERS.†

THE problem of obtaining the maximum stress for which a part must be designed is sometimes a rather difficult matter. Often the designer arbitrarily assumes certain conditions to produce the maximum stress, which may be closely in accordance with the facts or may be far from them, depending entirely upon the judgment exercised.

Because of the time required to investigate, the extended operations necessary, men fully capable of performing the calculations, and often having a good understanding of the principles involved, sometimes make rash assumptions. In fact, there are many temptations to use a sort of combination of rough figures, judgment, and guess; satisfying the conscience by a wonderful faith in the factor of safety to cover a multitude of sins. It is often really necessary to pursue such a course in order to turn out the work with the expediency required by present-day employers. In some cases it is cheaper to be liberal with material than to virtually waste good time and brain fat on refinement of design. This is especially the case with the less important elements entering into a design. Too often, however, designs made with the foregoing ideas in mind are used over and over again, thus

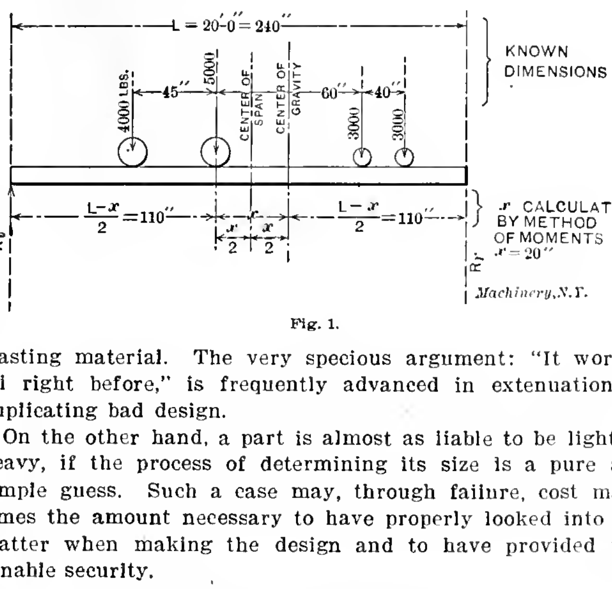

Fig. 1.

wasting material. The very specious argument: "It worked all right before," is frequently advanced in extenuation of duplicating bad design.

On the other hand, a part is almost as liable to be light as heavy, if the process of determining its size is a pure and simple guess. Such a case may, through failure, cost many times the amount necessary to have properly looked into the matter when making the design and to have provided reasonable security.

Purpose of Present Article.

It is the object of this article to present a few common cases of variable and of combined stresses, showing the manner of obtaining the maximum stress for which the part should be designed, these various cases leading up to the presentation of tables and diagrams, in data sheet form, whereby the labor of computing the stresses may be very much shortened.

Moving Loads.

The most common case of moving loads is that of two wheels equally loaded, such as a crane trolley on the crane bridge or the bridge upon the runway. There is nothing difficult about finding the maximum moment, provided the location of the load upon the span which produces the moment a maximum be known. This is also very simple, once the general rule covering the case is known. It is a fact, however, that many draftsmen, especially those engaged in mechanical work, do not know from positive knowledge what this location is. In many cases, they simply place the load in the center of the span or place one wheel in the center, and take it for granted that this location produces the maximum moment. If both locations be tried, the same moment will be found for each, which apparently confirms the supposition, and a man prone to jump at conclusions might readily draw the inference that the moment remains constant for any point intermediate between these two locations. Such is not the case.

General Rule.

For moving loads, when all the loads are upon the span at once, the maximum moment under any particular load will occur when the center of the span is midway between this load and the center of gravity of all the loads.

The load which produces the maximum moment will in nearly all cases be the heaviest one of the two loads adjoining the center of gravity, hence the rule may be stated:

Place the center of gravity of all the loads and the heaviest load adjacent to the center of gravity equidistant from the supports, and find the moment under the heaviest load.

Example.—What is the maximum moment produced by the system of wheel loading shown in Fig. 1?

Solution.—First find the center of gravity of all the loads by taking moments about some point of reference. Dividing the algebraic sum of the moments by the sum of the loads gives the distance from the point of reference to the center of gravity, thus:

Taking the 5,000-pound load as the point of reference,

Loads.	Distances.		Moments.
5,000 ×	0	=	000
3,000 ×	(+60)	=	+180,000
3,000 ×	(+100)	=	+300,000
4,000 ×	(—45)	=	—180,000

15,000 lbs. = total load. $\dfrac{300{,}000 = \text{moment}}{15{,}000} = 20$ inches,

distance of center of gravity to the right of the line of reference $= x$ in Fig. 1.

Placing the load such that the center of the span is midway between the center of gravity and the heaviest wheel load, or what is the same thing, placing the load such that the center of gravity of all the loads and the heaviest load are equidistant from the supports, gives the locations as indicated at the bottom of Fig. 1. To find R_l and R_r take moments as follows: Since the center of gravity of all loads is now known, consider them concentrated at this point; then $R_l = \dfrac{15{,}000 \times 110}{240} = 6{,}875$ pounds and $R_r = \dfrac{15{,}000 \times 130}{240} =$ 8,125 pounds. Adding the two reactions as a check, 6,875 + 8,125 = 15,000 pounds = total load. Taking moments under the 5,000-pound load,

$$6{,}875 \times 110 = +756{,}250$$
$$4{,}000 \times (-45) = -180{,}000$$

Maximum moment = 576,250 inch-pounds, the required answer.

Sections suitable for such purposes will be given in a later data sheet.

Two Wheels Equally Loaded.

The general rule previously stated, when applied to two wheels equally loaded, may be given as follows:

When the wheel base is less than $(2 - \sqrt{2})$ times the span $(= 0.5858 \times \text{span})$ the maximum moment occurs with both wheels on the span and when the distance from one support to the wheel nearest to it is equal to one-half the span minus one-fourth the wheel-base.

When the wheel-base exceeds 0.5858 times the span, the maximum moment occurs when one wheel is in the center of the span.

* For additional information on this and kindred subjects, see the following articles previously published in MACHINERY: Notes on Design, March and April, 1904; Charts in Designing, September, 1904; Flexure Simplified, December, 1903.

† Address: 1925 Hunting Park Ave., Philadelphia, Pa.

The equations expressing the various relations between the quantities involved and the method of deducing formulas equivalent to the foregoing rules are given below:

Referring to Figs. 2a, 2b, and 2c,

Let W = total weight carried by the two wheels,

$W/2$ = weight on one wheel,

L = length of span,

B = wheel-base.

Consider the load to be moving from left to right; and

Let D_f = distance to front wheel from left support.

D_r = distance to rear wheel from left support,

M_{f1} = moment under front wheel with but one wheel on the span.

M_{f2} = moment under front wheel with both wheels on the span.

M_{r1} = moment under rear wheel with but one wheel on the span.

M_{r2} = moment under rear wheel with both wheels on the span.

Then,

$$M_{f1} = \frac{W D_f}{2L}(L - D_f) \qquad (1)$$

$$M_{r1} = \frac{W D_r}{2L}(L - D_r) \qquad (2)$$

$$M_{f2} = \frac{W}{L}\left(D_f - \frac{B}{2}\right)(L - D_f) \qquad (3)$$

$$M_{r2} = \frac{W D_r}{L}\left(L - D_r - \frac{B}{2}\right) \qquad (4)$$

To find what location of the load upon the span produces the maximum moment when both wheels are on, differentiate* equation 4, whence we get

$$D_r = \frac{L}{2} - \frac{B}{4} \qquad (5)$$

which is the value of D_r which produces the maximum moment and agrees with the general principle previously stated.

To find the maximum moment, insert this value of D_r in equation 4 when it becomes, maximum

$$M_{r2} = \frac{WL}{4}\left(1 - \frac{B}{2L}\right)^2 \qquad (6)$$

For B = or exceeds $\frac{1}{2}L$ and one wheel in the center of the span, the load on this wheel being $\frac{W}{2}$, the moment is $\frac{WL}{8}$.

Substituting this moment for M_{r2} in equation (6) thus:

$$\frac{WL}{8} = \frac{WL}{4}\left(1 - \frac{B}{2L}\right)^2 \text{ and solving for } B,$$

$$B = (2 - \sqrt{2})\,L = 0.5858\,L \qquad (7)$$

Equation (7) shows that when $B = 0.5858L$ the moment with one wheel in the center of the span is just equal to the maximum moment with both wheels on the span, consequently equation (6) does not apply for values of B greater than this.

Let M = the maximum bending moment,

Z = section modulus,

S_b = stress due to bending.

Then,

$$S_b = \frac{M}{Z}; \text{ or } Z = \frac{M}{S_b} \qquad (8)$$

From this the maximum stress can be calculated when the section modulus is known, or the section modulus required to withstand a given moment and not exceed a specified stress may be determined.

It is interesting to note that for two wheels equally loaded, when the wheel-base equals or exceeds the span, the moment at any point of the beam is the same as for a uniformly distributed load, and that for wheel-bases equal to 0.5858 of the span or greater the maximum moment is the same as the maximum moment for a uniformly distributed load. For such cases, the beam required may be taken from the tables given in the various steel companies' hand-books by adding to the actual load a percentage to allow for impact, or by making the proper reduction in fiber stress. It follows from the above that, when the load is all carried on a single wheel, the moment at any point is double that for a uniformly distributed load. Hence, a beam may be picked out from the tables listed for double the load.

The Data Sheets.

Data Sheet No. 1.—The first part of data sheet No. 1 gives in condensed form the location for maximum moment, with formulas for same.

The second part gives a summary of the formulas for two wheels equally loaded, together with diagrams showing how

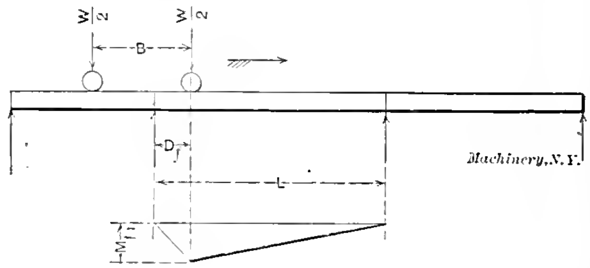

Fig. 2a.

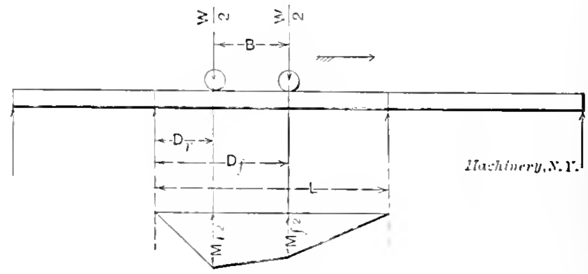

Fig. 2b.

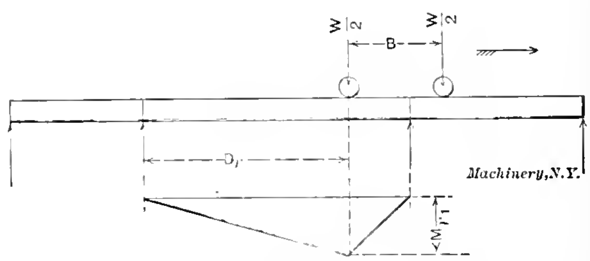

Fig. 2c.

the moment and shear varies for a specific location of the load or for any point of the beam.

The third part of sheet No. 1 will be discussed under its proper heading.

Data Sheet No. 2.—This sheet gives values of the variable Y_m in the formula $M = WLY_m$, where M = the moment occurring at any point throughout the length of the beam, L = length of span, and W = the load. The lower table on this sheet gives values of the variable Y_s in the formula $S = WY_s$ where S = the shear at any point of the beam and W = the load.

Data Sheet No. 3.—This sheet gives the same data as sheet No. 2, but in diagram form, which is easier to interpolate for intermediate values and will, therefore, recommend itself to those not prejudiced against diagrams. By the aid of these tables, or diagrams, the moment or shear at any point on the beam or girder can be quickly determined. This being known, it is easy to find the section modulus required, how close to the supports it may be necessary to bring the cover plates if a built-up section be used, and at what point the shear decreases sufficiently so that the web stiffeners may be omitted when such is permissible.

Example.—A girder of 20 feet span supports a load of 30,000 pounds carried on two wheels equally loaded, the wheel-base being 10 feet. (*a*) What is the maximum moment, and (*b*) what section modulus is required, assuming 12,000 pounds per square inch fiber stress?

$$* \; d\,M_{r2} = W\,d\,D_r - \frac{W}{L}\,2\,D_r\,d\,D_r - \frac{W\,B}{2\,L}\,d\,D_r. \quad \text{Placing}$$

$$\frac{d\,M_{r2}}{d\,D_r} = 0, \text{ and solving for } D_r \text{ gives,}$$

$$D_r = \frac{L}{2} - \frac{B}{4} \qquad (5)$$

Solution.—$L = 12 \times 20 = 240$ inches; $W = 30,000$ pounds; $B = 10$ feet $= 0.5L$. From the table (data sheet No. 2) or the diagram (data sheet No. 3) the maximum value of V_m is found to be 0.1406, say 0.14, then $M = WLV_m = 30,000 \times 240 \times 0.14 = 1,008,000$ inch-pounds. Ans. (*a*).

By formula 8, $Z = \dfrac{M}{S_b} = \dfrac{1,008,000}{12,000} = 84$. Ans. (*b*).

Example.—A girder carries a moving load on two wheels equally loaded, the wheel-base being 0.2 of the span. At what point could the outside cover plate be stopped off if it constitutes one-third of the flange area?

Solution.—It could be stopped off at a point where the moment is two-thirds the value of the maximum moment. Referring to the diagram on sheet No. 3 the curve for $B = 0.2L$ shows the maximum value of V_m to be 0.2025. Two-thirds of $0.2025 = 0.135$. The same curve shows for $V_m = 0.135$ that $D =$ about $0.158L$, which is the required answer. If the girder were 40 feet long, the outside cover-plate could be stopped off at $0.158 \times 40 = 6.32$ feet from each end. The plate should be carried beyond the theoretic point for a distance sufficient to insert two or three rivets.

Example.—The wheel-base being 0.4 the span, what is the maximum shear?

Solution.—By referring to either the table or diagram, the maximum shear is found to be 0.8 of the load.

Example.—If, in the last example, the web of the girder will carry 0.6 of the load without stiffeners, how far from each end must stiffeners be provided?

Solution.—Referring to the shear diagram, it is found that for $B = 0.4L$ and $V_s = 0.6$; $D = 0.2L$, or stiffeners must be provided at each end for a distance equal to 0.2 of the span.

Moving Load and Oblique Reaction.

Often a beam carrying a moving load is supported at one end by a tie-rod or a strut making an acute angle with the beam. In the case of a strut, this produces a direct tensile stress in the beam in addition to the bending stress, and in the case of a tie-rod a direct compressive stress is induced. A familiar example of this latter is found in a jib crane as illustrated by Fig. 3.

Let the notation be the same as in the case of simple beams with moving loads, making the addition of dimension H and angle α as indicated in Fig. 3; then let T = thrust on beam caused by the angle of the reaction. (If a strut be used, this angle is measured from the bottom of the beam, and a pull instead of a thrust is the result.)

$L =$ length of beam which is to be measured to the intersection of the center line of the rod with the center line of the beam.

α = angle of oblique reaction with beam,

A = cross-sectional area of beam,

S = direct stress,

S_b = stress due to bending.

Since the section modulus is based upon square inches, and stresses are expressed in pounds per square inch, all values should be expressed in inches and pounds.

The following formulas may then be developed:

$$T = \frac{W}{H}\left(D_r + \frac{B}{2}\right) \qquad (9)$$

or,

$$T = \frac{W}{L}\left(D_r + \frac{B}{2}\right)\cot\alpha. \qquad (9a)$$

$$S = \frac{T}{A} = \frac{W}{HA}\left(D_r + \frac{B}{2}\right) \qquad (10)$$

or

$$S = \frac{T}{A} = \frac{W}{LA}\left(D_r + \frac{B}{2}\right)\cot\alpha \qquad (10a)$$

$$M_{r2} = \frac{W D_r}{L}\left(L - D_r - \frac{B}{2}\right) \qquad (11)$$

$$S_b = \frac{M_{r2}}{Z} = \frac{W D_r}{LZ}\left(L - D_r - \frac{B}{2}\right) \qquad (12)$$

$$S + S_b = W\left(\frac{D_r + \frac{1}{2}B}{HA} + \frac{D_r(L - D_r - \frac{1}{2}B)}{LZ}\right) \qquad (13)$$

or

$$S + S_b = \frac{W}{L}\left(\frac{(D_r + \frac{1}{2}B)\cot\alpha}{A} + \frac{D_r(L - D_r - \frac{1}{2}B)}{Z}\right) \qquad (13a)$$

To find the value of D_r such that $S + S_b$ becomes a maximum, let $S + S_b = y$, substituting this in equation 13 and differentiating* gives

$$D_r = \frac{LZ}{2HA} + \frac{L}{2} - \frac{B}{4} \qquad (14)$$

which is the value of D_r which gives the combined stress $S + S_b$ a maximum.

The first term of equation (14) may be considered to be made up of two factors, namely, $\dfrac{L}{2H}$ and $\dfrac{Z}{A}$. The first, $\dfrac{L}{2H}$, will, in practice, generally be approximately equal to unity; the second, $\dfrac{Z}{A}$, will be quite approximately equal to one-third the depth of beam when the section used is a single, light weight I-beam, which is the section most commonly used in constructions of this kind. Formula (14) may then, with sufficient accuracy for all practical purposes, be expressed thus:

$$D_r = \frac{L}{2} - \frac{B}{4} + \frac{1}{3}\text{ the depth of beam.} \qquad (15)$$

Equation (13a), treated in a similar manner to that pursued in deriving formula (14), results in the expression

$$D_r = \frac{Z}{2A}\cot\alpha + \frac{L}{2} - \frac{B}{4} \qquad (14a)$$

which is the value of D_r giving the maximum combined stress $S + S_b$ expressed in relation to the angle α.

If the direct compressive stress S is greater than the tensile stress due to bending, S_b, the entire cross sectional area of the beam is subjected to compression. In this case the member must be treated as a strut or column, the maximum stress being determined by formula (13) or (13a) by inserting the value of D_r as given by formula (14), (14a), or (15), whichever best suits the case in hand. The allowable stress may then be determined by any approved column formula. Gordon's formula seems to be the most popular, tables based upon it being given in all the large steel companies' handbooks.

It will be found, however, in practice, that the direct compressive stress is nearly always much less than the tensile stress produced by bending, hence the compression flange only is liable to buckle, and it would give too heavy a member to treat the entire section as a column. This leads to the consideration of

Beams Unsupported Laterally.

Let P = ultimate strength in pounds per square inch.

L = length unsupported laterally in inches,

r = radius of gyration in inches.

b = breadth of compression flange in inches.

Considering the compression flange of a beam as a rectangle,

$$r = \frac{b}{\sqrt{12}} \text{ and } r^2 = \frac{b^2}{12}.$$

Gordon's formula for columns is,

$$P = \frac{50,000}{1 + \dfrac{L^2}{36,000\, r^2}} \qquad (16)$$

Inserting the value of r as given above in (16) gives,

$$* \; dy = \frac{W}{HA}dD_r + \frac{W}{Z}dD_r - \frac{W}{LZ}2D_r\,dD_r - \frac{WB}{2LZ}dD_r.$$

Placing $\dfrac{dy}{dD_r} = 0$ and solving for D_r gives

$$D_r = \frac{LZ}{2HA} + \frac{L}{2} - \frac{B}{4} \qquad (14)$$

$$P = \frac{50{,}000}{1 + \dfrac{L^2}{3{,}000\,b^2}} \qquad (16a)$$

This is the ultimate unit stress provided the compression flange received no support from the parts in tension. The 1900 hand-book of the Pencoyd Iron Works (now American Bridge Co.) states: "Experiments have shown a reduction of about one-third of the normal modulus of rupture when the unsupported length becomes 80 times its flange width." But as the long beam may suffer if exposed to accidental cross strains, they recommend the greatest safe load to be reduced in such a ratio for long beams that when the length is 70 times the flange width, the greatest safe loads will be reduced one-half. This gives safe loads, corresponding to given lengths, as follows:

Length of Beam.	Proportion of Tabular Load forming Safe Load, or Ratio of Safe Compressive Stress to Safe Tensile Stress.
20 times the flange width	1 whole load
30 times the flange width	9/10 of load, or of tensile stress
40 times the flange width	8/10 of load, or of tensile stress
50 times the flange width	7/10 of load, or of tensile stress
60 times the flange width	6/10 of load, or of tensile stress
70 times the flange width	5/10 of load, or of tensile stress

The same table is given in the Carnegie Steel Co.'s hand-book.

The Cambria Steel Co. gives the following formula,

$$S_c = \frac{18{,}000}{1 + \dfrac{L^2}{3{,}000\,b^2}} \qquad (17)$$

in which S_c = safe compressive stress when the safe tensile stress is 16,000 pounds per square inch. This formula is derived from Gordon's by making an allowance for a factor of safety and taking into account the fact that the compression flange receives some support from the parts in tension. The diagram on data sheet No. 4 is based upon this formula,

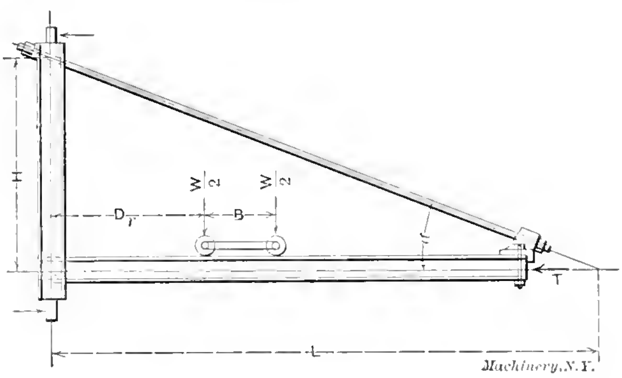

Fig. 3.

which seems more logical than the preceding table, and gives values on the side of safety. The curve giving safe compressive stresses for various ratios of $\frac{L}{b}$ corresponding to 16,000 pounds per square inch tensile stress was laid out from values calculated by the above formula. The curve for the lower allowable tensile stresses were reduced proportionally; thus, for 14,000 pounds tensile stress any value of $S_c = \frac{14{,}000}{16{,}000} = \frac{7}{8}$ of the value for 16,000 tensile stress.

From the foregoing it is seen that when applying formula (13) or (13a) the value of $S + S_c$ should not exceed the safe value of S_c as given by formula (17) and shown by the diagram on data sheet No. 4.

Example.—In a jib crane similar to Fig. 3, $W = 3{,}000$ pounds, $L = 10$ feet 0 inches, = 120 inches, $B = 24$ inches, $H = 60$ inches, the beam being a 6-inch, 12.25-pound I-beam, $Z = 7.3$ and $A = 3.61$ square inches. What is the maximum stress?

Solution.—By formula (14) the value of D_T for maximum stress is

$$D_T = \frac{LZ}{2HA} + \frac{L}{2} - \frac{B}{4} = \frac{120 \times 7.3}{2 \times 60 \times 3.61} + \frac{120}{2} - \frac{24}{4} = 56.023 \text{ ins.}$$

Inserting this value in equation (13),

$$S + S_c = 3000 \times \left(\frac{56\ 023 + \frac{1}{2} \times 24}{60 \times 3.61} + \frac{56.023 \times (120 - 56.023 - \frac{1}{2} \times 24)}{120 \times 7.3} \right)$$

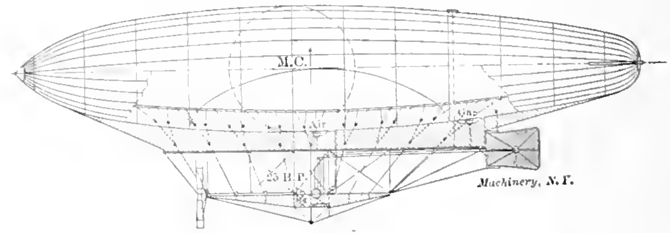
= 10,900 pounds per square inch approximately. This shows ample security until the fact that the compression flange is unsupported is taken into account. This flange is 3.33 inches wide, then $\frac{L}{b} = \frac{120}{3.33} = 36$, and referring to data sheet No. 4 it is seen that for this value of $\frac{L}{b}$ and $S_c = 10{,}900$, the corresponding tensile stress is about 14,000, which shows that there is not the security which at first seemed apparent.

* * *

THE ARRIVAL OF THE FLYING MACHINE AS A COMMERCIAL PRODUCT.

We received the other day what is, so far as we know, the first catalogue of a flying machine manufacturer, building a line of standard machines. We are not quite sure from the information given that the maker carries his product in stock, but the designs are evidently standardized and are adapted to building in large quantities.

The circular referred to is that of Louis Godard, of Saint-Ouen, France. Two examples of flying machines are shown.



"Yacht Aerien de Plaisance et de Tourisme."

One of them is the "1907 Model, Destroyer Type." It is stated that this can attain a speed of from 31 to 34 miles per hour. It has a gas bag 215 feet long and 38 feet maximum diameter, approximating a symmetrical cucumber in shape, though somewhat pointed at the leading end. Two motors of 70 horse-power each drive the two screws, one at the front and the other at the rear of the operator's platform. These motors are said to weigh about 6½ pounds per horse-power. The entire apparatus weighs about 6,150 pounds. With passengers and supplies on board, including fuel for ten hours ("essence for ten hours' march," literally), cooling water, seven passengers in all (a pilot, his assistant, two "mecaniciens" and three "invites") and a supply of food, the total weight is 9,200 pounds.

The other standard machine, of which we show a cut, is called a "Yacht Aerien de Plaisance et de Tourisme,"—which the reader can translate to suit himself. This is considerably smaller, being only about 130 feet long, and with a 30 horse-power motor which is capable of giving the machine a speed of 20 miles per hour, or thereabouts. It is hoped that this will suit the needs of sportsmen and aerostatic amateurs. It is also suited for military use in the instruction of "sky pilots," and in scouting work in colonies and other rough countries.

It begins to look as if the flying machine had arrived.

* * *

According to *Page's Weekly*, some experiments have recently been made on the Egyptian State railways, with regard to the heating of locomotive feed water. It is stated that the use of a heating apparatus for this purpose has effected a saving of 21.4 per cent in the coal consumption. The water is heated by the exhaust steam. It is claimed that the feed water heating apparatus saves its own cost in a year, allowance being made for depreciation.

* * *

A new recently completed mountain railway, built up the Wetterhorn in Switzerland, has a rise of about 1,500 feet in a distance of 2,000 feet, which is a "grade" of 75 per cent. On account of being so steep, the railroad is commonly referred to as the "elevator."

GEAR-CUTTING MACHINERY.—3.

RALPH E. FLANDERS.*

This installment of the series of articles on gear-cutting machinery describes the application of the molding-generating principle to the cutting of spur gears.

In the molding-generating method the processes which have been found most practical are planing or shaping, milling, and to a very limited extent, grinding or abrasion. For spur gears, so far as the writer knows, no use has been made of the impression process; it would be as practicable as in the case of bevel gears, of which an example will be shown in a succeeding issue, but there is no need for trying it. In the shaping process the commercial use of the molding-generating idea is confined largely to one machine, which has found a very extended application. In the milling process, there has been a wonderful development in the past few years, which

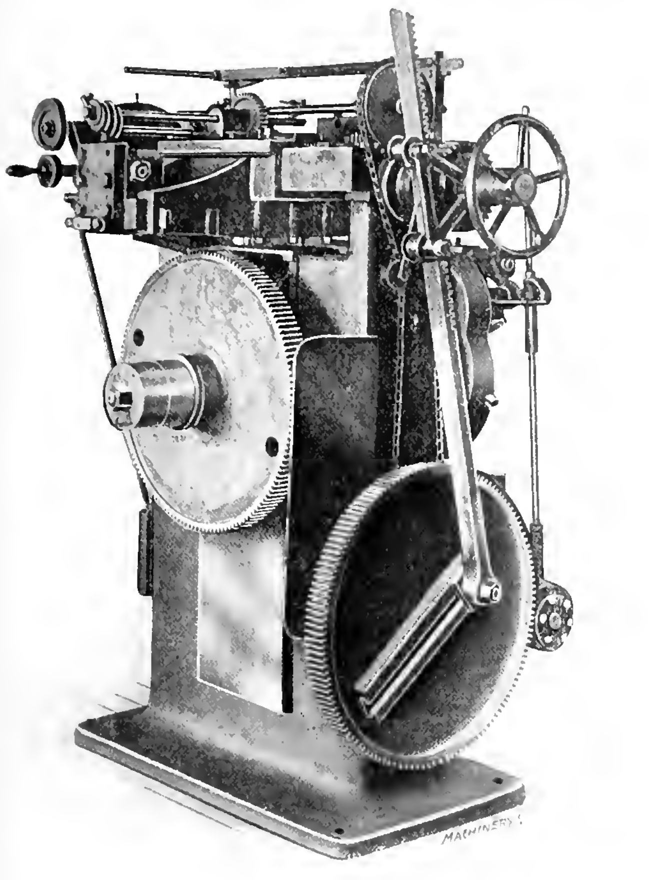


Fig. 48. The Bilgram Automatic Spur Gear Machine, using a Shaper Tool shaped like a Rack Tooth.

is witnessed to by the large number of machines we are able to show involving this operation. But one example can be given of the use of grinding.

Molding-Generating Machines Working by Shaper Action.

In Fig. 48 is shown an automatic spur gear cutting machine made by Hugo Bilgram, Philadelphia, Pa., and in use in his plant. The tool acts as a rack tooth, and generates the gear teeth in accordance with the principle of Fig. 8. Instead, however, of finishing one tooth space complete and then indexing to the next one, the operation is continuous. As has been explained, in the molding process the blank and tool must be rolled on each other as if the former were a gear meshing with a rack, of which the latter represents a tooth. In the Bilgram machine, instead of having this rolling action take place for each tooth, it takes place but once in the completion of the gear. The tool starts in at one side of the blank, being given a motion similar to that given by a shaper. It cuts its first stroke in the work, which is thereupon indexed for the tool to take a second cut in the next tooth. This indexing proceeds with every stroke of the shaper ram so that the teeth are all formed together. Besides the rotation of the blank due to the indexing, there is imposed on this that which we have described as being necessary for the rolling motion. For this, the blank is uniformly rotated, and the ram carrying the tool is fed along sideways to agree with the motion of the imaginary rack. These various movements are all attended to by change gearing. It will be seen that with this machine, as with others of the molding-generating type, but a single tool is needed for a given pitch. This may be used to cut any gear, from the smallest to the largest. This machine

Fig. 49. Detailed View of the Action of the Fellows Gear Shaper; see also Fig. 63.

is unusually interesting in its mechanical movements, and it is unfortunate that we have not the space here to go into its details more thoroughly.

The other machine we show of the molding-generating type involving the shaping process is one widely used, built by the Fellows Gear Shaper Co., of Springfield, Vt.* One of these machines is shown later in Fig. 63, engaged in cutting an internal gear, while in Fig. 49 is a nearer view which shows the action of the cutter in forming the teeth of a long spur pinion. The principle by which it operates is exactly that shown in Fig. 6. The cutter is a gear having the outline of a member of the interchangeable series to which the gear to be cut belongs. It and the blank are rotated together in the proper ratio. The cutter is first fed in to full depth and

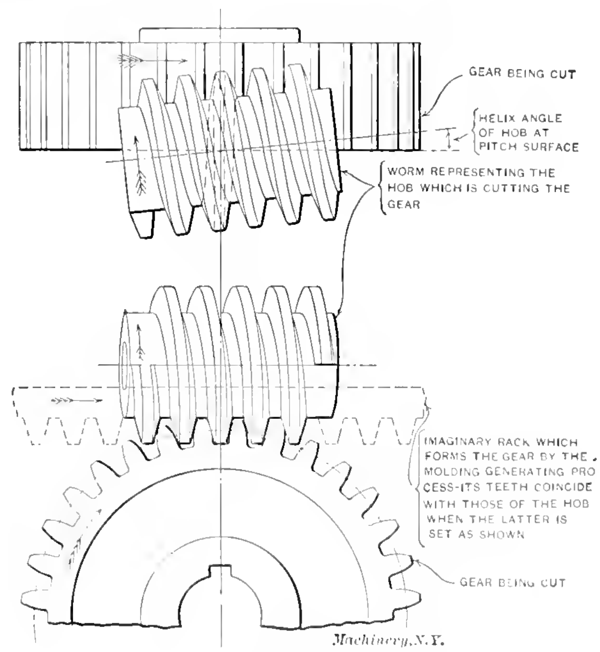

Fig. 50. Diagram illustrating the Principle of the Hobbing Process of Forming Spur Gears.

then the rotation is started and continued until the full periphery of the work has been formed. It is understood, of course, that the cutter is given a vertical shaping movement by the ram to which it is attached. The proper ratio between the cutter and the blank is obtained by change gears set for the number of teeth it is desired to have in the gear. The

* Associate Editor of MACHINERY.

* Previously described in MACHINERY in articles entitled "A Gear Shaper," January, 1898, and "Gear Shaper Improvements," February, 1900.

movements of the machine are automatic, in that when it has been set for the pitch of cutter and number of teeth, the machine will automatically feed itself to depth, stop this feeding and commence the slow rotary movement, continuing this until the work is completed, when the machine will stop. In the case of gears which have to be very accurately cut in refractory materials, provision is made for automatically taking a second cut around at a slightly increased depth, so as to give assurance that the form of the tooth is as true as can be obtained. There are many interesting phenomena connected with this method of gear cutting which cannot be entered into here. A study of it will serve as well as anything we know to introduce a student to the principles underlying the science of providing gears with suitable tooth outlines.

The Molding-Generating Milling or Hobbing Machine.

The most widely used process involving the milling operation of molding-generating is the hobbing process. The principle of this method is shown diagrammatically in Fig. 50. Here we have an imaginary rack meshing with a gear, and molding its teeth in the same way as in Figs. 7 to 10. The teeth of this rack, shown in dotted outline, coincide with the outlines of a hob, shown in full lines, which has been set at such an angle as to make the teeth on its front side parallel with the axis of the gear. In other words, it has been set at the angle of its helix, measured at the pitch line. It will be seen that the teeth of the hob, when set in this position, correspond with the teeth of the rack. If, now, the hob and blank be rotated at the ratio required by the number of threads in the hob and the number of teeth in the gear, this movement will cause the teeth of the hob to travel lengthwise in exactly the same way as the teeth of the imaginary rack would travel, if in mesh with the gear whose teeth are to be cut. It will thus be seen that the hob fulfills the requirements necessary for molding the teeth of the gear to the proper form. In practice the hob is rotated in the required ratio with the work, and fed gradually through it from one side of the face to the other. When it has passed through once, the work is completed.

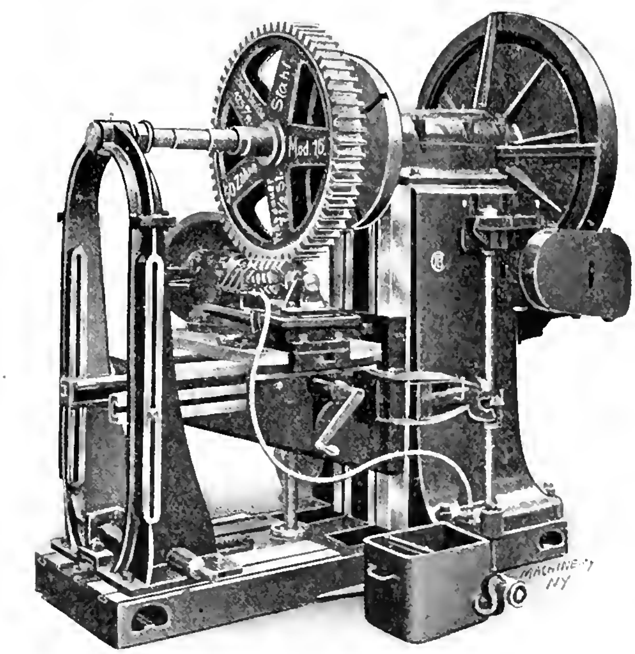

Fig. 51. The Reinecker Spur Gear Hobbing Machine.

Of the great number of machines built during the past few years involving this principle, many are arranged for cutting spiral gears as well as spur gears. In describing these tools part of them have been classed as spur gear cutting machines, while the remainder will be found under machinery for cutting spiral gears. Of course, all of the machines in the latter division are capable of cutting spur gears also, and in referring to machines for cutting spur gears they should be classed with those described in the following paragraphs. Some of the machines illustrated in Figs. 51 to 57 can be used for cutting spiral gears as well, but have been described in this section because the engravings we have at our disposal show them arranged for cutting spur gears.

The spiral gear-hobbing machine bears about the same relation to the plain spur gear hobbing machine that the universal does to the plain milling machine. The added adjustments and mechanism required in each case tend to somewhat limit the capacity of the machine in taking heavy cuts,

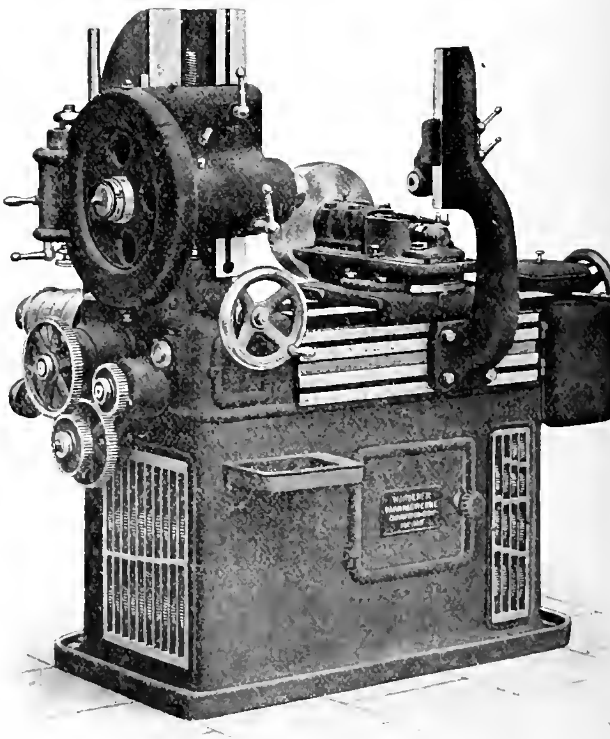

Fig. 52. The Wanderer Spur Gear Hobbing Machine.

though they add to its usefulness by extending the range of work it is capable of performing. The requirements of the successful gear hobbing machine are:

First. A frame and mechanism of great rigidity.

Second. Durable and powerful driving mechanism.

Third. Accurate indexing mechanism.

The first requirement is one of great importance, not only in its influence on the heaviness of the cut to be taken and the consequent output of work, but on the matter of accuracy as well. The connection between the hob and the work, through the shafts and gearing, is liable to be so complicated that the irregular cutting action of the hob produces torsional deflections in the connecting parts, leading to serious displacement from the desired relation between the hob and the teeth being cut. This displacement from the desired position results in teeth of inaccurate shape, weak and noisy at high speeds.

In its effect on the output, rigidity is even more important in the hobbing machine than in the orthodox automatic gear cutter. A heavier cut is taken, since a greater number of teeth are cutting on the work at once. The number of joints between the cutter and the work-supporting table and spindle, must therefore be reduced to a minimum, and the matter of overhang both for the work and the cutter must be carefully looked out for. The reduction of overhang is hampered at the cutter head by the necessity for a strong drive and an angular adjustment. In the case of the work-supporting parts, it is difficult to bring the cutting point close to the bearing on account of the necessity for plenty of clearance below the work for the hob and its driving gear to run out into.

The matter of design of the driving mechanism for the hob and the work is a difficult one. Not only must it be rigid for the sake of accuracy, as previously explained, but careful attention must be given to durability as well. It requires great skill to design a durable mechanism for the purpose within the limitations imposed—in the cutter head by the

necessity for reducing the overhang, and in the work table by the high speed required for cutting small gears.

Since the indexing wheel works constantly and under considerable load, it and the worm must be built of such materials as will preserve their accuracy after long continued use. Particular attention should be given to the homogeneity of the material of the index worm-wheel, to make sure that it does not wear faster on one side than on the other.

The field of the hobbing process for cutting spur gears has not yet been definitely determined. In some work it appears to have certain advantages over the usual type of automatic gear-cutting machine, while in other cases it falls behind. It will doubtless require continued use, with a variety of work, and for a considerable length of time, to determine just what cases are best suited for the hobbing machine, and what for the machine with the rotating disk cutter. It is not probable that in the future either of them will occupy the field to the exclusion of the other.

Examples of Spur Gear Hobbing Machines.

The first gear hobbing machine we show (see Fig. 51), is built by J. E. Reinecker of Chemnitz-Gablenz, Germany. This builder was one of the first to make a commercial success of the hobbing process, having applied it several years ago in his "Universal" gear-cutting machine. The tool we show is a specialized form of that universal machine, adapted particularly to the hobbing of spur gears. As may be seen, in form the machine is derived from the standard milling machine, bearing about the same relation to it that the Becker-Brainard gear-cutter in Fig. 20 does. The spindle is mounted on what corresponds to the carriage of the milling machine, which may be swiveled so as to bring the teeth of the hob on the upper surface parallel to the work spindle. The spindle is driven by an internal gear of large diameter. The work spindle is driven from the rear of the column by the index worm-wheel, which is connected with the cutter spindle through change gears (shown at the left of the picture) and the splined shafts and bevel gear connections. The knee of the machine having been raised so that the cutter is set at the proper height to cut teeth of the desired depth, and

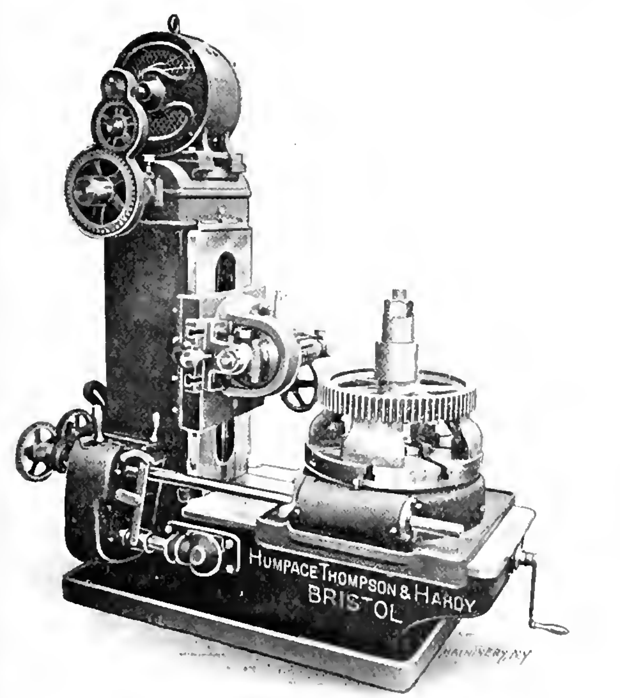

Fig. 53. An Electrically-driven Gear Hobbing Machine built by Humpage, Thompson & Hardy.

the machine being started, with hob and gear blank rotating in the proper ratio, the table with the hob is fed in along the knee toward the column of the machine, cutting the teeth in the wheel as it does so, the operation being completed when the hob has made one pass through the work. It will be noted that the work arbor, the knee and the base of the machine are all very firmly tied together by a rigid brace, which may be adjusted to suit different conditions of diameter and length of work.

Another machine, built by the Wanderer Works, formerly Winklhofer & Jaenicke, Ltd., Schoenau, near Chemnitz, Germany, is shown in Fig. 52. It is of the same type, so far as the frame work is concerned, as a regular automatic machine, it being almost identical in its lines with those shown in Figs. 21 to 28, inclusive. The differences in mechanism, of course, are those due to the necessity for connecting the work spindle and the cutter by change gearing to give the proper ratio, and for setting the spindle, as well, at the proper angle to agree

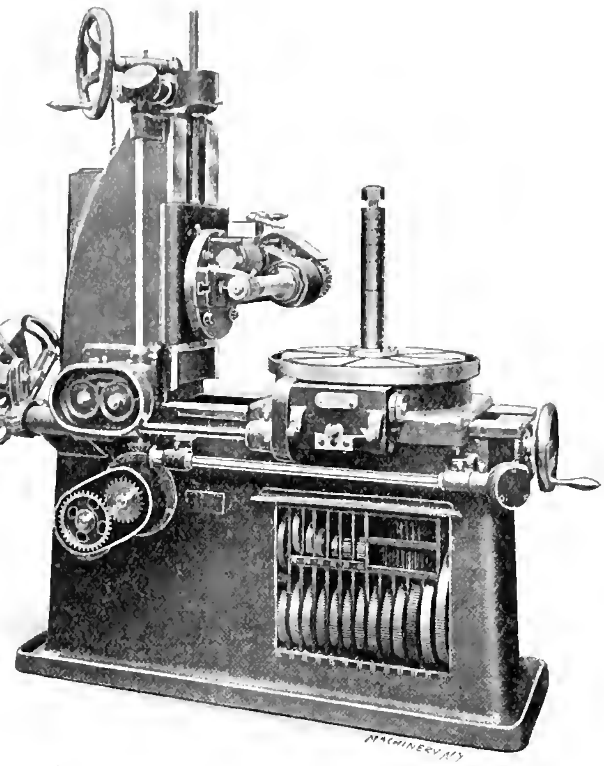

Fig. 54. The "Rhenania" or "Burton" Spur Gear Hobbing Machine.

with the helix angle of the hob. The feed, also, is continuously forward until the work is completed, instead of having a quick return for each tooth cut. It is readily seen that this rearrangement means, on the whole, a somewhat simpler machine in the case of the hobbing machine than for the automatic gear-cutter, particularly since intermittent indexing is avoided. The cutter spindle is driven by an internal gear of large diameter.

The orthodox type of spur gear hobbing machine differs from the examples we have just described in the position of the spindles. In this case the cutter spindle is mounted in a slide on the column, while the work is carried on the bed, being adjusted in or out on it according to its diameter. In its general arrangement it bears a strong resemblance to the standard type of formed cutter machine for heavy work as illustrated in Figs. 30 to 36.

In Fig. 53 is the first example we show of this type, a machine built by Humpage, Thompson & Hardy, of Bristol, England. It appears to be of unusually heavy construction. The machine as shown is entirely self-contained, a motor being mounted on top of the column. It can be made either motor or belt driven without other alteration than the removal of the motor and gears and the substitution of a pulley, or *vice versa*. The drive is of the constant speed type, the speed changes being obtained through gearing, running constantly in a bath of oil. The machine is provided with an unusually ingenious feed mechanism. A pair of taper pulleys, carrying a light belt, is used as a primary means of changing the feed. This operates, however, through the medium of an epicyclic gear arrangement through which most of the strain of transmission is taken. The cutter slide is over-balanced, so that it has to be fed against the pull of the counterweight, thus taking up all back lash.

The manufacturers call attention to the results of tests made on their machines; $2\frac{1}{2}$-pitch gears in cast iron have been cut at the rate of 4 inches of tooth length per minute; 3-pitch gears of the same material at 5.9 inches per minute,

while the same style teeth in mild steel have been cut at 4 inches per minute. The size shown will cut work 23 inches in diameter by 13½ inches face.

The machine shown in Fig. 54 is sold on the continent by Alfred Schütte, and there known as the "Rhenania." In England it is sold by Burton Griffiths & Co. and called the "Burton." This is one of the machines which can be furnished for cutting spiral gears if desired, though in the form

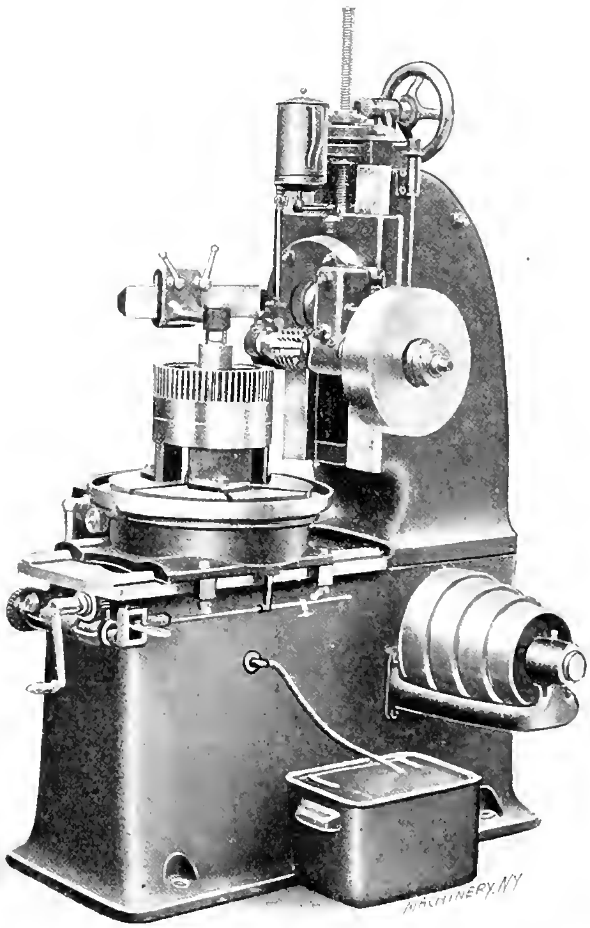

Fig 55. A Continental Gear Hobbing Machine, sold by Selig, Sonnenthal & Co.

shown it is adapted for spur gears only. The spindle of this machine is driven somewhat differently from the previous ones shown. A worm connected at its inner end by bevel gears to the vertical power transmission shaft, and located on the axis of the angular adjustment, drives a worm-wheel on the short shaft mounted above and to the rear of the cutter. Spur gears connect this short shaft with the spindle. This arrangement reduces the overhang of the cutter slide. The work table may be revolved freely in setting the work by withdrawing the index worm, this being mounted on a dove-tail slide, which is withdrawn or inserted again by operating the square head collar screw shown. Adjustable stops limiting this motion determine its adjustment, which may be altered to compensate for wear. The worm is of hardened steel, ground all over after hardening. The work spindle may be supported, when necessary, by a stiff outboard bearing on an arm which is fastened to the back of the table and the back of the bed, tying the work, work table and bed rigidly together.

Another machine of German origin, made by the Schubert & Salzer Maschinenfabrik, of Chemnitz, and sold by Selig, Sonnenthal & Co., of London, England, is shown in Fig. 55. This machine, like the one shown in Fig. 52, has the spindle driven by an internal gear. To allow this to be made of unusually large diameter and still bring the hob as close to the face of the column as possible, so as to give a rigid construction, the hob is carried below the axis around which the swiveled head is adjusted, instead of centrally with it, as is usually the case. This limits the adjustment to the comparatively slight angle required for spur gears, but it would seem to greatly increase the stiffness of the construction and the power of the drive. As may be seen, the outboard support for the work arbor is of unusual design, consisting of an arm bolted to the side of the column, carrying a slide which may be adjusted in or out to suit the position of the work table.

The machine shown in Fig. 56 is built by Henry Wallwork & Co., Ltd., Manchester, England, and sold by Alfred Herbert, Ltd., Coventry, England. A number of interesting features will be noted in this machine. The spindle drive, for instance, is unusual. A train of spur gears connects the shaft on the axis of the swiveling adjustment with a short vertical shaft which drives the cutter arbor by worm or spiral gearing. The work support consists of a triangular arm supported by two vertical posts, the outer end of the arm having a bushing for the work arbor. One of the vertical posts is longer than the other, and the arm may be raised from the shorter one and swiveled about the longer one when removing or replacing the work. Since this support always travels with the table it does not have to be adjusted when adjustments are made in the position of the latter. The table has a large annular bearing, with an extended shank having a tail bearing fitted with lock nuts to prevent lifting. The chip pan is solid with the slide and does not rotate with the table as in some of the other machines.

The machine shown in Fig. 57 (Sir W. G. Armstrong, Whitworth & Co., Ltd., Manchester, England,) belongs with the machines just described, but is differentiated from them by the fact that the column carrying the spindle is adjusted on the bed for the diameter of the work, instead of having the work table adjustable. In this respect it resembles the gear cutter shown in Figs. 37, 38 and 39. Since the work spindle is stationary, the index wheel is placed below the bed. The spindle drive is through spur and bevel gears from the vertical shaft alongside the column. This machine is so large that special provision is made for handling most of the movements, there being a power elevating device for the spindle head, and a power traverse of the head on the bed. As shown, also, the spindle head is swiveled by a worm meshing with worm-wheel teeth cut on a portion of the periphery of the sector.

An ingenious hobbing machine built a number of years ago by Warner & Swasey Co., Cleveland, Ohio, has been illustrated in our columns.* Instead of using a worm-shaped hob, the hob was formed with parallel circular teeth, but made in two halves which were shifted endwise with relation to each other by a cam mechanism. This split hob and the blank were geared together in the proper ratio and rotated together

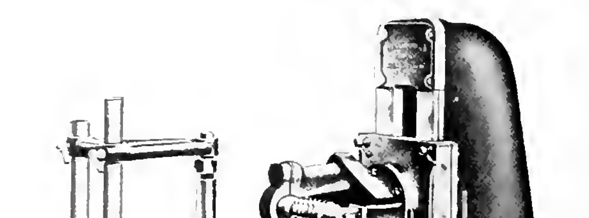

Fig. 56. The Wallwork Gear Hobbing Machine.

the same as in other hobbing machines. The half of the hob which was cutting was fed forward axially to correspond with the rack movement required by the rotation of this blank. When that half had left the cut, it was brought back by a cam movement, ready to start in again on its forward

* See article entitled "American Gear Cutting Machinery" in the June, 1898, issue of MACHINERY.

axial movement as soon as it again reached the cutting position. The other half of the hob was similarly controlled, the parts thus sliding in and out with each other alternately.

As previously explained, this list does not include all the machines of the hobbing type adapted to cutting spur gears. Those described under the heading of spiral gear cutting machines, found in a succeeding installment of this article, include examples by the following makers: Biernatzki & Co., Chemnitz, Germany; Gould & Eberhardt, Newark, N. J.; Grant Lees Machine Co., Cleveland, Ohio; John Holroyd & Co., Milnrow, England; Maschinenfabrik Lorenz, Ettlingen, Germany; Newton Machine Tool Works, Philadelphia, Pa., and Schuchardt & Schutte, Cologne, Germany. It will be seen that this list is quite an imposing one, including fourteen manufacturers of machines of this type. With the exception of the Reinecker machine, which dates from an earlier time, all of these were designed within the past few years, most of them to meet the demand for gear-cutting machinery created by the automobile trade.

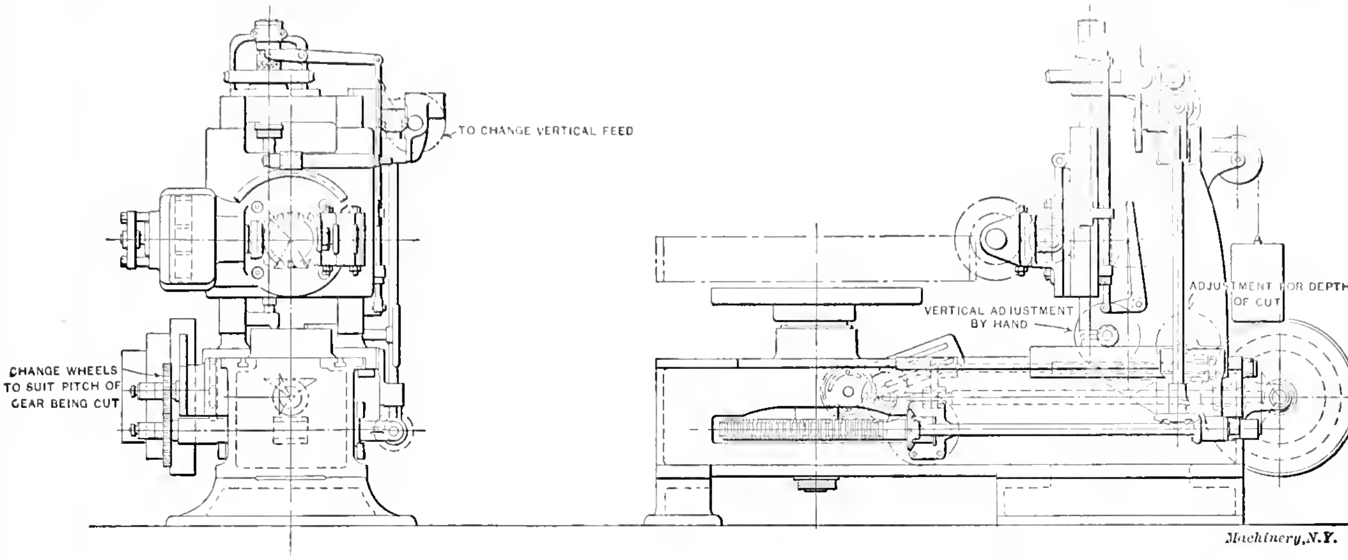

Fig. 57. Armstrong Whitworth & Co.'s 6-foot Hobbing Machine, with Column adjustable for Diameter.

The Grinding or Abrasion Operation, applied to the Molding-Generating Process.

One application of the molding-generating process involving the grinding operation, uses the rack tooth principle in a manner exactly identical with that shown in Fig. 10, in forming the cutters used with the Fellows system of gear tooth shaping. A special machine is provided, carrying an emery wheel with a plane face which can be constantly kept straight by means of a diamond truing device incorporated in the machine itself. The hardened gear-cutter, which has been cut to leave but a few thousandths of metal to finish on the sides of the teeth, is placed in the machine and rolled past the face of the emery wheel under the restraint of metallic tapes in a way that is identical with that shown in Fig. 10.

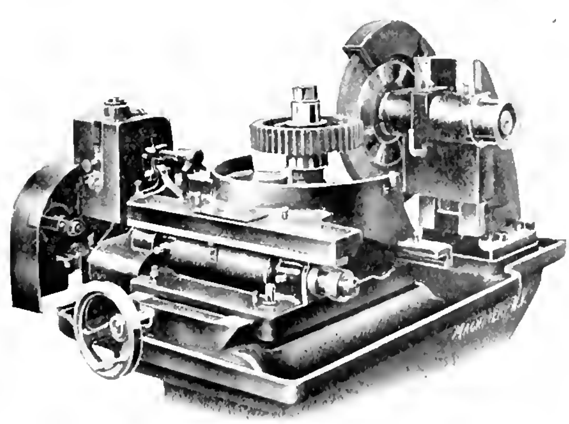

Fig. 58. Another View of the Machine shown in Fig. 59.

An application of this principle to the finishing of the teeth of hardened gears is shown in Figs. 58 and 59. This machine trues the teeth of hardened gears used in automobile construction. The principle of its action is also the same as in Fig. 10, though carried out in a somewhat different way than in the case of the Fellows cutter grinding machine just mentioned. In this case, the emery wheel has its outline beveled to the shape of the rack tooth, using for this purpose both sides of the wheel, which has an outline more nearly resembling the shaper tool T_1 in Fig. 8, than the grinding wheel of Fig. 10. Attachments permanently set to the proper angle (14½, 15 degrees or any other angle desired) are provided, by means of which the operator can almost instantly bring the wheel to the proper shape whenever it shows signs of losing it. The emery wheel has a continuous vertical reciprocating movement, great enough to cover the whole face of the wheel. It will be seen that it is thus made to cover the whole surface of the rack tooth which it represents in the molding-generating process.

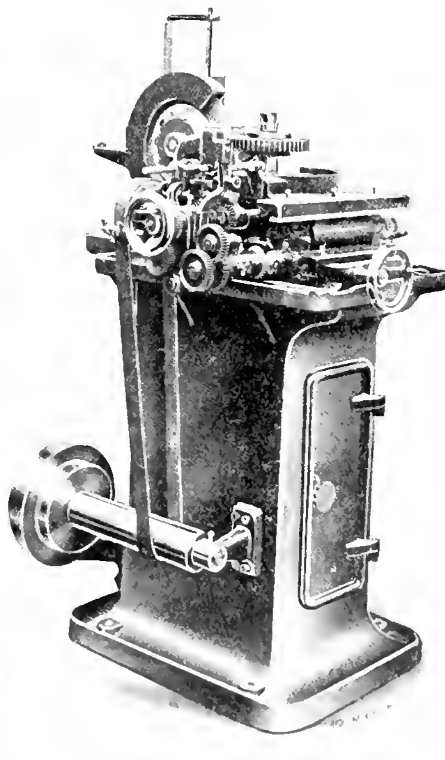

Fig. 59. A Machine for Grinding the Teeth of Gears to Accurate Shape after Hardening.

The hardened gear to be operated on, previously cut to leave a few thousandths for finishing, is mounted on the vertical work arbor on the table as shown. By suitable change gears and controlling mechanism, this slide is made to travel across the face of the wheel while the work is rotated at the same time, in such a ratio as to give the identical movement that would result from rolling the wheel on the imaginary rack, a tooth of which is represented by the outline of the emery wheel. The work starts in at one side of the wheel, out of contact with it, rolls into it until the grinding wheel is in action, passes by to the further side, and returns to its first position, thus finishing one tooth space to proper form. An automatic indexing mechanism (adjustable for any number of teeth within 12 and 60 inclusive) then indexes the wheel one space, and it again rolls along the front of the emery wheel and returns, thus finishing another tooth space.

This operation is repeated automatically until the whole gear has been ground to perfect form. The diameter of the wheel used is 12 inches. The maximum diameter of gear which can be finished is $11\frac{3}{4}$ inches with a 2-inch face.

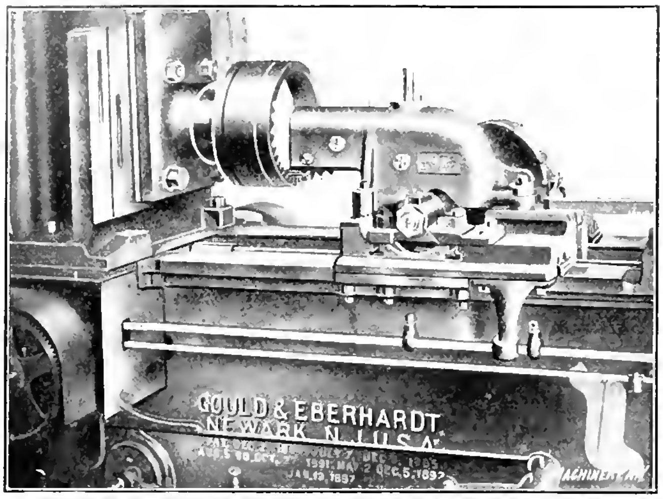

Fig. 60. Attachment to the Gould & Eberhardt Gear-cutter for Cutting Internal Gears.

This machine, which is built by J. E. Reinecker of Chemnitz-Gablenz, Germany, is sold by E. Chouanard, 3 Rue Saint-Denis, Paris, and by C. W. Burton, Griffiths & Co., Ludgate Square, London.

Machines and Attachments for Cutting Internal Gears.

As has been stated, the internal gear is akin to the spur gear, and the machinery for cutting it acts on practically the same principles, except as limitations are imposed by the concavity of the surface in which the teeth are cut, as compared with the convex shape of external gearing. As before, the formed tool method is the most obvious and the most commonly used. The teeth may be cut by a shaper tool with a projecting head, formed somewhat after the fashion of the tools used for cutting keyways in the hubs of pulleys, etc., the work being mounted on the face-plate of an indexing fixture on the table of the shaper, slotter or planer. We have * described a further development of this idea, in which the work was fastened on a face-plate on the spindle of an ordinary automatic gear-cutting machine while the shaping tool was operated by a shaper bodily lifted to a position on the bed of the gear-cutter, and clamped in place there. In such cases the movements are, of course, largely controlled by hand, the tool-holder being fed down into the work.

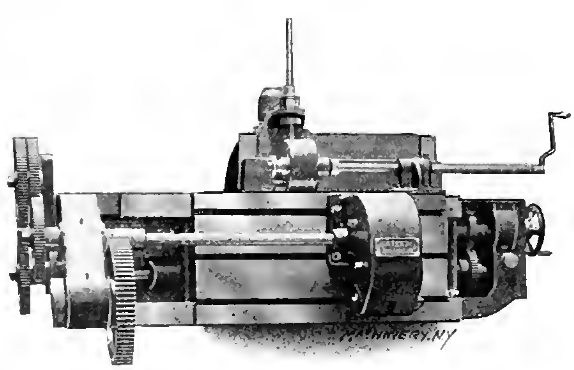

Fig. 61. The Atlas Machine as arranged for Cutting Internal Gears; compare with Fig. 34.

Most machines for internal gears use the formed milling cutter to shape the teeth. A common method of using this process employs an attachment to the regular automatic spur gear cutting machine, carrying the cutter on a projecting arm, adapted to enter the internal gear and work on its inner periphery. An example of this is seen in Fig. 60, which shows the attachment provided by Gould & Eberhardt, of Newark, N. J., for cutting internal gears on their regular spur gear cutting machine. The cutter is driven by a train of spur gears from a driving gear on the regular cutter arbor. The pivots of these gears are shown by the projecting ends of the studs on which they run. While this arrangement furnishes a practical and much-used means for cutting internal gears, it is evident, of course, that it is not possible to take quite so heavy cuts as when cutting spur gears, on account of the indirectness of the means by which the cutter is driven, and the necessarily small diameter of the gear from which it receives its motion.

An attachment of a very similar kind, modified to suit the changed design of the machine, is shown in Fig. 61. This is the Atlas gear-cutter shown in Fig. 34. As may be seen, the attachment is bolted to the face of the cross rail, and is fed down into the work in the same way that the attachment in Fig. 60 is fed forward into it. Other manufacturers make similar devices for use with their machinery.

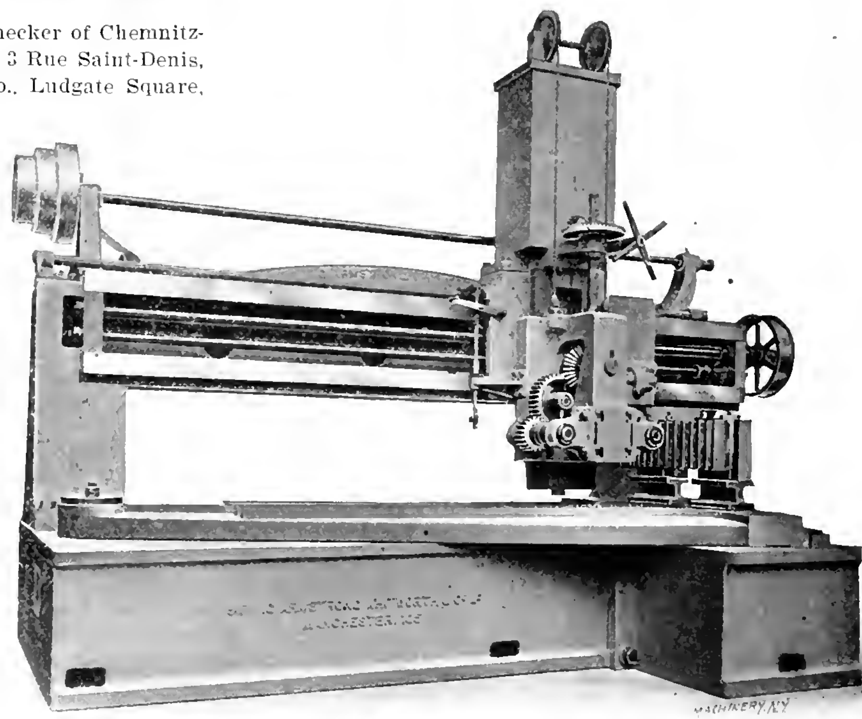

Fig. 62. Armstrong Whitworth Machine for Cutting Internal or External Teeth in Segments of Large Diameter.

In Fig. 62 is shown a machine of great capacity, arranged for the cutting of both internal and external spur gear segments. As posed, it is cutting internal teeth. The work is mounted on a sector pivoted at the left hand end of the bed, and having gear teeth cut in its periphery, by which it is indexed. The work is clamped to this sector at the proper distance from the pivot to give the radius desired. The cutter slide operates on vertical ways on a carriage carried by the cross rail. Two cutter spindles are provided, one on the right and the other on the left hand side of the cutter head, one being used for internal and the other for external gears. The movement is brought to the spindles through a train of spur and bevel gears as shown. This machine, which was designed primarily for dealing with gear segments for gun mountings, will cut teeth in segments having an extreme radius of 13 feet, and a face of 12 inches. It is automatic in all its movements, including the dividing mechanism. Sir W. G. Armstrong, Whitworth & Co., of Manchester, England, are the builders.

The Fellows system of gear cutting, previously described on page 429, is perhaps the most striking method of cutting internal gear teeth. The machine shown in Fig. 63 is forming the teeth in an internal gear. The process, which belongs

* See article entitled "Emergency Methods in Gear Cutting" in the November, 1907, issue of MACHINERY.

to the molding-generating order, is exactly identical to that employed for external spur gears, the cutter and work being geared to rotate together in the proper ratio. It has a number of advantages over the formed cutter method. It does not require the exaggerated clearance at the bottom which the rotary cutter needs for running out into. The cutting tool

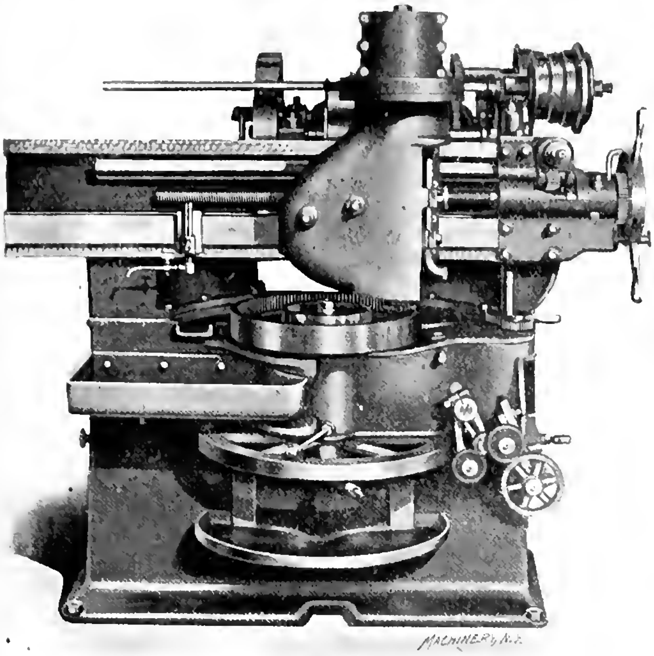

Fig. 63. The Fellows 36-inch Gear Shaper at Work on an Internal Gear.

works to as good advantage as when cutting external gears. No change in the machine is necessary, and special cutters are not required, the same tool being used as in cutting an internal gear of the same pitch. The ease with which internal gears may be cut with this machine, and the fact that it is quite generally used for this work, have encouraged the use of internal gearing in the past few years for cases in which it is better fitted than external spur gearing, but where the difficulty of making it would formerly have barred its use.

The odontographic and describing-generating methods are as limited in their application to internal gearing as to ex-

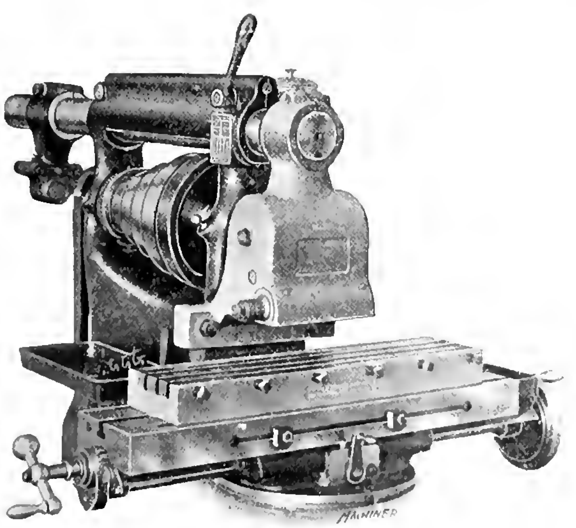

Fig. 64. The Rack-cutting Attachment used with the Brown & Sharpe Milling Machine.

ternal gearing. The grinding or abrasion, and impression operations, also, are seldom, if ever, applied to the cutting of internal gears.

Rack-cutting Attachments to Standard Machines.

As was the case with internal gearing, the formed tool method is that most largely used for cutting racks. The primitive means consists in clamping the work on the table of the planer or shaper, and cutting the tooth spaces with a properly shaped tool in the regular tool-post of the machine. After each space has been cut, the tool-post is moved along the proper distance to bring it in position for a new space—or, in the case of the shaper, the work table is shifted the same amount for the same purpose. A new tooth space is then formed as before, and the operation is repeated until the work is done. In making the measurements for the amount by which to shift the relative position of the work and the tool for each cut, various means may be used. A stop may be provided, set ahead of the previous position by an amount determined by a gage of a thickness equal to the circular pitch of the tooth being cut. After the adjustment has been made for a new tooth, it may again be located in position for the next cut by setting to the proper distance away, as determined by the thickness of the gage. If the screw by which this adjustment is made is provided with a dial reading to thousandths, this may be used. One way is to set the dial carefully to zero before making each setting; then operate the screw to move the slide the proper amount in thousandths of an inch as determined by the circular pitch of the tooth being cut. The dial may then be brought back to zero, repeating the operation when the next adjustment is to be made.

More elaborate means of indexing are provided for special rack-cutting machines. The arrangement generally used is identical with that shown in Fig. 16 as applied to the spur gear cutting machine, excepting that the index worm and

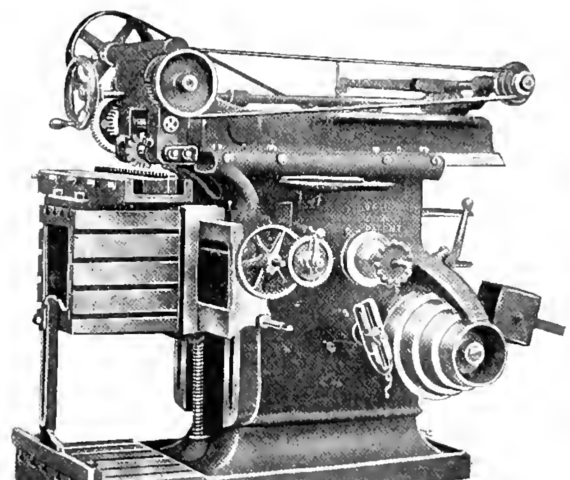

Fig. 65. The Gould & Eberhardt Shaper with Attachment for Cutting Racks.

index wheel are replaced by a lead-screw and nut, which serve to give a longitudinal movement to the work table in the same way that the rotary movement is given to the work spindle of the gear-cutting machine. This longitudinal movement equals the circular pitch, of course, and is obtained by using appropriate change gears between the one-revolution shaft and the lead-screw.

In Fig. 64 is shown an attachment for the milling machine used for cutting racks. This device, which is applied to the Brown & Sharpe milling machines, consists simply of a holder clamped to the front of the column and the overhanging arm, and carrying a short cutter spindle at right angles and below the main spindle of the machine. This is connected to the main spindle by suitable gearing. On the projecting end of it a formed cutter of ordinary construction is fastened. The vise shown in the cut is provided for holding the work. The work may be indexed by using the graduated dial as explained, or by making use of a change gear attachment furnished by the makers, operating on the principle described in the preceding paragraph.

Rack-cutting attachments are also made to apply to the shaper as well as to the milling machine. An example of one made by Gould & Eberhardt, Newark, N. J., is shown in Fig. 65. The regular swiveling tool head has been removed from the ram, and its place is taken by a casting carrying a cutter

arbor, and the necessary gearing and other mechanism for driving it. In addition to this, the ram is provided with attachments for giving a gradual forward screw feed for advancing the cutter through the work, in place of the usual reciprocating movement, which is disconnected when the machine is used in this way. A suitable vise for the work is clamped on the work table, and an indexing arrangement involving the use of change gears is provided for shifting the table from one cut to another.

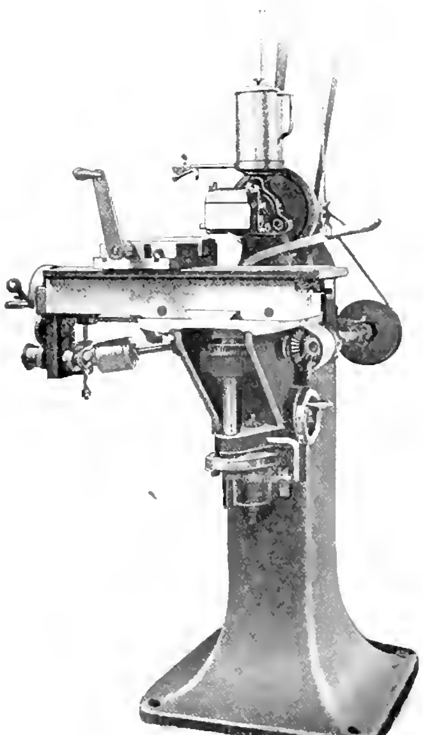

Fig. 66. The Sloan & Chace Rack-cutter for Small Work.

Rack-cutting Machines.

Most commercial rack-cutting machines in their structural design are developments of the milling machine idea. The automatic rack-cutter for small size and accurate work, shown in Fig. 66, is an example of this type. This tool is built by Sloan & Chace Mfg. Co., of Newark, N. J.* Its resemblance to the milling machine and attachment shown in Fig. 64 is obvious. It is automatic in all its movements, which are mostly cam-operated, as is usual in gear-cutting machinery of the precision type built by manufacturers of watch and clock-making machinery.

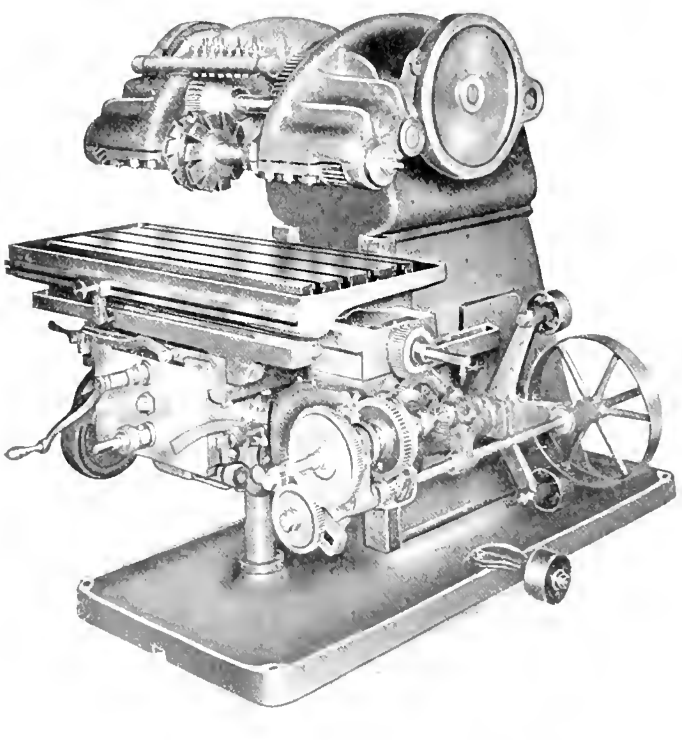

Fig. 67. The Walcott & Wood Automatic Rack-cutter.

Another machine of this kind is built by Walcott & Wood Machine Tool Co., Jackson, Mich.,† (Fig. 67). This machine, as may be seen, involves the same structural features as the preceding one, but is built for much larger and heavier work. Its movements are obtained by screws and gear-driven mechanisms, instead of by cam movements. As shown, the cutter spindle is driven by gearing on each side, the main drive on the left being by herring-bone gears. This tends to give a smoothness of action which the necessarily small diameter of the driving pinion would otherwise make impossible. The cutter arbor is driven by a tongued connection from each end. It is held in position by two bolts passing through the driving spindles at each side, which, when tightened together, make driving spindles and cutter arbor practically a solid piece, giving a very powerful support. There being 10 inches of cutter space on the arbor, it is well adapted to the use of gang or multiple cutters. Provision is made for this in the gearing, there being two sets of change gears, one of them set for the pitch in the ordinary way, while the other is set for the number of teeth it is desired to index at once. All of the gears shown are provided with guards, which have been removed in taking the photograph so that the drive may be more easily understood. A feature of this machine and the previous one is the automatic mechanism provided for throwing off the counter-shaft belt shifter when the required number of teeth has been cut.

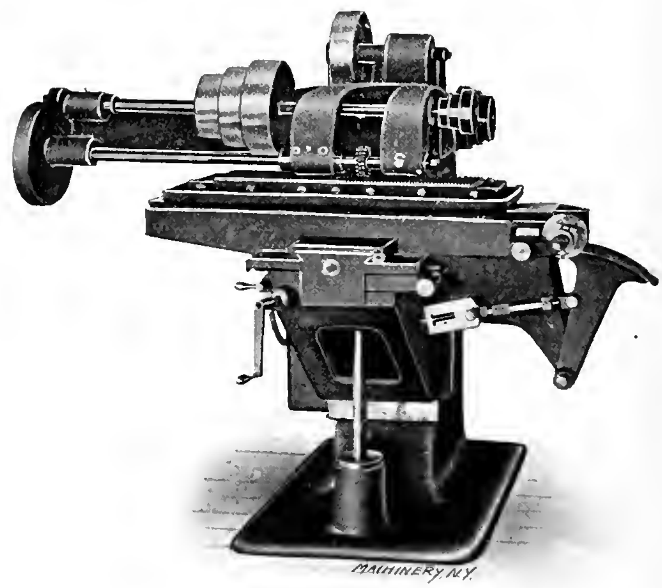

Fig. 68. The Machine built by Warner & Swasey Co., to overcome the Driving Difficulty.

In the machine shown in Fig. 68, formerly built by Warner & Swasey Co., of Cleveland, Ohio, the difficulty in the driving of the cutter spindle has been ingeniously overcome. The cutter spindle has been extended to great length at the left side of the machine, where it is driven by a gear of as large diameter as is necessary to give it a powerful, yet smooth and even movement. Of course the capacity of the machine for cutting racks is limited to the length from the cutter to the face of the driving gear. This is beyond the extreme indexing range of the table any way, but the possible range may be doubled by cutting half the rack, and then reversing it so that the overhang of the work is at the right end of the table. The efficacy of this method of driving the spindle in avoiding some of the difficulties inherent in the rack-cutter, may be vouched for from the fact that the idea in a modified form has been applied to all the rack-cutters of various types in the plant of one of the largest firms making a special business of cutting gear teeth.

Another point of interest is the indexing movement, which differs somewhat from that previously described. A slotted crank on the front of the bed is given one complete revolution for indexing. This crank operates the sector shown at the left of the table. This sector has teeth on its periphery, meshing with a ratchet gear by which the indexing lead-screw is driven. The setting of the crank-pin in the slotted crank at various positions determines the arc through which the toothed sector swings, and determines, in consequence, the amount of movement given by the ratchet to the lead-screw, thus determining the circular pitch of the rack.

JIGS AND FIXTURES IN THE PRATT & WHITNEY CO.'S SHOPS.

There are three distinct reasons for the use of jigs and fixtures in the manufacture of machinery. In the first place, jigs and fixtures are employed for reducing the cost of the article manufactured; in the second place, a higher degree of accuracy is attained; and in the third, the interchangeability of the parts manufactured is effected. One of the first firms in this country to realize the importance of these points and to use tools for interchangeable manufacture on a large scale was the Pratt & Whitney Co., which, in the late seventies and early eighties, was one of the pioneers of modern machine tool construction in this country, and which then commenced to introduce the application of jigs and fixtures in a degree previously unheard of. Since these early days of machine tool construction, the company has adhered to its policy of using special tools in the greatest possible degree, and many of the appliances designed and used are both elaborate and costly, but, as they serve the three objects mentioned above, the tendency is constantly toward more tools and more efficient devices.

Hardly any operation of consequence in the shops of this company is performed without the use of some special tool or fixture, whenever time or accuracy can be gained by the use of such appliances, and many of the tools used are so ingenious and complete in their design as to classify them rather as special machines than as jigs or fixtures. In the following, a few of the tools used in the Pratt & Whitney Co.'s shops, are described and shown. Some of the tools will be found to have a direct bearing on nearly any kind of machine construction, while others will have at least a great deal of suggestive value, and indicate the lines along which similar tools for kindred operations may be designed.

As is well known to almost every mechanic, one of the standard products of the Pratt & Whitney Co. is turret lathes, of which several sizes are built. In the half-tone, Fig. 1, the bed of one of these turret lathes is shown in position on a horizontal boring machine, to bore the spindle bearings. As will be noticed, the head and bed are cast integral. The fixture, which is shown clamped to the table of the boring machine and which holds the bed while the bearings are being bored, clamps the work by means of pneumatic pressure. The general design of this fixture is shown in the line illustration, Fig. 2, the only difference between the fixtures in Figs. 1 and 2 being that in Fig. 2 a fixture is shown which is used for turret lathes having back gearing, while the fixture shown in Fig. 1 is for one of the smaller sizes, not provided with back-gears. Referring to Fig. 2, the work is held down by four clamps A continuing down through the body of the fixture to an equalizing lever B, which is connected to a piston C actuated by air pressure. The required movement of this piston and of the clamps A is very small, because the ways of the bed are finished before being placed on this fixture, and consequently there is no need of allowance for variation. The air for the cylinder in which piston C moves is supplied through the pipe D. There are two sets of clamps, one at the front and one at the back end of the bed, both being supplied from the same main pipe as is plainly shown in the half-tone, Fig. 1, the clamping being effected by simply turning the handle on the air valve P.

In order to place the bed casting in position before clamping, the beveled surface E, Fig. 2, on the fixture, is planed to the same angle as the ways of the bed, and the bed is forced up against this bearing surface by means of two clamps F, previous to applying the air pressure. Springs G, of which one is shown in the end view of Fig. 2, serve the purpose of lifting the clamps from the work, as soon as the

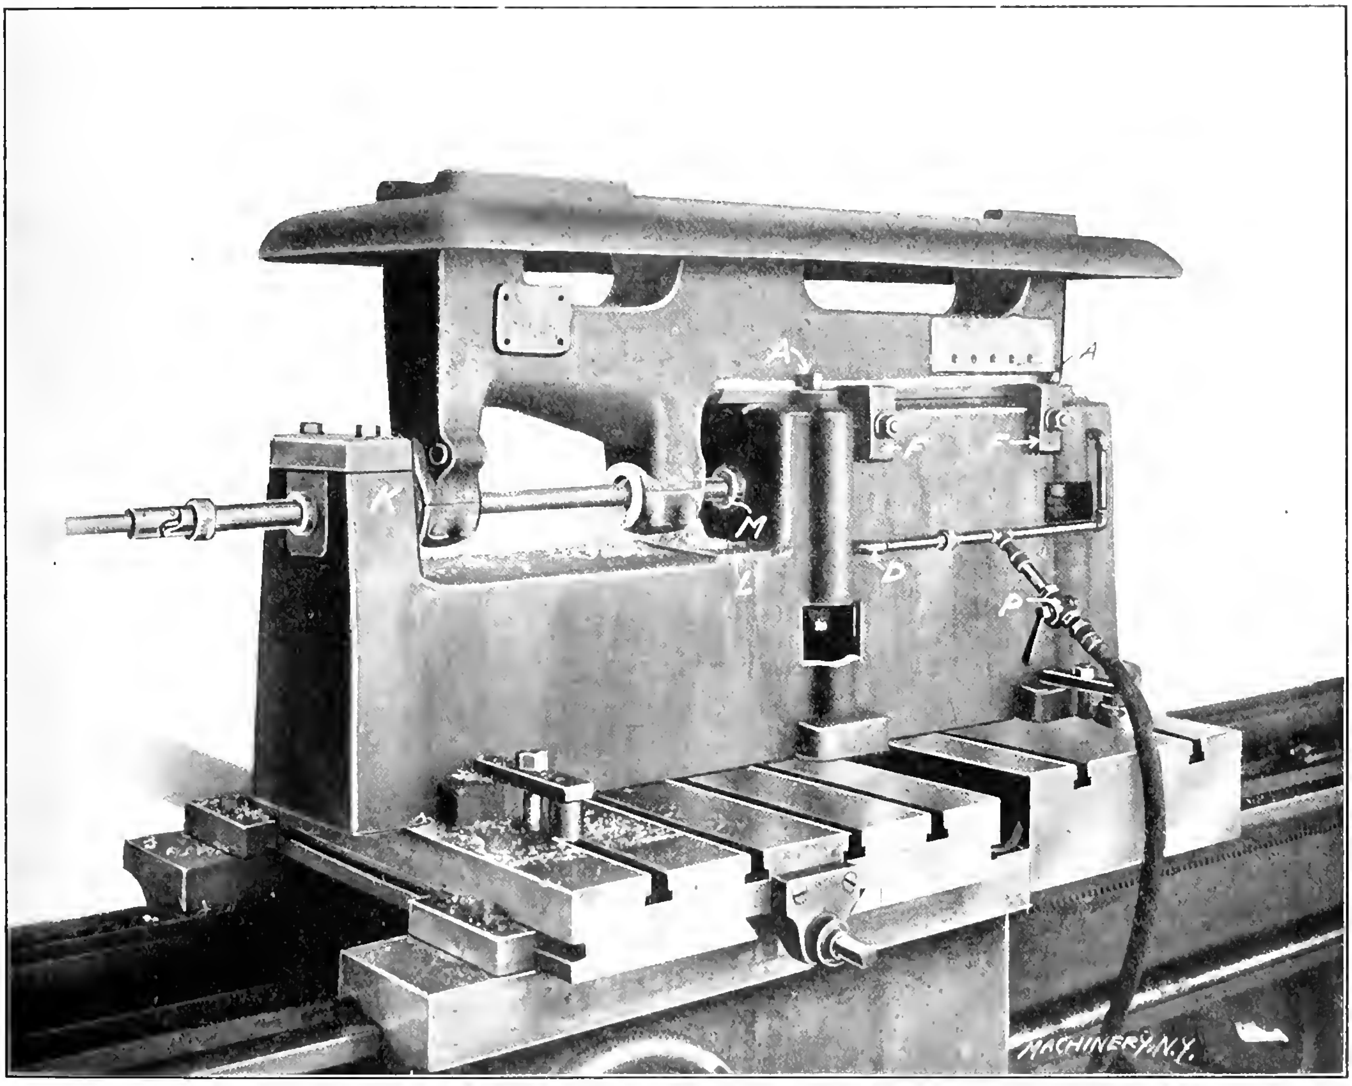

Fig. 1. Boring Fixture for Turret Lathes, with Pneumatic Clamping Arrangement.

air pressure on the piston is relieved, and the clamps can then be swung aside so as not to interfere with lifting the casting out of place, or the placing of a new casting in position.

The general construction of this fixture is also rather interesting. At *H* is shown a supplementary projection or lug, which is removed as soon as the holes in the back end *M* of the fixture have been bored to receive their bushings. This lug, containing bushings the same as these in the front projection *K*, serves simply the purpose of giving support to the boring bars, while boring the fixture, so that the holes in the fixture itself may be placed exactly in line. In Fig. 1 the pad *L* shows where this auxiliary lug has been removed.

One difficulty has been experienced with this clamping device. When a head was half bored at the time when the power was shut down at night, it was found that the clamps, on which, of course, the air pressure was relieved during the night, would not hold the bed in exactly the same position when the air pressure would be again applied, but that some slight variations were noticeable, and it became necessary to start the boring of the holes anew, in order to get them to line up exactly. For this reason, some of the fixtures of this design have been provided with small auxiliary clamps, which can be applied before the air pressure is relieved, whenever it is desired to hold the bed over night in exactly the same position as before. These clamps, being applied, will then prevent any motion of the casting, when the clamps *A* release their grip. The auxiliary clamps, of course, need not be applied excepting in such cases when the air pressure is to be shut off. In order to insure that the bed bears properly against the locating surface *E*, and also on the top portion of the fixture, feelers of tissue paper are put in between the bed and the fixture at six places—two on each side and two at the back end—and by means of these the proper location is ascertained.

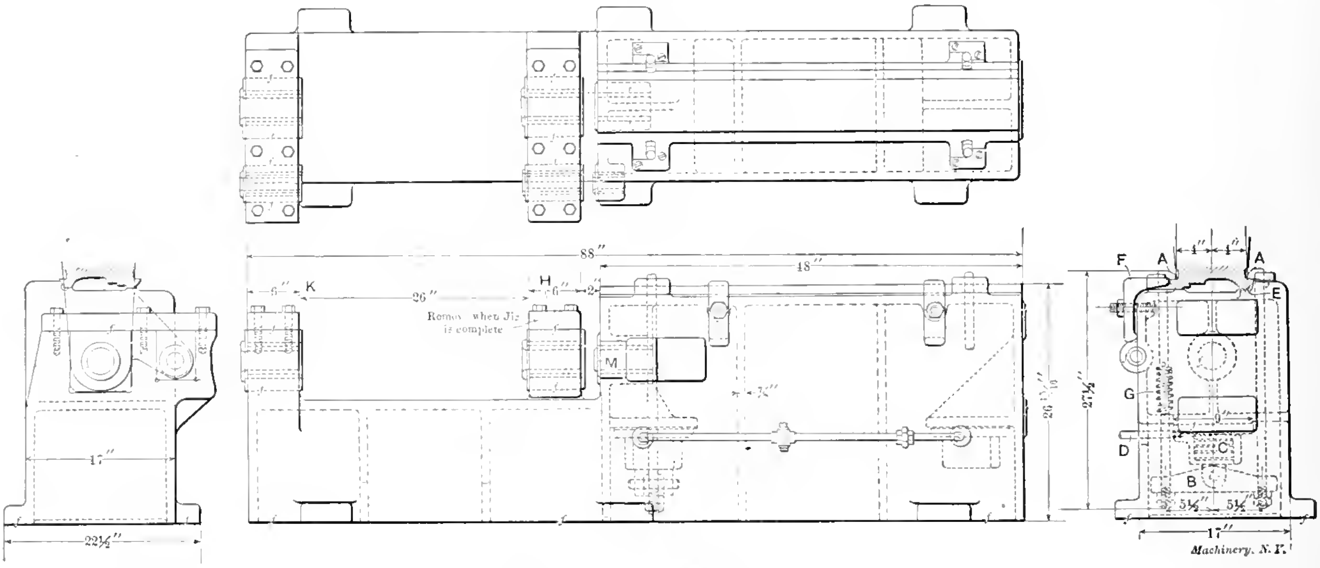

Fig. 2. Plan and Elevation of Fixture shown in Fig. 1.

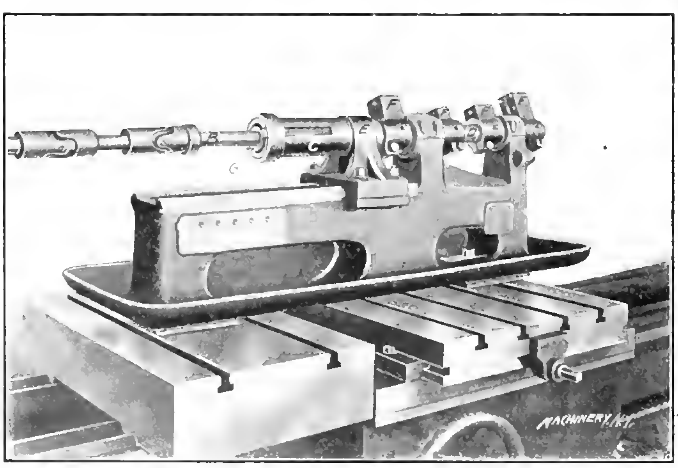

Fig. 3. Device for Facing the Head of Turret Lathes.

It will be noticed that there are a number of circular grooves cut on the surface of the plunger *C*, Fig. 2. It has been found advantageous to have these grooves on the plungers, and to fill them with vaseline, as this will act as a lubricant and permit the plunger to move freely, and at the same time act as a packing, preventing the escape of air.

Another tool of great interest and ingenuity of design is used for facing the ends of the bearings in the head of the turret lathes. This tool is shown in operation in Fig. 3, and details showing some of the component parts are shown in Figs. 5, 6, 7, and 8. The principle of this fixture is that the facing tool, inserted at *A* in the tool-holder shown in Fig. 6, moves automatically from the outside of the boss to be faced toward the center, the four faces of the head being faced off simultaneously. The fixture consists, in general, of a feed bar *B*; a feed bar sleeve *D*; a driver *C*; a driving clutch *G*; a supporting thrust bracket *E*; and four tool-carrying heads *F*, with tool-holders and tools. The bracket *E* is first clamped to the bed of the machine, the bearings of which are to be faced, the machine itself being placed on the table of the boring machine. This bracket *E* acts as a support and guide for the boring-bar sleeve *D*, on which the heads *F* are mounted, and which is keyed to driver *C*, thereby giving the rotary motion to the heads. Sleeve *D*, however, is held stationary endwise. There is little or no actual end thrust, as far as the cutting operation is concerned, inasmuch as all the four faces are finished at once, and the two opposing ones actually equalize one another in regard to end thrust. What end thrust there is, is caused by the feeding in of the tools toward the center, as explained in the following.

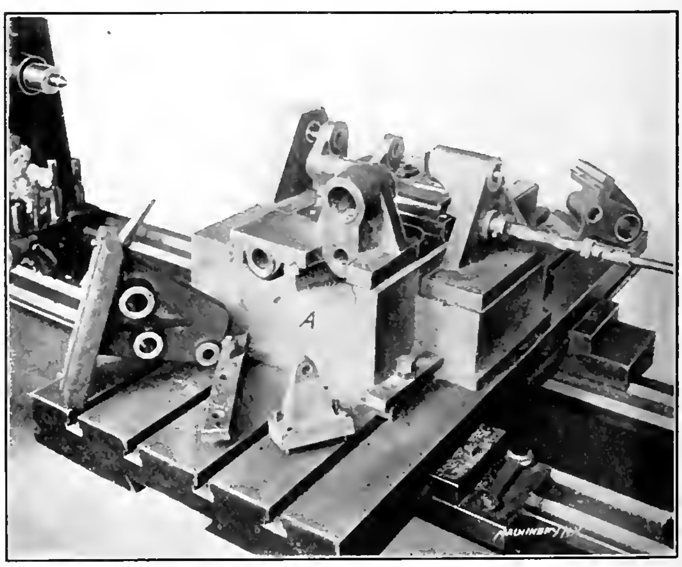

Fig. 4. Fixture for Boring Head-stock, Foot-stock, and Carriage for Thread Milling Machines.

The feed-bar B is designed in a manner as shown in Fig. 5. On the end, connecting with the ball joint, it is circular, but the portion of the bar which enters in the sleeve D is milled down, as indicated, and at the places where the four heads F are located, it is provided with ridges and grooves, as shown at H, Fig. 5. These ridges and grooves engage with similar ridges and grooves in the tool-holder, Fig. 6, and it is evident that when the table of the boring machine, to which the bed of the machine being faced is clamped, moves toward the head of the boring machine, so that the boring bar B is pushed forward, the engagement of the grooves in this bar, with the ridges in the tool-holder, forces the tool-holder to move in a direction at right angles to the axial direction of the boring-bar, so that the tool inserted at A in the tool-holder is fed from the outside periphery toward the center of the bosses on the head. The heads F, as mentioned before, are mounted on the sleeve D and are held stationary in relation to the bed through bracket E, so that there is no endwise motion of the tools in relation to the bed of the machine.

In Fig. 7 is shown a detailed drawing of one of the tool-carrying heads F, which acts as a guide and holder for the tool-holder in Fig. 6, and in Fig. 8 is shown a section through the head, when the tool-holder and feed bar are inserted. In this section, B represents the feed bar; D, the sleeve; F, the head itself; K, the tool-holder; and L, the facing tool. At M is shown a pin having a knurled head. This pin presses against the side of the tool-holder, and is actuated by the spring N. As soon as the tool-holder has been fed inward by the forward motion of the feed bar, so that the ridges and grooves of the feed bar have passed entirely through the corresponding grooves in the tool-holder, and the bar has disengaged the holder, the end of this pin enters into the corresponding hole P in the tool-holder. This prevents the tool-holder, which still has a rotating motion imparted by the head, from being entirely loose in the head, and from falling to and fro, according to which side of the head is turned upward.

The half-tone, Fig. 4, shows a fixture which is used for boring the head-stock, foot-stock, and the carriage which holds the cutter head for the thread milling machines, built by the Pratt & Whitney Co. Originally, special fixtures were made for boring each one of these three parts of the machine, but it was found that it was difficult to get all the holes to line up exactly when the different parts were placed on the bed of the machine. It is evident that it is necessary that the center of the holes, in which the cutter head swivels when it is set for milling, should be exactly at the same height as the center of the spindle of the machine, in order that the cutters may cut the exact shape of the thread desired, in the same way as it is necessary to have the thread tool set exactly at the height of the centers of the lathe, in order to obtain a perfectly shaped thread. In order to overcome the difficulty referred to, the fixture shown was designed. This fixture, in fact, consists of a short portion A of the bed of the machine itself, and the various parts are placed directly on this bed when being bored. The brackets shown lying on the table of the boring machine are used for the different parts of the machine, and are put in place as required. They are being located by dowel pins, so as to insure that they will always come in the same exact relation to the main bed A. It is evident that this provision permits all the parts that go on the bed of the thread milling machines to be bored so as to be perfectly interchangeable with one another, and at the same time that all the holes required to line up in the assembled machine will have a correct location.

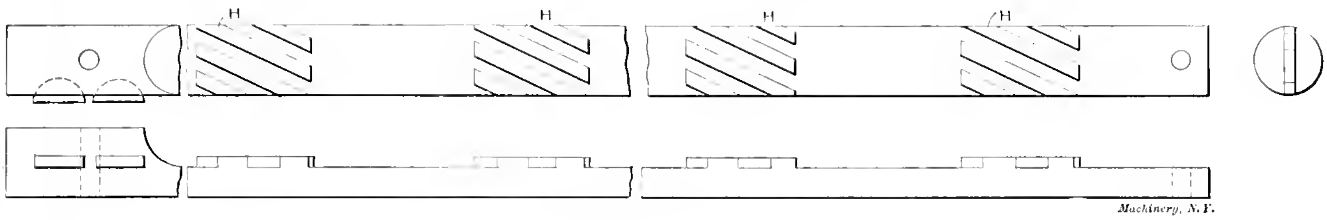

Fig 5. Feed Bar used in Device shown in Fig. 3.

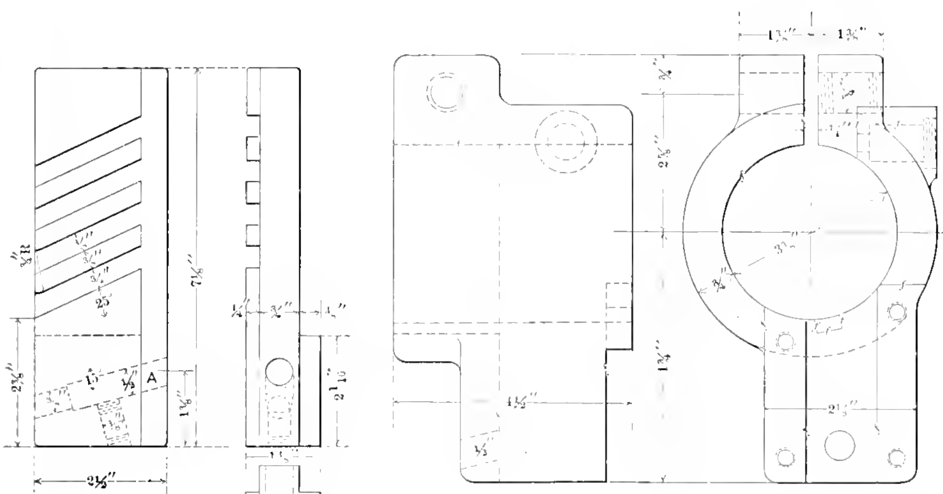

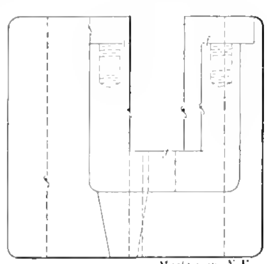

Figs. 6 and 7. Tool-holder for Facing Device, and Tool-carrying Head.

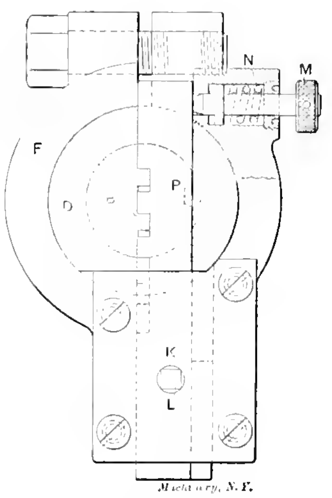

Fig 8. Section through Tool-carrying Head, with Feed Bar and Sleeve in Position.

The fixture shown in the half-tone, Fig. 9, is used for drilling the holes K and L in the casting in the line cut, Fig. 10, and also for drilling the corresponding holes in the bed of the machine onto which the casting is attached. This casting is what is known as the motion bracket on an automatic screw machine, built by the company, a worm being placed between the faces A A, working with a worm-wheel located on a stud in the frame of the machine. The fixture is also used as a gage for testing the worm-wheel after hobbing. As will be seen from the line cut, the casting is of a rather complicated design, and it would be rather difficult to drill holes in this casting, and then drill the corresponding holes in the bed of the machine, so that they would line up perfectly, unless as here, the same jig were used for both operations. When the piece in Fig. 10 is placed in the jig, shown in Fig. 9, the bottom face B is already planed, and it is clamped with its face against the finished pad on the jig, the holes then being drilled in the bracket. For sideways location, the

bracket is located by a movable stop, shown at M, so located that the center between faces A comes exactly in line with the center of the worm-wheel, which, when this fixture is used for a gage, is held on a stud entering the hole, shown at C in Fig. 9. The side of stop M locates the work by pushing face A of the casting up against it. When the bed is

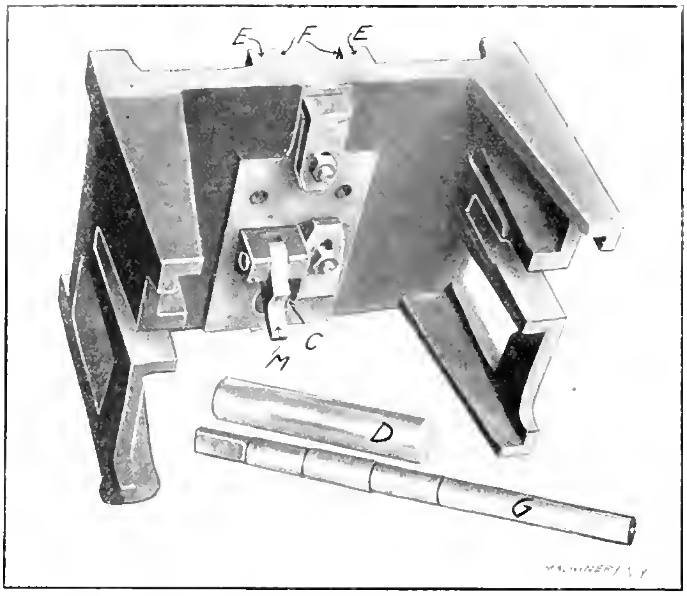

Fig 9. Jig for Drilling Screw-holes in Casting shown in Fig. 10, and for Drilling Corresponding Holes in Frame; also employed as a Worm-wheel Gage.

drilled, the jig is located through the stud D, Fig. 9, entering through the hole C in the drill jig, and at the same time through the hole already bored for the shaft of the worm-wheel in the bed. This locates the jig in relation to the height. To locate it sideways, the two lugs E, shown on the back of the fixture, are employed, the faces F fitting a finished projection on the machine. In order to permit the holes K to be tapped while in the jig, the bushings are removable. When the fixture is used as a gage for the hobbed worm-wheel, the bracket is clamped to the fixture in the same manner as when it is being drilled. The shaft G is

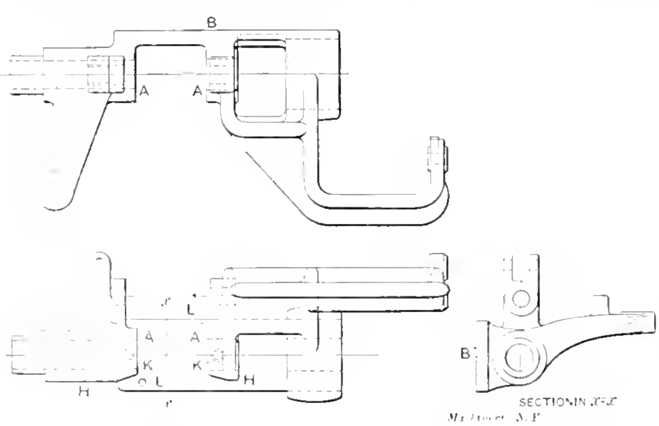

Fig. 10. Motion Bracket for Automatic Screw Machines—drilled in Jig Fig. 9.

placed in the bracket through the hole H, and a master worm is placed on this shaft. The stud D is then placed in the hole C, and the worm-wheel is placed on this stud. It is evident that, if the master worm fits the worm-wheel exactly when tested under these conditions, both the bed and the bracket having been drilled in this jig, it must necessarily follow that the worm and the worm-wheel will fit each other, when placed in position in the machine.

A most interesting device is shown in the half-tone, Fig. 11, and the line cut, Fig. 12. This device is intended for milling dove-tail slides in a vertical milling machine. As will be seen from the half-tone, Fig. 11, the device consists of a bottom plate A, in the center of which is pivoted a table B, provided with three T-slots. On this table is mounted the work holder plate C, provided with screws and studs for holding the work. At D is shown a dove-tail slide, placed on the device and milled to the desired dimensions. At the corners of the base plate A are shown disks E and H. These disks serve as gages when the device is used. The operation is as follows: When the work has been placed in position on the work holder, the table is fed forward, and one side of the slide is milled, the cutters used for milling being of the form shown in Fig. 14. As soon as one side is completed, the operator releases the handle F, which is attached to a stud, which binds the table B to the bottom plate A, and, with the other hand on the handle G, he swings the table around until it rests up against the side of the disk H at the other end of the base plate. In this position it is located to mill the other side of the dove-tail slide without changing the setting of the machine. When the disks E and H are of equal size a straight dove-tail slide will result, but if it is required to have the slides so milled that a tapered gib may be used, then one of the disks may be made larger than the other, the dimensions, of course, being determined by the taper required. One side of the dove-tail slide will then be milled straight, while the other will be made on the required taper. A tool steel piece K is inserted in the table B, where it strikes up against the hardened disks E and H, so that the device will stand without perceptible wear the constant impact that results from being pressed up against the disks.

In order that the disks may be figured and made once for all, and standard gages used for setting the cutters, it is necessary that one end of the slide to be milled be always

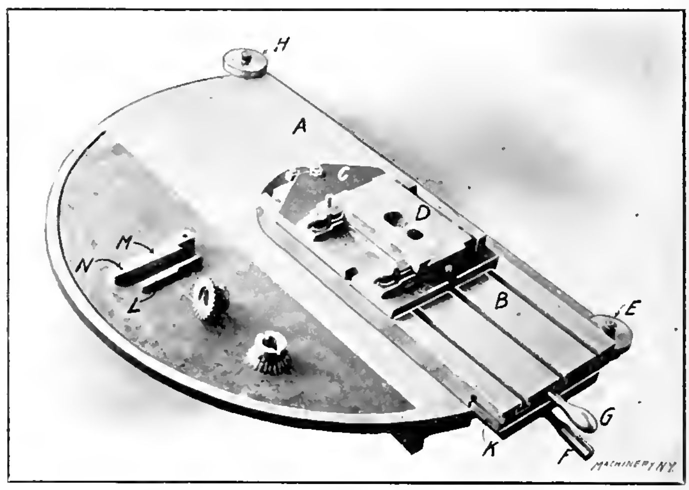

Fig. 11. Dove-tail Slide Milling Device.

a certain distance from the center of rotation. To ascertain this, a hole is drilled in the work holder C, and the work is located so that the center of this hole is exactly in line with the end of the work being milled. This hole is not shown in the cut, but the work is always so set that the end of the slide to be milled comes exactly at the center of this hole. The work-holding slide must, of course, itself be so clamped

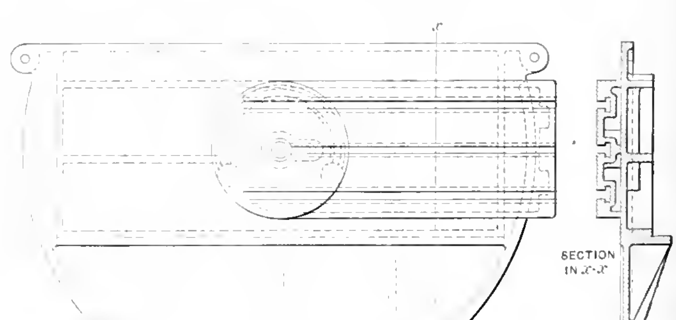

Fig. 12. General Construction of Dove tail Slide Milling Device.

in relation to the table B that the distance between the center of the hole referred to and the center of rotation is constant. The gage pin L is used for this purpose. A hole is drilled in table B, exactly three inches from the center of rotation, and the gage L is put through the holes in the work holder C and the table B, so that the exact relation is obtained. At M is shown one of the gages used for setting milling cutters to obtain exact sizes of the dove-tails. The hole at N is also

intended for the gage L which enters into this hole and into the hole in C, before mentioned, and thus locates the gage exactly in relation to the device.

The line cut, Fig. 12, simply shows the general details of the construction of the device. The cutters used, shown in Fig. 14, have one interesting feature. The cutter is first turned up to the shape shown at O, and then every alternating tooth is made as shown by the full line at P, and every remaining tooth as shown by the dotted line. This construction is used in order to get a sharp corner at R, it being desired to mill, at the same time that the dove-tail is milled, the small flat, which terminates the dove-tail, and prevents a sharp corner at the upper edge between the top and the beveled surface. Of course, in order to make a cutter this way, each tooth will have to be operated upon separately and given the desired shape. It is evident that this is rather a costly operation, but it insures efficient results.

In Fig. 13 is shown a universal fixture used for the boring of the largest size of turret lathes (3 x 36 inches), and also for the die-sinking machines made by the company. This

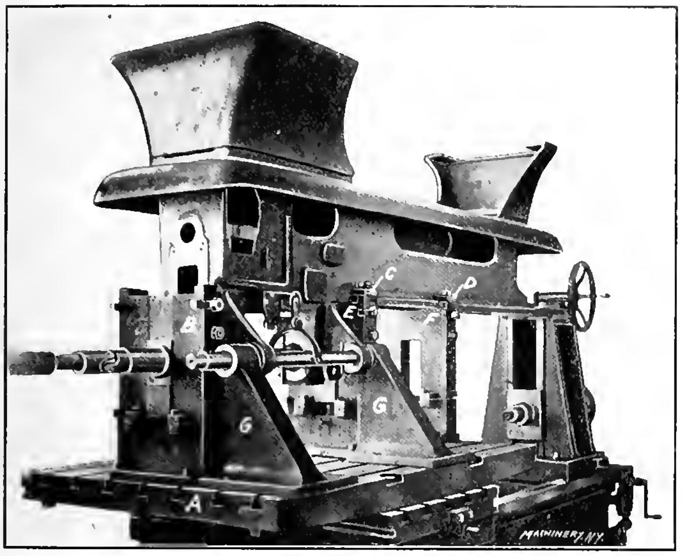

Fig. 13. Fixture for Boring Large Size Turret Lathes.

fixture consists of an auxiliary table A which is placed on the regular table of the boring machine. On this table are placed the brackets and uprights which guide the boring bars. The uprights B, E and F are provided with slots for a certain distance down, and in these slots are placed square guide blocks which hold the bushings for the boring bars. The construction permits of adjusting the bushings to different positions for different machines, and the arrangement makes a very useful and universal tool for interchangeable work. The

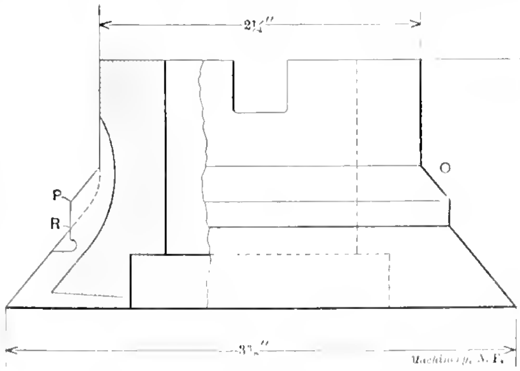

Fig. 14. Cutters used for Milling Dove-tail Slides.

machine is clamped to the fixture by clamps at C and D, and rests entirely on the uprights E and F. The bed and the pedestals complete, arranged on the table of the boring machine, as shown, weigh approximately 2,800 pounds.

It will be noticed that, for boring the holes for the backgear shaft, two separate brackets G are used, shown at the front of the table A. For some work, which is not made in sufficient quantities to warrant the expense of making separate brackets, two heavy knees, with adjustable arms, as indicated in the perspective drawing in Fig. 15, are used. As will be seen, there are vertical slots in the knee, and slots at right angles to these in the arm clamped to the knee, so that the guide bushing for the boring bar can be placed at any position required. These arms are provided with removable bushings, so as to accommodate the different sizes of boring bars and fill the requirements fully as well as the removable brackets, excepting, of course, that they have to be set to the correct position every time they are changed from one job to another. The arrangement shown in Fig. 13

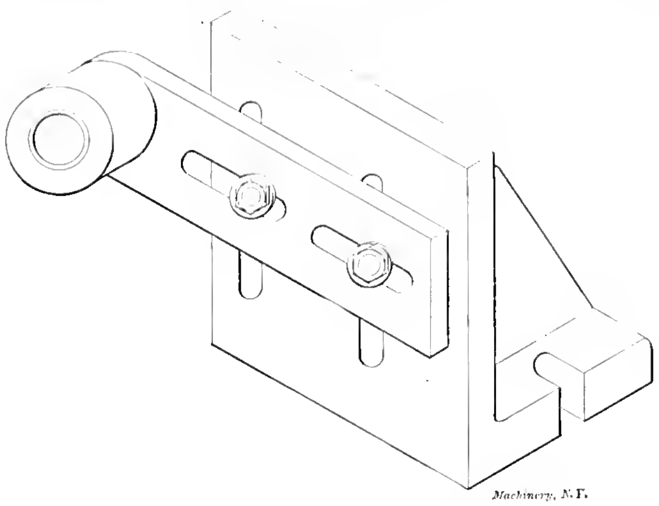

Fig. 15. Bracket with Adjustable Arm for holding Boring Bar Bushings used with Fixture shown in Fig. 13.

illustrates also how in the modern machine shops the size or the weight of the machines being operated upon does not interfere in any way with their being placed in the most convenient way for the operation of the tools, and that comparatively simple devices, if provided with adjustable features, may be used for operations requiring great accuracy.

The illustrations of the tools shown above (the devices having been reproduced directly as used in the shops) may suggest a great deal more than has been conveyed by the description itself. Photographs are one of the best means of conveying ideas in mechanical work, as they often show to each individual exactly the things that he may be most interested in, whereas a description may often ignore certain points, seemingly of more trivial interest, which to some may be considered as the most interesting points. The half-tones shown also illustrate plainly that in our most modern machine tool shops there is no limit to the application of special tools to the operations performed in building machinery, and that by the use of such devices work can be carried out in a fraction of the time that was formerly required to carry out the same operations.

E. O.

* * *

Some years ago (October, 1899) an article was published in MACHINERY on the manufacture of hydraulic jacks as carried on by a well-known concern, and in it the importance of the unit system was pointed out as applied to this business. The number of devices and designs of hydraulic apparatus is very large, there being literally hundreds of jacks, presses, etc., listed which the concern is prepared to supply on short notice, but this does not mean that there are as many designs of the pumping mechanisms as there are designs of jacks listed. On the contrary, these costly parts are standardized and are manufactured entirely apart from the general construction of the apparatus in which they may be used. The general line of apparatus is designed to use these standard parts, and they are assembled in exactly the same essential form as they appear, for example, in the ordinary hydraulic jack.

* * *

The common process of protecting metals by plating them with copper or other metals by electrolysis is often inconvenient because of the large size of vat necessary. It has been found possible to apply the electrolyte with a paint-brush attached to one pole of the source of current. By this means a smooth, strong coating of metal may be built up to any reasonable thickness. This process, it is said, has been successful in plating with silver, gold, copper and nickel.

TAPER TAPS.—1.

ERIK OBERG *

Taper taps, if the expression be properly understood, are taps which have the diameter of the thread nearest the shank larger than the diameter of the full thread at the point, the intermediate portion being formed by the gradual taper from one end of the thread to the other. It is necessary to call attention to this proper meaning of the expression taper tap, because of the fact that the first tap in a set of hand taps is commonly, but not properly, referred to as a taper tap. As this expression is used to designate two widely different things, and as its common usage in connection with the first tap in a set of hand taps prevents any possible change, it is always well, when speaking of taper taps, to state which of the two meanings is referred to in any particular case. In the present discussion, we are referring to the taps properly termed taper taps; that is those with the diameter of the full thread at the point smaller than the diameter of the thread at the end nearest the shank.

There are three particular points to take into consideration when making taper taps. In the first place, the threading tool must be presented to the tap at right angles to the axis

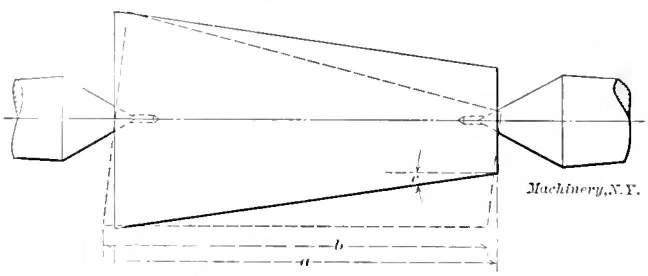

Fig. 1. Showing Effect of setting over Tail-stock when threading Taper Taps.

of the tap, and not at right angles to its tapered surface, unless the tool is specially made for taper threading of taps with a definite taper. In the second place, taper taps should, if possible, be turned on lathes being provided with taper attachments, and not by setting over the tail-stock of the lathe, and, finally, proper relief should in all cases be given a taper tap. The first of these questions was treated at length in the article entitled "Cutting Taper Threaded Taps with Chasers," which appeared in the May, 1907, issue of MACHINERY. The second and third questions will be dealt with in the following.

Effect of Setting Over Tail-stock when Threading Taper Taps.

If the old method of setting over the tail-stock is used when cutting taper threads, two errors will be introduced, and these errors will increase as the taper of the taps increases. The first error consists in the pitch of the thread becoming finer than the standard, which is readily seen by referring to Fig. 1. The length of the work shown between the centers of the lathe is a, if measured along the axis of the work. If measured along the tapered surface the length is b; but $b = \dfrac{a}{\cos v}$, if v be the angle which the side of the tapered piece makes with the center line. If the piece is threaded with a certain number of threads per inch c, the number of threads when threading by means of a taper attachment would be $a \times c$, but if the threading is done with the tail-stock set over, as shown by the dotted lines, the number of threads would be $\dfrac{a}{\cos v} \times c$, or a greater number of threads, and consequently a finer pitch, than in the first case.

An example will plainly demonstrate the case. Let the length a, measured parallel to the axis, be 12 inches. Assume that we wish to cut 10 threads per inch and that the angle v is 8 degrees. The number of threads on the whole length of the piece, when cut in a correct way by means of a taper attachment will be 120 threads. Now, the length b, or the length of the piece measured parallel to the outside, equals $\dfrac{12}{\cos 8 \text{ deg.}} = 12.121$, or $12\frac{1}{8}$ inches approximately. In this length we would get $121\frac{1}{4}$ threads instead of 120. It is thus evident that for steep tapers the difference is quite considerable, and cannot be overlooked.

"Drunken" Thread.

The second error, due to setting over the tail-stock when cutting a taper thread, consists in that the thread, instead of becoming a true, continuous helix, becomes "drunken." An exaggerated drunken thread is shown in Fig. 2. The drunken thread is due to the fact that in taper turning with the tail-stock set over, the work does not turn with a uniform angular velocity, while the cutting tool is advancing along the work longitudinally with a uniform linear velocity. The change in the pitch and the irregularity of the thread is so small as to be imperceptible to the eye if the taper is slight, but as the tapers increase to say ¾ inch per foot or more, the errors become more pronounced. While the setting over of the tail-stock for cutting taper threads should be as much as possible discouraged, in such cases where it is necessary, however, the detrimental effects of the method may be partly overcome, at least in as far as the cutting qualities of the taps are concerned, by relieving the threads liberally. This will, obviously, not correct the errors in regard to incorrect pitch or imperfect helix of the thread, but it will cause the tap to cut freely, even if it does not produce a theoretically perfect thread of the desired pitch and form.

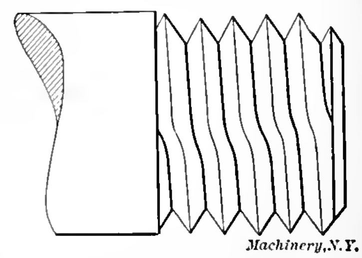

Fig. 2. "Drunken" Thread, Exaggerated.

Amount of Error due to Setting Over the Tail-stock.

In Table I, figures are given stating the amount a tap will be *short in the lead per foot* for various tapers, if threaded with the tail-stock set over. The amount of taper is always, in regard to taps and reamers, intended to mean the *difference in diameters per foot of length* measured along the center line or axis of the tool. By means of the table given, it is easily seen whether the inaccuracy produced will be of consequence

TABLE I. AMOUNT OF SHORTAGE IN LEAD IN ONE FOOT OF SCREWS THREADED BY SETTING OVER THE TAIL-STOCK.

Taper per foot.	Error in Lead per foot.	Taper per foot.	Error in Lead per foot.
⅛	0.0001	1½	0.023
¼	0.0006	1¾	0.031
⅜	0.0014	2	0.042
½	0.0026	2½	0.065
⅝	0.0041	3	0.094
¾	0.0058	3½	0.126
1	0.0108	4	0.164
1¼	0.0168	..	.....

in a particular case or not. It is also seen that the error for reasonable tapers is very small indeed, so small, in fact, as to have no commercial importance whatever.

The amount of the error in one inch is figured from the formula

$$\text{Shortage in lead in one inch} = 1 - \cos v,$$

if v is figured from the formula

$$\tan v = \frac{t}{2 \times 12},$$

in which latter formula t is the taper per foot of the piece to be threaded.

An example will tend to make the formula more easily understood. Suppose the taper per foot of a particular piece of work is ⅝ inch. The angle v is then first determined:

$$\tan v = \frac{0.625}{2 \times 12} = 0.026$$

$$v = 1 \text{ degree } 30 \text{ min.}$$

The amount the lead of the thread will be short is one inch, if threaded with the tail-stock set over, equals

$$1 - \cos 1 \text{ deg. } 30 \text{ min.} = 0.00034,$$

or about 0.004 inch per foot. Being a fairly small taper we see that the amount of the error is comparatively slight. If

* Associate Editor of MACHINERY.

the taper is increased, however, the error will soon assume such proportions as to be negligible only in very rough work.

Relief of Taper Taps.

The third, and perhaps the main, consideration in regard to making taper taps is the question of a proper relief. This question has been a greatly perplexing one in machine shop practice, particularly in the case of taps with steep tapers. It is evident that a taper tap, not relieved either on the top or in the angle of the thread, will refuse to cut altogether, or, if forced through a hole, will either leave a very rough and irregular thread, or break off its own teeth. This depends upon that, as the tap is continuously tapering upward, the heels of the teeth are always located in a circular section of a larger diameter than the cutting edge of the corresponding tooth. Consequently, if forced to cut a thread, the tap, if not relieved, will squeeze the metal back of the cutting edge in order to find room for the increasing diameter. While the edge cuts, the space produced by the cutting point of the thread is not large enough for the increasing diameter of the part of the thread immediately following. On account of this, it is imperative that taper taps be relieved the full length of the thread, on the top as well as in the angle of the thread, for the full width of the land. Referring to Fig. 3, the relief should also be greater on the side D than on the side E of the thread. This will lessen the friction and the resistance while cutting a thread, inasmuch as it is obvious that the greater pressure on the thread of the tap created by the cutting process comes on the side D. Thus, if this side is properly relieved so as to permit only the cutting edge to come in contact with the material to be cut, the friction is reduced to the smallest possible amount, and at the same time the keenness of the cutting edge is increased.

Fig. 3. Section of Threads of Taper Tap.

With the exception of the previous remarks, there is nothing to be said in regard to taper taps which has not already been discussed in these columns in relation to straight taps. (See MACHINERY, June and July, 1907.) As a rule there is not the necessity of the extreme accuracy in taper taps as is sometimes expected from hand taps, because, with incidental exceptions, of course, taper taps are usually employed on work of a rougher character. Besides, being tapered, there is never any requirements for a working fit between the stud and the nut, as the taper taps are used mainly for tapping holes where a water, steam or air-tight fit is required.

TABLE II. NUMBER OF FLUTES OF PIPE TAPS.

Nominal Size of Tap.	Number of Flutes.	Nominal Size of Tap.	Number of Flutes.
1/8	4	1 1/2	6
1/4	4	2	7
3/8	4	2 1/2	8
1/2	4	3	9
3/4	5	3 1/2	10
1	5	4	11
1 1/4	6	..	..

Pipe Taps.

The most common of all taper taps is the pipe tap. The shape of the thread for this tap was referred to in the February, 1907, issue of MACHINERY in the article entitled "Screw Thread Systems" under the sub-head "Briggs Standard Pipe Thread." The pipe tap tapers 3/4 inch per foot, or 1/16 inch per inch, measured along its axis. The taps are known by the nominal size of the pipe for which they are intended; consequently a pipe tap is a great deal larger, measured in inches, than the size by which it is designated. The largest diameter of a half-inch pipe tap, for instance, as seen from Table IV, is 0.887 inch.

Fluting.

Pipe taps are fluted with the same kind of cutters as are used for hand taps. (See June, 1907, issue of MACHINERY.) As there is a considerable difference in the manner in which a hand tap and a pipe tap cut, there is some difference in regard to the required chip room. In the case of a hand tap, as soon as the thread has been cut by the chamfered portion, the straight part of the thread does not cut or produce any chips. The pipe tap, again, being tapered, is constantly cutting, no matter which part of the tap is in contact with the work, and therefore there is a necessity for large chip room, and the flutes should be made as deep as possible without impairing the strength of the tap.

TABLE III. AMOUNT MEASURED ALONG THE TAPERED SURFACE, CORRESPONDING TO ONE INCH ALONG THE AXIS.

Taper per foot.	Amount Measured along the Tapered Surface corresponding to one inch along the Axis.	Taper per foot.	Amount Measured along the Tapered Surface, corresponding to one inch along the Axis.
1/8	1.0000	1 1/2	1.002
1/4	1.0001	1 3/4	1.0025
3/8	1.0001	2	1.0035
1/2	1.0002	2 1/2	1.0055
5/8	1.0003	3	1.008
3/4	1.0005	3 1/2	1.011
1	1.0009	4	1.014
1 1/4	1.0015	..	......

The number of flutes for pipe taps may be approximately determined by the formula:

$$N = 1.75\,A + 3,$$

in which N is the number of the flutes, and A, the diameter at the size line of the tap. This formula gives the number of flutes given in Table II for sizes up to 4-inch pipe tap.

The formula given for the number of flutes makes the distance from cutting edge to cutting edge at the size line larger as the sizes grow larger, thereby making possible deeper flutes in the larger sizes.

Testing Lead of Taper Taps.

In testing or inspecting the lead of taper taps, it must be remembered that the correct lead should be measured on a line parallel to the axis of the tap, and the lead of the thread cannot be measured in the same manner as is done with straight taps, unless due allowance is made for the differences in length along the axis and the tapered surface. In Table III the values are given which should be measured along the tapered surface to correspond to one inch along the axis, for different tapers. In other words, if a tap is tapered 3/4 inch per foot, and is provided with eight threads per inch, the distance covering 8 threads on the surface of the tap is not one inch but 1.0005 inch, as seen from the table opposite 3/4 taper per foot. If the lead of the thread is tested by comparing it with a standard tapered thread plug, this need, of course, not be taken into consideration, as then any device for comparing the lead of straight taps is equally applicable to taper taps. The distance on the tapered surface corresponding to one inch along the axis is $\frac{1}{\cos v}$, if v, as before, is determined by the formula

$$\tan v = \frac{t}{2 \times 12},$$

where t is the taper per foot.

Thus, if a tap tapers 1¼ inch per foot, and has 8 threads to the inch, if 16 threads were measured at the surface of the taper, the length, if the lead be correct, should not be 2 inches, but 2.003 inch, which we find from

$$\tan v = \frac{1.25}{2 \times 12} = 0.0521,$$

$$v = 3 \text{ deg. (approximately), and } \frac{1}{\cos 3 \text{ deg.}} = 1.0014;$$

$$2 \times 1.0014 = 2.003 \text{ (approximately).}$$

In Tables I and III figures have been given for tapers as steep as 4 inches per foot. Of course, such steep tapers are very seldom encountered.

Dimensions of Pipe Taps.

The dimensions of pipe taps are given in Table IV. Referring to Fig. 4, a dimension A is given at the distance B from the point of the tap. This diameter is the essential diametral measure of a pipe tap, and the circular line which may be

imagined to be drawn around the tap at this point is termed the size line. The two smallest sizes are provided with a neck between the threaded part and the shank. On the remaining sizes the shank is made small enough to come below the root diameter of the thread, and a neck is therefore unnecessary.

As pipe taps must be made according to the established manufacturing standard, formulas for the dimensions cannot be given, excepting for those measurements which are unessential, like the dimensions for the shank and square; but

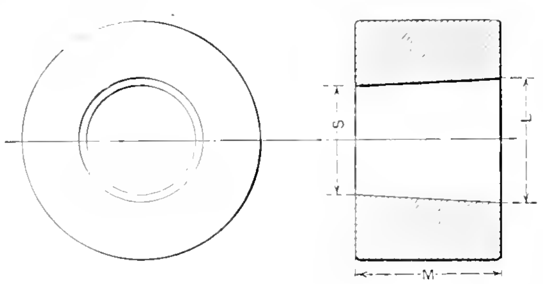

Fig. 5. Ring Gage for Testing Diameters of Taper Taps.

Table IV gives all necessary information in regard to all standard sizes, and formulas, even if they could be given, would consequently be superfluous.

Limits of Accuracy.

The accuracy usually demanded of taper pipe taps in regard to the exact location of the size line is given below. The method of testing or measuring taper taps in order to insure that they are within the permitted limits of variation in this respect is by means of a plain ring gage, as shown in Fig. 5, the diameter L at the large end of which is the dimension at the size line; the diameter S at the small end of the hole is the diameter at the point of the tap, and the length M of the ring gage equals the dimension B in Fig. 4, representing the distance from the size line to the point of the tap. Thus, when the tap is tested with this ring gage, if the end of the tap comes exactly flush with the end of the gage, the location of the size line is exactly correct. If the end of the tap projects through, or comes short of the face of the ring gage at the small end of the hole, such projection or shortage represents the error in the location of the size line. The permissible errors are as follows:

Pipe Sizes.	Error Permitted in the Location of the Size Line.
1/8 – 1	± 1/32
1 1/4 – 3	± 1/16
3 1/2 and up	± 1/8

Plus in the above table signifies a projection of the tap through the ring gage, and minus the amount by which the point of the tap fails to reach through the gage in order to come flush with the end of the gage.

* * *

DON'TS FOR MACHINISTS.

W. H. ADDIS.

Don't talk too much.

Don't attempt to bore a taper hole unless the cutting edge of the tool is in line with the centers.

Don't throw in the feed and lead at the same time.

Don't say, "I'll finish this up to-morrow;" earn your money to-day.

Don't believe that every micrometer dial is so graduated that every graduation measures 0.001 inch.

Don't forget to take up lost motion in the feed screws before starting an accurate job.

Don't forget that a little chalk will prevent your file from filling up.

Don't force or jam your turret tools into the work; it is better to sharpen them.

Don't say, "This is good enough"; do it right.

Don't leave oily waste as a collection in the corners. It may cost you your job, and your employer his shop building.

Don't file the cutting edge of a tool to see if it is hard; it may be.

Don't let the emery from the tool-post grinder fall on your lathe ways; newspapers are cheaper.

Don't allow steel chips or filings to become imbedded in your copper vise jaws.

Don't ream a center without using a little oil.

Don't wash a finished screw or bolt with gasoline, and then use it in assembling; gasoline is a poor lubricant.

Don't cut off a piece of work between centers.

Don't stand with your face in line with an emery wheel; the face might get spoiled.

Don't forget to oil the shanks of your turret tools.

Don't forget to measure the rough stock when you receive a job; the stock might be wrong.

Don't forget that a common bottle cork placed over the spout of your oil-can may save you an eye.

* * *

It has been stated over and over again, in the daily as well as in the mechanical press, that fast ocean liners are not directly paying propositions, excepting that, of course, they possess a great advertising value. German periodicals, in particular, have been eager to put forth this theory since the two new Cunarders have taken the blue ribbon of the ocean from the German liners. If a statement, which lately appeared in a Liverpool paper, regarding the expense of running the new Cunard liners is founded on good authority, as it appears to be, fast liners are, however, by no means failures, even from a commercial point of view. According to this statement, the passage money, with the passenger accommodations used to the fullest extent, for a single trip of the *Lusitania* or *Mauretania* amounts to about $140,000, while other incomes from carrying cargo, proportion of ship subsidy, etc., amount to about $16,000. All expenses, including coal, food supplies, harbor dues, insurance, interest, sinking fund, etc., amount to about $90,000. According to this, there should be a clear profit of something like $66,000 on each voyage.

PRACTICAL POINTS ON SURVEYING.*

CHARLES L. HUBBARD.†‡

It frequently happens around manufacturing plants that simple work along the line of surveying is required, such as locating new buildings or extensions, establishing property boundaries, determining grades for drains or steam and return mains, etc. The object of this article is to describe, briefly, the use of transit and level, methods of taking measurements, arrangement of notes, and the plotting of results. No attempt will be made to go into the accurate methods required in important engineering undertakings, as work of this kind is entirely beyond the scope of the present article.

Measurements.

Measurements were formerly made either with a Gunters' or an engineer's chain. The former has 100 links, each 7.92 inches long, making the total length 66 feet, or 4 rods. The handles and the center of the chain are fitted with swivels to

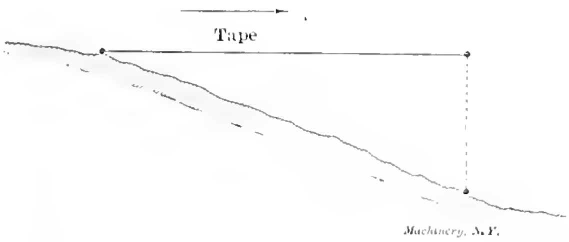

Fig. 1. Method of Holding Tape when measuring over Uneven Ground.

prevent kinking, and at every tenth link from either end is attached a brass tag with one, two, three, or four prongs to assist in measuring. The fifty-link mark is round in form, so it may be easily distinguished from the others. The engineer's chain is similar in construction to the one just described, except the links are one foot long, making the total length of the chain 100 feet. Measurements made with a chain are liable to be inaccurate unless great care is taken, owing to the sagging at the center due to its weight, and also to changes in length caused by wearing at the joints or by the links becoming bent. For the usual work around a manufacturing plant a steel tape of good quality, divided into feet and decimals of a foot, is much better than a chain. Tapes of this kind may be had either in 50- or 100-foot lengths. In addition to the tape, there should be provided eleven marking pins. These should be furnished with a strip of red flannel tied into the loop or handle to prevent their being overlooked in the grass.

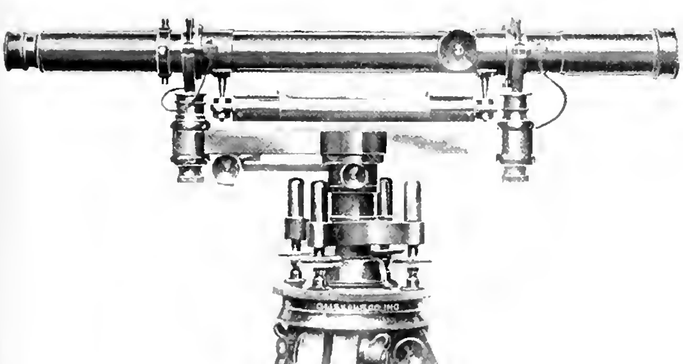

Fig. 2. A Wye Level.

For measuring a line with a tape, two men, one called the leader, and the other the follower, are required. A stake is driven at the starting point, and another provided with a flag, if the distance is considerable, is set to mark the farther end of the line. The tape is then unrolled in the direction of the line, the 100-foot mark going ahead. The leader takes the pins and the forward end of the tape and walks in the direction of the line, dragging the tape after him. When near the end of the tape, the follower ranges him exactly in line by word or gesture, the tape is drawn taut, the follower holding the end exactly over the starting point, while the leader puts down a pin at the 100-foot mark. This operation is repeated at each tape length, the follower taking up the pins as each measurement is completed. If the line is less than 1,000 feet in length, the distance is determined by counting the pins which the follower has taken up, multiplying the number by 100, and adding the last measurement taken. If a 50-foot chain is used, the number of pins should, of course, be multiplied by 50 instead of by 100. If the line is more than ten tapes in length, the follower should give the pins to the leader when he has collected ten, and a note made each time this exchange is made.

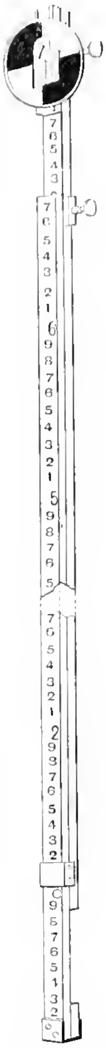

Fig. 3. Leveling-rod.

Since distances used in surveying are horizontal distances, it is necessary that the tape, in measuring over uneven ground, should always be held in a horizontal position. In going down hill, the leader must hold his end of the tape elevated, and in going up hill, the follower must elevate the tape to maintain a horizontal position, as shown in Fig. 1. For ordinary work, the tape is leveled by the eye. If the slope is too steep to permit of one end of a full tape being raised enough to bring it horizontal, the tape is broken, that is, only a part of it is used at each measurement. To do this, the tape should be stretched to its full length, the leader returning to such a point that the portion between himself and the follower may be properly leveled. A measurement is made with this portion of the tape, the operation being repeated with the next section, and so on until the entire tape has been used. The high end of the tape may be transferred to the ground by means of a plumb-bob if great accuracy is desired, but for ordinary work this may be accomplished by dropping a pebble, or a pin with its head down. In measuring up hill, the follower must hold the plumb-bob directly over the pin in the ground while he aligns the leader, and sees that he sticks the pin when the bob is directly over the proper point. It is much easier to measure down hill than up, so that when close measurements are required on slopes, the measurement should, if possible, be made down hill.

Leveling.

Leveling may consist in simply finding the difference in elevation between two points, or, the elevation of a series of points. The former would apply to finding the pressure or head to be obtained at a given point from a pond or reservoir at a higher elevation; or, it might be desired to know the elevation of a steam main above the water line in a boiler located in another building. Again, this applies to the laying out of buildings upon sloping or uneven ground where it is desired to maintain a certain relation between the floor elevations of the different buildings. A series of elevations is required in case of excavation or trenching, in order to determine the depth at different points and the quantity of earth to be removed.

Leveling-rod.

One of the instruments used in leveling is the leveling-rod, a common form of which is shown in Fig. 3. This consists of a wooden rod, usually 6½ feet high, graduated to hundredths of a foot, and provided with a sliding target. The rod is made in two parts, so arranged that its length can be extended to 12 feet. The target is provided with a vernier for accurate work, reading to thousandths of a foot, but the vernier is not often used in the class of work covered by this article. In using, the rod is held in a vertical position with its lower end resting upon the point, the elevation of which is desired, and the target moved up or down until its center coincides with the cross-wires of the telescope of the level.

* See "Surveying without Instruments," by A. L. De Leeuw, July, 1906.

† CHARLES L. HUBBARD was born in Surry, N. H., 1866. He graduated from the New Hampshire State College of Mechanical Engineering in 1893, after which he took a post graduate course of one year at Cornell University. He has held positions as draftsman with the Brown and Sharpe Mfg. Co., Providence, R. I.; head draftsman with the Holly Steam Engineering Co., Providence, and as assistant engineer with Professor Woodbridge, the well-known authority upon heating and ventilating. He has also contributed widely to the technical press, and is the author of a book entitled "Power Heating and Ventilation." His specialty is heating, ventilation, and power plant engineering.

‡ Address: 420 Boylston St., Boston, Mass.

The reading of the elevation is made from the rod on a line corresponding with the center-line of the target. There are several forms of rods in common use, some of which are read by the rodman, while others are read through the telescope of the level.

The Level.

The instrument usually employed for determining the difference in elevation between points, is called a level. A common form known as the wye level is shown in Fig. 2. It consists of a telescope mounted upon two supports which from their shape are called wyes. The cross-bar supporting the telescope is attached to a vertical spindle which allows it to be turned in a horizontal plane. Directly beneath the telescope, and attached parallel to it, is a spirit level by means of which the line of collimation of the telescope may be rendered horizontal. The telescope is provided with a diaphragm at its focus, consisting of a vertical and horizontal thread or wire. Another instrument in common use is known as the Dumpy level. This is somewhat simpler and more compact than the one just described.

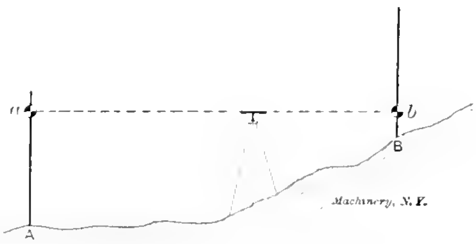

Fig. 4. Finding the Difference in Level between Two Points when the Difference is Less than the Height of the Leveling-rod.

As the various adjustments depend upon the type of level, and as suitable directions are furnished by the makers, only the use of the instrument after it is properly adjusted will be considered. Both types of levels are mounted upon a tripod head and supported upon a tripod. In using the instrument, it should be set up as nearly level as possible by adjusting the legs of the tripod, and then brought to a true level by means of the adjusting screws. To do this, turn the telescope upon its vertical spindle until it is in line with one pair of the leveling screws, then by the proper adjustment of these screws, bring the bubble of the spirit level to the center of the scale; then turn the telescope until it is in line with the other pair of screws, and bring the bubble to the center. Turn back to the first pair of screws, and so repeat the process until the bubble stands at the center of the scale for any position of the telescope in the horizontal plane. The instrument is now ready for sighting upon the leveling-rod.

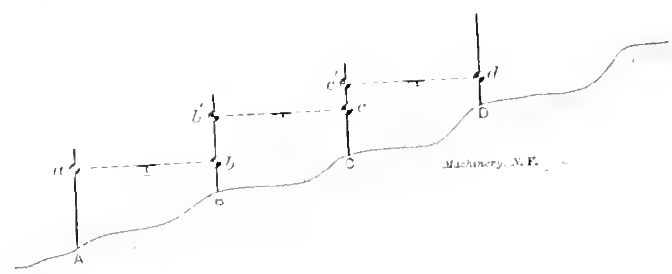

Fig. 5. Finding the Difference in Level when the Difference is Greater than the Height of the Rod.

To find the difference in level between two points which are visible from a third point, is a simple matter. First, set up and level the instrument, as described, at some point approximately midway between the two given points, but not necessarily in line with them. The leveling-rod should now be held vertically upon one of the points (see Fig. 4) and the target moved until its center coincides with the cross-wires of the level, and the reading on the rod taken. This gives the distance $A\,a$. The rod should now be held on the other point B, and the telescope turned upon its spindle and a reading taken with the rod in its new position. This gives the distance $B\,b$, and from the figure it is evident that the difference in level between A and B is equal to $A\,a - B\,b$.

The method just described applies only to cases where the difference in level is less than the height of the rod. Let Fig. 5 illustrate a case where the difference is greater than the height of the rod, as between A and D. First, divide the distance into sections of such length that the difference in level between the dividing points A, B, C, etc., called *stations*, shall be less than the height of the rod. Set up the level between A and B, and measure the distance $A\,a$, called the *backsight*; then reverse the telescope and measure distance $B\,b$, called the *foresight*. Next set up the level between B and C, and measure distances $B\,b'$ and $C\,c$. Repeat the operation with the instrument between C and D, measuring the distances $C\,c'$ and $D\,d$. Referring to Fig. 5, it is evident that the difference in level between stations A and D is equal to the sum of the differences between the intermediate stations, which is

$$(A\,a - B\,b) + (B\,b' - C\,c) + (C\,c' - D\,d),$$

or written in another form is

$$(A\,a + B\,b' + C\,c') - (B\,b + C\,c + D\,d).$$

This shows that the difference in level between two stations is equal to the difference between the sum of the backsights and the sum of the foresights. When the object is simply to determine the difference in level between two points, the above process is all that is necessary, and the only notes required are a record of the foresights and backsights.

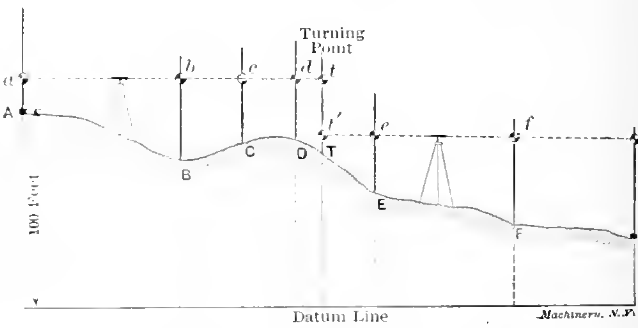

Fig. 6. Finding the Relative Elevations of Several Points.

When it is desired to find the relative elevations of several points, as in grading or trench work, it is necessary to keep more elaborate notes, and to measure the distances between the stations. The first step is to assume a datum line which shall be below the lowest point in the contour, and to refer all elevations to this line. It is also customary to start the line at some fixed mark which cannot be easily disturbed, such as the corner or top of a rock, the stump of a tree, a mark on a building wall, or the top of a hydrant, etc. This is called a bench-mark. In Fig. 6 let A be a bench-mark, and let us assume a datum line 100 feet below the level of the bench-mark A. The field notes corresponding to the operations shown in Fig. 6 are given in Fig. 7. Starting with the instrument between A and B, and taking a backsight on A, we find the distance $A\,a$ to be 4.2 feet, which added to 100 gives the height of the instrument. We next take foresights on B, C, and D, and record them in the proper column. It is evident from Fig. 6 that readings $B\,b$, $C\,c$, etc.,

Station.	Distance.	Backsight.	Height of Instrument.	Foresight.	Elevations.	Remarks.
A	0	4.2	104.2	......	100	Bench-mark, top of hydrant.
B	100	....	......	10 1	94.1	
C	60	......	......	7.3	96.9	
D	50	......	......	5.8	98.4	
T	......	4.1	99.1	9.2	95.1	Turning point.
E	70	6.8	.....	....	92.3	
F	110	......	......	9.5	89.6	
G	80	......	......	11.5	87.6	

Fig. 7. Field Notes corresponding to the Operations illustrated in Fig. 6.

subtracted from the height of the instrument will give the elevation at B, C, etc. This is done, and the results recorded in the proper column. The ground falls away so rapidly beyond D that it is necessary to set up the level further along and establish a new height of instrument. This is done by holding the rod at some convenient point as at T, called a *turning point*, and taking a foresight, which measures the

distance $T\,t$ (9.2). The level is then set up in its second position between E and F, and a backsight taken on the rod in the same position which gives the distance $T\,t'$ (4.1). Then the distance $t'\,t = 9.2 - 4.1 = 5.1$, and this subtracted from the previous height of instrument gives the new height which is $104.2 - 5.1 = 99.1$. A backsight is now taken on E, and foresights on F and G. These are recorded in the proper columns, and the elevations found by subtracting these distances from the new height of instrument.

The horizontal distances between the stations are measured with a tape as already described, and recorded in the second column. In plotting a cross-section from notes kept in this way, the datum line is first drawn, and perpendiculars erected at points corresponding to the different stations. The proper elevations are then indicated on these vertical lines, and a contour-line drawn through the points so marked.

The Transit.

The transit (see Fig. 8) is an instrument for measuring both horizontal and vertical angles, although for ordinary

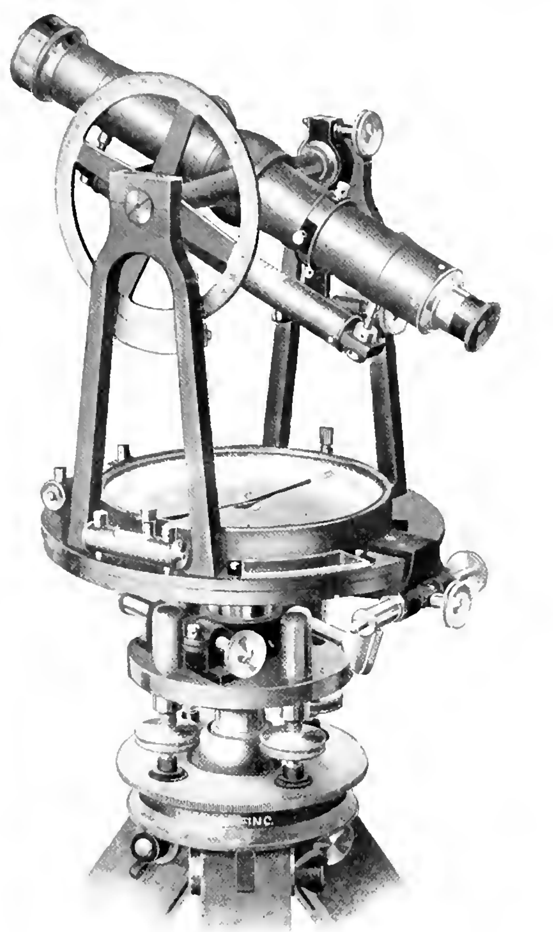

Fig. 8. Transit used for Measuring Horizontal and Vertical Angles.

work the vertical attachment is omitted. This instrument consists of a telescope mounted in standards which are attached to a horizontal plate called the *limb*. Inside of the limb, and concentric with it, is another plate called the *vernier-plate*. The lower plate or limb turns on a vertical spindle or axis which fits into a socket in the tripod head. By means of a clamp and tangent-screw, shown in the figure, it may be clamped fast in any position, and made to move slowly through a small arc. The circumference of this plate is usually graduated in divisions of either one-half or one-third of a degree, and in the common form of transit these divisions are numbered from some one point on the limb in both directions around to the opposite point which will be 180 degrees. The graduation is generally concealed beneath the plate above it except at the verniers. This upper plate is the vernier-plate, which turns on a spindle fitted into a socket in the lower plate. It is also provided with a clamp by means of which it can be held in any position, and with a tangent-screw by which it can be turned through a small arc.

A vernier is a device for reading smaller divisions on the scales than could otherwise be done. The method of reading a vernier is shown in Figs. 9 and 10. The lower scale represents a portion of the graduations upon the limb, and the upper scale, the graduations of the vernier. In Fig. 9 the vernier is set at zero, and in Fig. 10 the vernier-plate has been revolved through a certain angle which we wish to read. Looking at the pointer at the extreme right of the

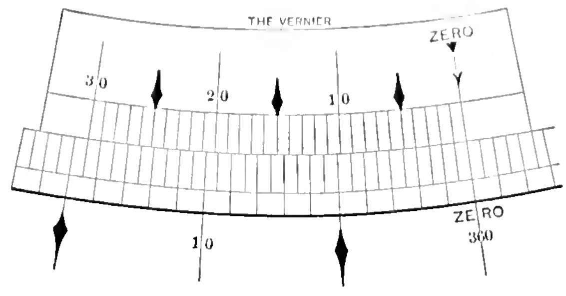

Fig. 9. The Vernier set at the Zero Mark.

vernier, we see that it stands between 20 and 20½ degrees on the lower scale. We next follow along the vernier until we find a division which is exactly in line with one on the lower scale; this we find to be 10 on the vernier, therefore, the reading is 20 degrees and 10 minutes. A vernier reading to minutes is sufficiently accurate for ordinary work.

The transit shown in Fig. 8 is provided with a compass so that the bearing of any given line with the magnetic meridian may be determined if desired. It also has a spirit level attached to the telescope so that it may be brought to a horizontal position and made to serve as a level. Fig. 11 shows an instrument known as the *architect's level*. This is a level with a short telescope, and is provided with a graduated circle and vernier for measuring horizontal angles. It is a very useful instrument for simple work, such as laying out buildings, etc., where great accuracy is not required. The transit requires various adjustments, a description of which may be had from the makers.

To center the transit over a stake, rest one leg of the tripod upon the ground, then grasp the other legs and place the instrument as nearly over the stake as possible. Then attach the plumb bob and center it accurately by means of the shifting head. Avoid having the plates too much out of level, as this will result in unnecessary straining of the leveling screws and plates. Having centered the instrument over the stake, level it up by the spirit levels upon the horizontal plate. To do this, turn the instrument upon its vertical axis until the bubble tubes are parallel to a pair of diagonally opposite plate-screws. Then, as you stand facing the instrument, grasp the screws between the thumb and forefinger, and turn the thumb of the left hand in the direction the

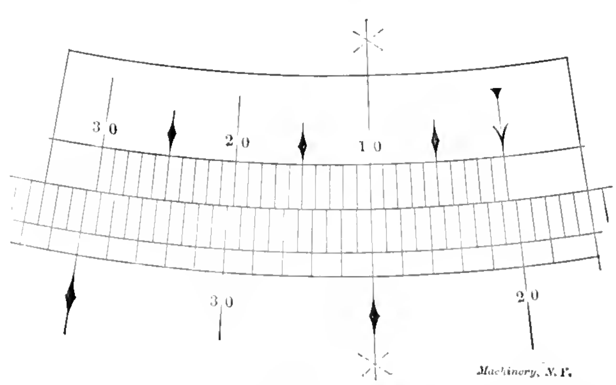

Fig. 10. The Vernier set 20 Degrees and 10 Minutes from the Zero Mark.

bubble must move. When adjusting the screws, turn both thumbs in or out, never in the same direction. Adjusting one level will disturb the other, but each must be adjusted alternately until both bubbles remain constant.

To measure an angle as between the lines $A\,B$ and $A\,C$ (Fig. 12), set up and level the instrument at A as already described, and clamp one of the verniers at the zero mark on the circle. Turn the telescope upon the target at B, and clamp the limb.

Unclamp the vernier-plate, and turn the telescope upon the other target at C. Read the vernier which had been set at zero, and the reading will be the horizontal angle through which the telescope turned from B to C. It is not necessary to set the vernier at zero before pointing at the first target The result will be the same if the vernier is read when pointed at the first target, and then again, when pointed at the second. The difference between the two readings will be the angle required. Care must be taken in this method to note if the vernier passes the 180 degree mark, and if so, to make the proper calculations. For simple work where there are but few angles to be measured, it is less confusing to set the vernier at zero each time, especially for those not experienced in the work.

The process of laying off a given angle is similar to that of measuring an angle. The transit is set up at the vertex

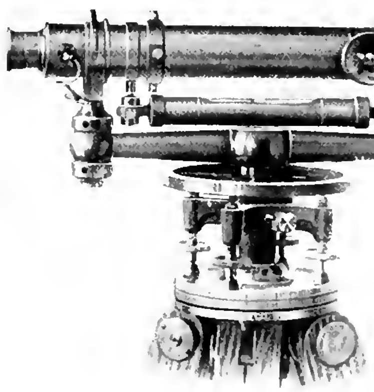

Fig. 11. Architects' Level.

of the angle, the vernier clamped at zero, and the telescope pointed at the target marking the direction of the fixed line. The limb is now clamped, the vernier unclamped, and the vernier-plate turned through the desired angle and clamped. A stake should now be driven in line with the vertical wire in the telescope, thus establishing the two sides of the angle.

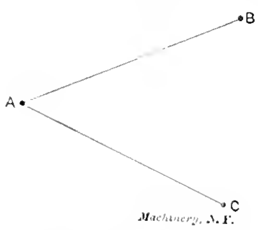

Fig. 12. Measuring a Horizontal Angle.

In laying out the foundations of buildings, a corner stake is first located by measurement, then the direction of one of the walls is laid out by driving a second stake. This direction may be determined by local conditions, such as the shape of the lot, or the relation to other buildings. If the building is to be an extension to, or in line with another building, the direction can be obtained by sighting along the building wall and driving two stakes in line with it. If it is to make a given angle with another building, this angle can be laid off as shown in Fig. 13. After the corner and the direction of one wall are determined, a right angle may be laid off (if the building is rectangular), thus locating two of the sides,

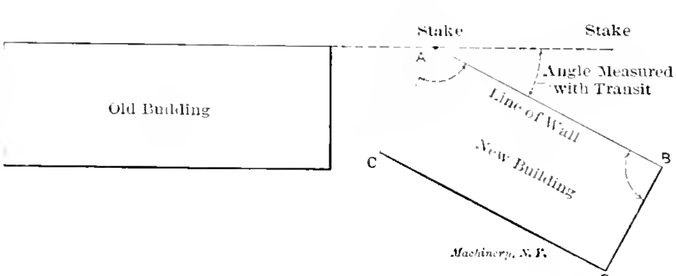

Fig. 13. Laying Out One Building at a Given Angle with Another.

as A B and A C. The length of the side A B is now measured, locating the corner B. The transit is now set up at B, and the line B D laid off at right angles to A B. A C and B D are then laid off the proper length, and thus the four corners of the building located. If the building had not been rectangular, the proper angles could have been laid off instead of right angles.

It is often desirable to make a block plan or map of the grounds and buildings of a plant. In Fig. 14 is shown the general method of plotting an irregular street or road, and of locating buildings with reference to it. First, locate a series of stations along the center of the street as A, B, C, etc. Then set the transit up at B and measure the angle A B C. Also measure the angle A B N by means of the compass which

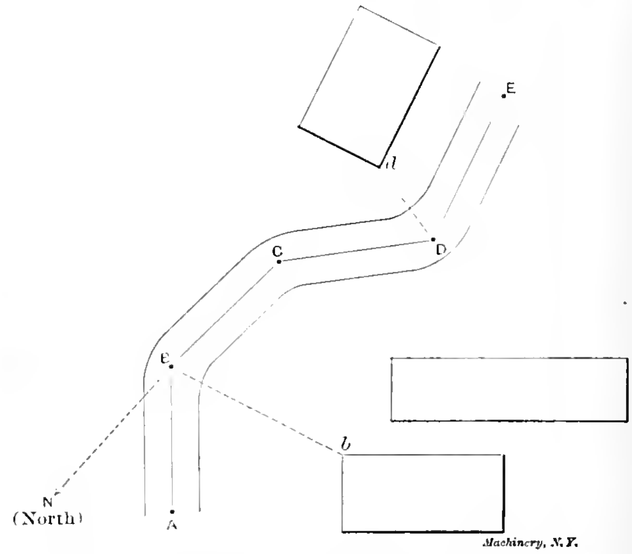

Fig. 14. Method of Plotting an Irregular Street or Road, and obtaining the Relative Positions of Adjacent Buildings.

is usually furnished with a transit, thus establishing the bearing of the line A B with the points of the compass. While the transit is at B the angle A B b should be measured, which, with the distance B b will locate the corner of the building. The direction of the building wall can be determined by continuing the direction of one of its sides, and measuring the angle between it and the magnetic needle of the compass. The instrument may now be set up at C and the angle B C D measured; also set up at D and the angle C D d measured, which locates the corner of the second building. Angle C D E is then measured in a like manner. All distances between stations should be measured by means of a tape.

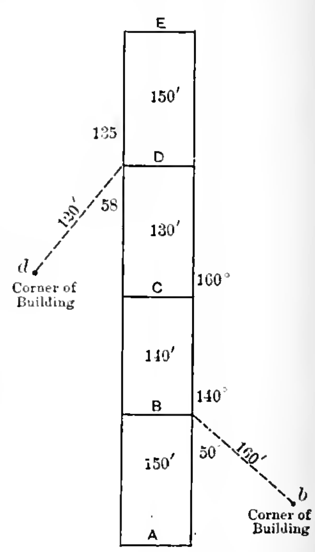

Fig. 15. Method of Keeping Notes for the Survey illustrated in Fig. 14.

The method of keeping the notes for the above survey may be as shown in Fig. 15. The different stations are represented by A, B, C, etc., and the distances between them are noted between the vertical lines, as 150′ 140′, etc. With each change in direction, the angle made by the preceding line is noted outside of the vertical column, and on the side which the line turns. For example, B C makes an angle of 140 degrees with A B, and turns toward the right; E D makes an angle of 135 degrees with C D, and turns toward the left. The line locating the corner of building at b, is measured from station B, and makes an angle of 50 degrees with A B. In plotting a map from the notes, the distances are measured off to a suitable scale, and the angles laid out by means of a protractor.

* * *

It is not too broad a statement to make, that it is of the utmost importance that every young engineer should from the start develop for his own use a system of record keeping of the information which he may use in his professional work and of the facts connected with the design, construction, maintenance, and operation of the plants, machinery, etc., with which he is connected.—*H. M. Brinckerhoff, in Stevens Institute Indicator.*

ON THE STATE OF THE PATENT OFFICE.

H. ADDISON JOHNSTON.*

If a prospector discovers gold-bearing rock on unclaimed land in the United States, he can, by doing certain things prescribed by law, secure to himself, his heirs and assigns, *forever*, the exclusive right to mine the gold that he has discovered. What he has discovered is *his* property.

If an inventor discovers (or invents) a new and useful combination of elements, in unclaimed ground in the United States, he can, by doing certain things prescribed by law, and *paying a considerable sum of money*, secure to himself, his heirs and assigns, *for seventeen years only*, the exclusive right to manufacture the invention that he has made. What he has discovered (or invented) is *his property*, but the government makes this bargain: "If the inventor will fully describe and make known his invention, and give it to the public after seventeen years, then the government will provide punishment for anyone who tries to steal the invention during the seventeen years, provided, however, that the inventor must himself catch the thief and prove his guilt.

What would be the result if the government passed a law that all the gold mines, the homesteads, and the coal fields were to be thrown open to the general public after seventeen years? Yet this is what happens to patented inventions.

Now, I do not wish to be understood as advocating an extension of the life of a patent; the point I wish to make is this: A man's invention is as truly his own property as is his house, or clothes, or farm; no one else has any right to it. Hence, in justice, there should be no attempt made to collect heavy fees from the inventor for the purpose of paying the expenses of the patent office. The country is benefited many times the cost of the patent by the mere fact of the invention being made and, in any case, if the government takes away his invention at the end of seventeen years, it has then much more than obtained value for any expense to which it may have been put in issuing the patent.

The present United States patent office stands in greater need of reorganization than any other institution with which I have had the misfortune to do business. It is safe to say that were any commercial firm to conduct its business with no greater regard for the satisfaction of its customers than the patent office shows in its treatment of applicants, it would close its doors in less than six months. A general criticism is productive of nothing but hard feelings, hence I proceed to details.

1. The whole story of the obtaining of a patent is delay, delay, delay. When an application is sent in it is delayed from a few weeks to several months before it is acted upon. When it is amended, another delay, and amendments and delays follow each other indefinitely. If the delays were eliminated many of the other sources of dissatisfaction could be borne with.

2. When an examiner makes citations against a case, instead of searching thoroughly and bringing out all the references to be had, either through lack of time, incompetence, or what not, he cites only two or three references. When the patent claims are amended so that the references are avoided, and the inventor expects the patent to be allowed on the next actions, instead, after a long delay, he gets two or three more references. This process may be repeated several times.

3. References are cited against applications which have no bearing on the case; when these references are shown to be irrelevant, they are dropped and new citations made which may have no more bearing on the case than the old ones. After each action there is a long delay. No other cause can be shown for this state of affairs than incompetence in the examiner. An examiner should be so familiar with the work of his class that it would be impossible for him to mistake the bearing of other inventions on the one in hand.

4. There is apparently no special examination made as to the ground covered by an application when it is first received. It is a most aggravating experience, after waiting several months for action on a case which has been amended several times to suit the office, and for which notice of allowance is expected, to receive an official communication asking for division of the application, and to find that nothing whatever has been done as to the merits of the case. This may cost the inventor six months of valuable time, and the worst feature of the case is that there is absolutely no reason for any lost time at all. Action as to the merits of the case need not be suspended just because division is required.

* Address: 118 Clinton St., Toronto, Canada.

5. Misleading information is published in the *Patent Office Gazette*. For instance, it may be stated in the *Gazette* that on February 1 in a certain class the oldest amended application awaiting action bears filing date of August 1 of the year previous. The applicant may have sent his amended application to the office many weeks before August 1 yet no action has been taken on his case. I have been unable to explain this discrepancy and it is exceedingly unfortunate that it should exist.

6. Copies of patents are allowed to run out. Surely it would be as easy to replenish the stock of copies just before the supply is exhausted as it is a month after.

It is not generally realized how much the present condition of the patent office operates to favor the large industrial corporations at the expense of independent inventors. A company that is already established and has its product on the market is continually taking out patents on improvements in its methods and manufactures. The longer such patents are delayed in issuing the better pleased is the company, for its mark "Pat. applied for," gives plenty of protection at first, and the effective life of the patent is lengthened by the time taken to have it issued. Patents have been purposely delayed in issuing for years for this very reason.

On the other hand the independent inventor needs his patent just as soon as he can get it. In 99 per cent of the cases he must obtain outside capital to develop his invention, and his only resource for so doing is his patent. When the patent is delayed, the inventor either has to stop work for lack of cash or is driven into hard bargains to obtain money to live.

Although justice demands that patents should be issued promptly, and to all alike, yet it has often seemed that a much more satisfactory method than the "general delay" practice now in use would be to give prompt action to those who requested prompt action, and delayed action to those who wanted delay or were indifferent. [We would emphatically object to delayed action in any case, because of the abuses fostered by delays.—EDITOR.]

After criticism of existing conditions, suggestions for betterment are in order, and I would suggest:

1. That the commissioner of patents be authorized to secure *sufficient* assistance in the patent office so that no application will be awaiting action more than ten days in any class.

2. That examiners be instructed to cite as nearly as possible all references upon the first action. The practice of continually bringing forward new references should be strongly condemned, and any examiner who constantly follows this practice should be deemed incompetent. In certain cases new references will naturally be found, but as a general principle the foregoing should apply.

3. That it should be deemed evidence of incompetence on the part of an examiner to cite references which have no bearing upon the case in point. The continual dropping of references upon explanation of the inventor and the citing of new ones is entirely unnecessary, and could be avoided by care on the part of the examiner.

4. That an examination as to correctness of form and ground covered by an application should be made immediately upon receipt of the application. If an examiner calls for the division of an application after one or two actions on the merits of the case, he should be made to pay the additional fees himself.

5. That the commissioner of patents be instructed to see that no further misleading information with regard to the amount of time the office is behind its work, is published in the *Gazette*. There is no reason why correct information cannot be given.

6. That a clerk be appointed to see that the stock of printed copies of patents is not allowed to run out. It is just as easy to start printing when there are 5 or 10 copies left, as to wait until some one has ordered a copy after the stock is exhausted.

7. That all the claims of a patent be printed in the *Gazette*. The recent decision to print only five claims of a patent in the *Gazette* seems to be extremely unwise. The value of the *Gazette* as a book of reference lies in its completeness. Printing the *Gazette* with claims missing all through it, would be on a par with publishing a novel with pages left out here and there. If it costs too much to sell it at its present price, raise the price, but publish all the claims.

8. That, if possible, a department of search be instituted at the patent office to make search of the records for intending patentees, at cost.

9. That the commissioner of patents be made a "general manager" with full authority to spend whatever money may

be necessary to get results, and that he be instructed to get results no matter at what cost. Would any man with common sense place an employe in charge of a business with these orders: "All business must be taken care of, no matter what the increase;" "The staff must not be increased nor any money spent except on postage, express and paper;" "Take in all the money offered; if the customers complain of delays, tell them it costs us nothing to wait"?

I have before me copies of Mr. Pratt's bills, H. R. 6173 and 6228 *re* patent office, one to increase the staff and salaries of examiners at the patent office, the other to increase the fees. I am certainly in favor of increasing the staff, and the efficiency of the staff, of the patent office, and, if it is necessary to increase the salaries to get competent men, by all means do so, but get them.

In regard to fees, as I look at the matter the fees should be kept at a merely nominal figure, say $25, or at just sufficient to keep down the number of applications for patents on inventions of little or no value. If the government absolutely refuses to consider the matter in this light and insists upon the office being self-supporting, then the funds should be obtained, not by raising the initial fee, but by requiring increasing license fees to be paid as the years pass. Let them be, say $25 for the third year, $50 for the fourth, $75 for the fifth, and $100 for the sixth, and succeeding years.

The independent inventor is an asset to the country and should be encouraged. Generally he finds money very hard to get at first. If his invention is worth anything by the time the third year is reached he will be able to pay the fees, if not, he can allow the patent to lapse without further loss to himself. The country does not lose anything in any case.

Since writing the above, the last report of the commissioner of patents has reached me, and in it some very interesting information may be found. I quote from it:

Over 56,000 patents applied for last year.

Total surplus to credit of patent office, January 1, 1908, $6,706,181.64.

Surplus last year, $275,000.

After stating that the force of examiners is not sufficient, and that more room is needed, and that part of the building now occupied is not suited for the work, he states:

"Examiners frequently work overtime to try to catch up with their work *in order that a good showing might be made before Congress met.* Their efforts under these conditions were at best spasmodic, and simply resulted in thousands of actions being made that were nothing more than frivolous. After one of these annual efforts it was necessary to do a greater portion of the work all over again, and it really had the effect of throwing the business of examination further back than ever. This resulted not only in vexatious delays to the inventors, but it caused hundreds of complaints to be filed, and what was still more embarrassing and serious, a great many applications were passed to issue that were not ready for patent, with the result that the inventors and owners of meritorious inventions forfeited valuable rights by these careless, ill-considered and hasty actions on the part of the office.

"The inventors are entitled to be protected as well as the public, and they should be helped by the office in all legitimate ways.

"The inventors pay the government for the work done in the examination and issue of their patents.

"Complaints against the conduct of affairs have been numerous and many have been based upon good and sufficient grounds. The affairs of the office should be so conducted that very few if any complaints could be lodged.

"I am most decidedly of the opinion that the present force cannot cope with it (the increased business of the patent office), and I have asked for a sufficient number of examiners and clerks to bring the arrearages up to date and to dispose of the great amount of increasing work material.

"If the force asked for is granted and made immediately available, I believe that the accumulated work can be disposed of, and that it will be possible in the future for the average inventor's application to be acted upon and either rejected or a patent allowed within thirty days of its receipt.

"The inventors are entitled to prompt action and they should be accorded it.

"The incompetency of a portion of the clerks in the examining and other divisions is in a measure responsible for the backward condition of the work."

The commissioner states that as soon as a man is well broken in to his work, he is offered more than the office is allowed to pay, to go to outside work. This is a fine (?) way to supply good patent attorneys for large corporations. The inventors pay for their education, and when they are worth something they move out. In the name of common sense, let the patent business be conducted in a businesslike way, which manifestly is not the present practice.

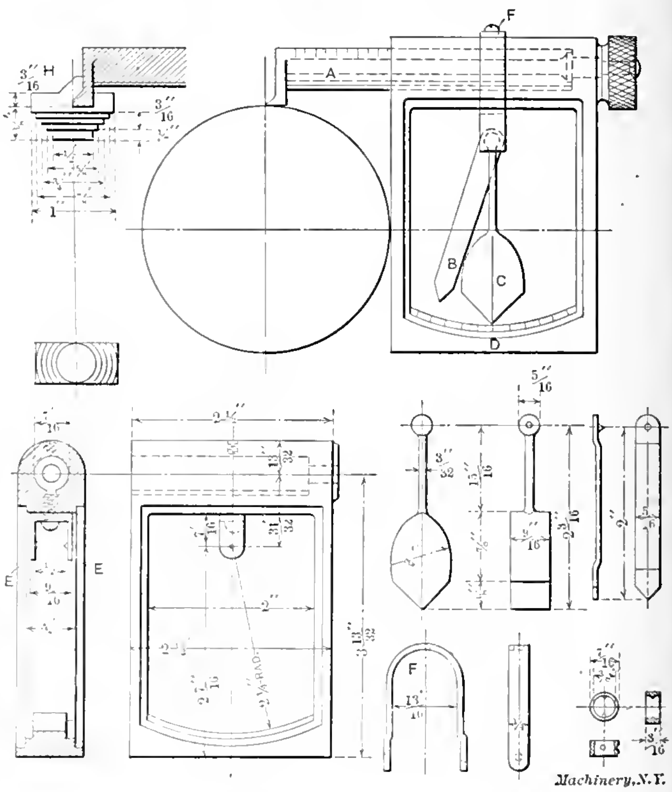
If proof is required as to the truth of my statements the report of the commissioner gives quite sufficient confirmation. The question is: "What are we going to do about it?"

* * *

DEVICE FOR LAYING OUT AND TESTING KEYWAYS.

W. O. RENKIN.

The accompanying cut shows a device which can be used either for checking the location of keyways already cut, or for locating the center line for keyways on shafts. Its particular usefulness comes into evidence when it is wanted to check the location of keyways at different parts of long shafts, the procedure of which is as follows: First, have the shaft lying free, but not necessarily level, and then place the side of the device against the shaft and the point of the bar *A* in the keyway, and set the indicator *B* directly over the center line of the plummet *C*. When the device then is moved to



Device for Laying Out and Testing Keyways.

different parts of the shaft, if the keyway is placed exactly in the center at each point, the plummet end and the indicator retain their relative positions. When it is wanted to locate the center line on shafts for cutting keyways, the bar *A* is screwed out until the point is located exactly one-half the diameter of the shaft from the side of the device, and then, with the shaft lying on a planer table or bed plate, adjust the device further until the plummet hangs directly over the center mark at *D*, after which the center of the shaft may be marked and the device moved to another point. As will be noticed from the detailed drawings shown, the body of the device has a recess on each side at *E*. This recess is intended for holding a thick piece of glass enclosing the plummet on the sides. The indicators are placed one on each side of the device, resting against the glass and held up to it by the saddle *F*. This permits the device to be used from either side. At *H* are shown different size "feet" for the center bar *A*. The writer believes that this is the only tool so far designed which can be readily used for this work without necessitating that the shaft be first levelled up.

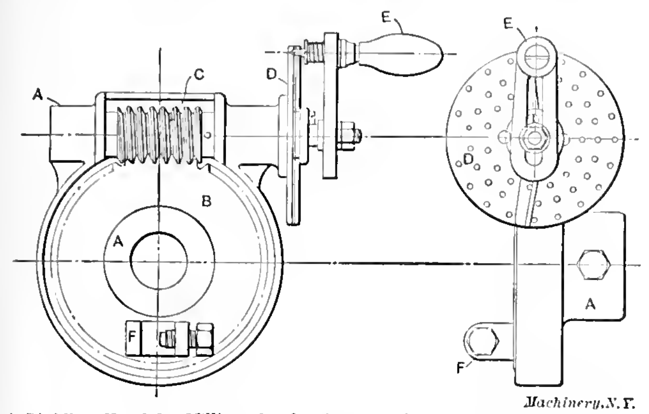
* * *

It is stated by the *Practical Engineer* that out of 824,000 tons of manganese used in this country, Great Britain, and Germany, during 1905, over 90 per cent was used for alloy steels.

ITEMS OF MECHANICAL INTEREST.

DIVIDING HEAD FOR USE WITH THE LATHE.

Occasionally it is necessary to do on the lathe a piece of work that requires dividing. If there is no milling machine in the shop, the lathe is sometimes rigged with a milling spindle on a knee attached to the carriage, for operating on work between centers. If a gear, for instance, is to be cut in this way, the question of indexing is often somewhat puzzling. If the number of teeth desired is a factor of the number of teeth in the main spindle driving gear, this may be used for indexing. If not, other more cumbersome methods have to be devised. The apparatus shown in the accompanying engraving is intended to give the lathe for such work, nearly as great facility as is offered by the milling machine



A Dividing Head for Milling, Graduating, etc., between the Lathe Centers; it is mounted on the Tail-stock Spindle.

with its dividing head. This device, which is patented, was illustrated in a recent issue of *Machines Outils et Outillage*, of Paris.

The main casting *A*, of the attachment is fastened, by the set-screw shown, to the tail-stock spindle. On the front side it is provided with a projecting hub which forms a journal for dividing worm-wheel *B*. The main casting encloses this wheel in a guard, and on its upper side is provided with bearings to support the shaft on which the worm *C* is mounted. The worm shaft is controlled by the adjustable crank *E*, having a pin entering holes in index plate *D*, substantially as arranged for the milling machine dividing head. The usual adjustable sectors are provided. The work, which is supposed to be mounted on centers, is driven by a dog whose tail is engaged in clamp *F*, bolted to the face of the index wheel *B*. It will readily be seen that any desired spacing can be given to the work thus mounted, by operating the index handle in the same way as in the milling machine.

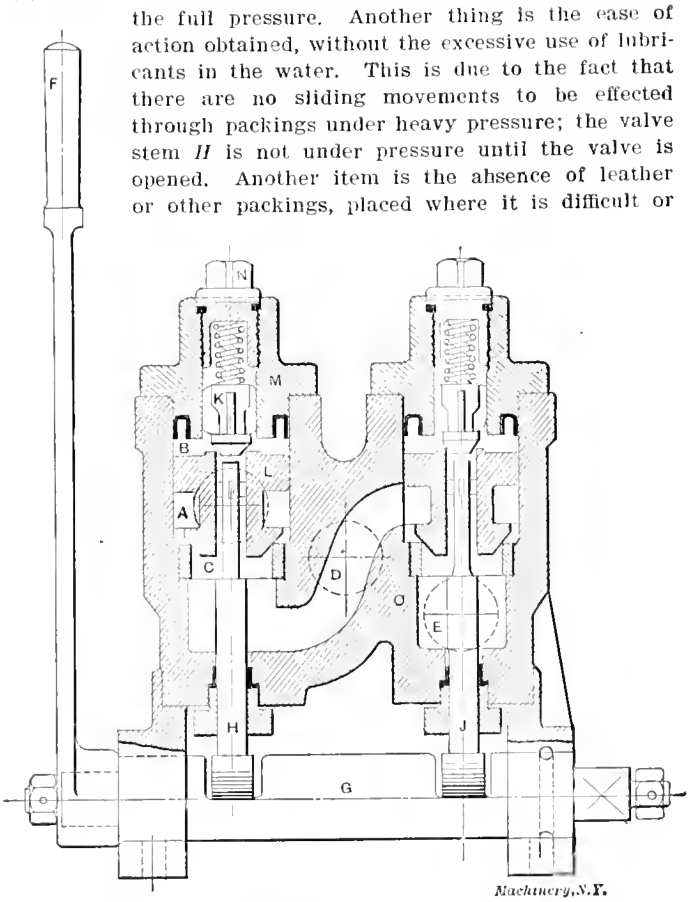
HYDRAULIC VALVE OF ENGLISH DESIGN.

A catalogue recently received from an English firm, Dewhurst's Engineering Co., Ltd., of Sheffield, describes a design of hydraulic valve for high pressures and large volumes that is ingenious enough to warrant some attention. A cross section of the valve is shown in the accompanying line engraving. In the case shown, there are two valves with an inlet at *A*, a connection at *D* for the hydraulic cylinder to be operated, and an outlet at *E*. These valves are operated by handle *F*, connected to rock-shaft *G*. Throwing *F* in one direction opens the inlet valve at *A*; throwing it in the other allows the water to escape from *D* through outlet at *E*.

The valve stems *H* are raised by cam surfaces cut in the upper side of rock-shaft *G*. The stems do not directly open the main valves; the upper end of a stem passes through main valve *L* in a hole large enough to allow it plenty of clearance, as shown, and when raised, it strikes against the bottom of pilot valve *K*, which it lifts against the pressure of the spring above it and against the pressure of the water in chamber *B*. Chamber *B* is filled with water leaking from inlet space *A*, past the easy fit of the piston portion of valve *L* between them. As soon as *K* is raised, the pressure in *B* rapidly drops to that in service connection *D*, since the outlet through the center of the main valve is much larger than the area through which the leakage escapes from *A*. Under these circumstances there is an unbalanced pressure on valve *L* from the water in *A*, which forces it from its seat on ring *C*. This unbalanced pressure is obviously due to the fact that the piston portion of main valve *L* is much larger in diameter than the seat on which it rests in ring *C*.

In closing, the reverse of this action takes place. Handle *F* being brought back to its central position, valve stem *H*, and with it pilot valve *K*, are lowered until the latter reaches its seat in valve *L*. Connection between *B* and *D* being thus closed, the leakage from *A* into *B* allows the pressure in the latter space to rise until it balances that in *A* when the coil spring has sufficient pressure to force valve *L* down against its seat. The two valves are identical in construction and operation.

This construction evidently has a number of advantages. The use of the small pilot valve, the only member which has to be lifted against the full pressure of the water, makes the apparatus more easy to handle than would be the case if the whole main valve *L* had to be raised from its seat against the full pressure. Another thing is the ease of action obtained, without the excessive use of lubricants in the water. This is due to the fact that there are no sliding movements to be effected through packings under heavy pressure; the valve stem *H* is not under pressure until the valve is opened. Another item is the absence of leather or other packings, placed where it is difficult or



A Hydraulic Valve which is controlled by the Operation of a Small Pilot Valve.

impossible to detect leakage past them. Packing is provided for plug *N*, cap *M* and valve rod *H*. All of these, it will be seen, pack against the atmosphere. It will also be noted that both the main and pilot valves can be easily reground without breaking any of the hydraulic joints. There would appear, also, to be little danger of shock from sudden closing of the valves, since the lowering of main valve *L* to its seat on *C* is effected by the leakage from *A* to *B*, which can be made as gradual as seems advisable, being regulated by the fit of *L* in its cylindrical chamber in main casting *O*.

* * *

Once in a while we find the idea cropping up of using an impeller instead of a propeller for driving a ship. In other words, the jet propulsion idea is one that inventors seem to still worry about. The jet or hydraulic propulsion has, however, been tried a great many times with very little success. The trouble seems to be the low efficiency of the pump or impeller, the combined propulsive efficiency of which is far below that of the screw propeller. The constant failures of many inventions seem to indicate that jet propulsion, like rotary steam engines, belongs to a class that are more interesting to the ingenious inventor than useful to the practical shipbuilding engineer.

DESIGN—CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

49-55 LAFAYETTE STREET, CORNER OF LEONARD, NEW YORK CITY.

Alexander Luchars, President and Treasurer.
Matthew J. O'Neill, Secretary.

Fred E. Rogers, Editor.
Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Associate Editors.

The receipt of a subscription is acknowledged by sending the current issue. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

MARCH, 1908.

PAID CIRCULATION FOR FEBRUARY, 1908, 22,714 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

THE RECOGNITION OF ABILITY.

From an interview with President Nash of the Corn Exchange Bank of New York, published in a recent Sunday issue of the *New York Times*, we quote the following:

"Too many of our young men seem to lack distinction, originality of thought—I might say initiative. In a word, they do not think for themselves, and make suggestions. I know how it is here in the bank. We have a number of young men who are capable, intelligent fellows. They do their work in a satisfactory way. Yet they do not come forward with new ideas. That is the thing a modern business man is always seeking in an employe. I know we are always glad to get them. We may not follow the suggestions, still the ideas are welcome."

We do not wish to put ourselves in the position of criticising Mr. Nash, who is a man of great ability and strong character; but it is not going too far to say that the sentiments he expresses, though superficially true, are radically false, as thousands of men of suppressed ability can testify. One would think from the banker's language that men in authority are always eagerly sensitive to the slightest sign of originality in the ranks of their subordinates. In reality this is so only in exceptional cases. In the first place, the commanding officer is often temperamentally unfitted to recognize ability in a subordinate. It is one of the rarest qualities of genius to be able to do this, and instead of seeking new assistants, most captains of industry have to be content with using, to the limit of their capacity, the men whom chance and natural aptitude combined, have brought to responsible secondary positions. Besides this, even though the leader may have this power of recognizing genius, there must necessarily be so great a gulf fixed between him and the private that it is only by some stroke of good fortune that the latter ever comes in contact with his superior at all. Even though he may persistently seek that contact, he has still to pass the high and wide barrier of arrogance and petty jealousy erected by secondary officials.

There is most certainly a fortuitous element in success. There are many men of the class of our banker, but without his unusual ability and character, who have been carried into power and place by the swelling tide of our national development, nothing more having been required of them than the ordinary common sense and application daily exhibited by tens of thousands of their less fortunate brothers. Where, for instance, are the life insurance presidents of yesterday, whose great ability (we were told) was the cause and justification of the enormous salaries they received? After the storm which swept these men from their lofty positions, down to the level where men compete with one another on the hard, cold terms under which such competition rages in our times, these men were never heard of more. Their places are acceptably filled by other men with smaller salaries, and who doubts but that there are scores yet left who could replace the present incumbents if they should step from their positions?

This fortuitous element in success is one of the most discouraging things the young man has to face. In "Captain Stormfield's Visit to Heaven" Mark Twain causes the narrator to discover that the other world is a place where men are rewarded according to their real ability, and not according to their earthly reputations. He found, for instance, that the greatest general in Heaven, to whom Napoleon, Cæsar, and Alexander bow in humble reverence, was an East Boston cobbler who lived during the Revolutionary War. He had in him a military genius the like of which the world has never seen. He tried again and again to enlist as a private, but was refused each time, owing to the fact that he had lost his trigger finger. Most young men are not content to wait for Heaven to have their abilities recognized, and they would chant an earthly hymn of praise to the wise counselor who would give definite, positive, practical information on the question of the successful marketing of ability. Let us have something of this kind, in place of the conventional lament over the lack of originality and initiative in the decadent generation to which we belong.

* * *

THE WIVES OF OUR READERS.

It may seem a trifle inquisitive, but we must admit that we are vitally—because pecuniarily—interested in the wives of our subscribers. As nearly as we can figure it out, a large proportion of the readers of MACHINERY are young men. Along about twenty-two years of age or thereabouts the normal young man is beginning to think quite seriously of the possibility of supporting a wife in the style to which she has been accustomed. He has perhaps had difficulty supporting himself on the salary he has been receiving, and the prospect seems almost hopeless for two. A condition of this sort is a powerful spur to ambition, and MACHINERY and other technical papers, as well as scientific text-books and the correspondence courses, all play their part in assisting the desperate youth to a better livelihood.

In too many cases the effort is a spasmodic one, never repeated; and this is often the fault of the wife. There are exceptional men, of strong enough personality to sink or swim independent of the influence of the other half of the family; but made up as most of us are, the need for courage and ambition in the wife is a vital one. As the man gets along toward middle age and loses the exhilaration of high animal spirits, the possibility of progress seems to be dependent on efforts which become more and more difficult. Take the simple matter of subscribing to MACHINERY, for instance. With a house full of children to feed and clothe, there seems to be a need for every available dollar that can be brought into the family, and the few luxuries have to be carefully planned for. Under such circumstances we can imagine the wife saying "Why do you keep spending money for that old MACHINERY? Why don't you get something we can both enjoy?" And thus MACHINERY and the machinist alike are foully dealt with.

There is a moral to this, which we leave those of our readers who are contemplating matrimony to discover.

* * *

The man who is worthy of being a leader of men will never complain of the stupidity of his helpers, of the ingratitude of mankind nor of the inappreciation of the public. These things are all a part of the great game of life, and to meet them and not go down before them in discouragement and defeat is the final proof of power.—*Elbert Hubbard.*

HIGH-SPEED STEEL FOR MILLING CUTTERS.

A great many opinions have been expressed in the technical press regarding the value of high-speed steels for milling cutters. An article by Mr. Robert Grimshaw appeared in February, 1907, MACHINERY, in which were given the opinions of several German firms, all of whom pointed out that high-speed steel was not very efficient for milling cutters, because the cutting speed cannot be increased in the same proportion as on lathe tools. The difference in the results of milling and turning is accounted for by the fact that high-speed steel must be heated to a certain degree by the cutting operation in order to most effectively perform its work; and continuous heating of the milling cutter teeth is impossible, because they are in contact with the work for only a part of each revolution, and are cooled off in the air during the interval.

While this reasoning is undoubtedly correct, we understand that both here and in England a number of the leading manufacturers, who are users of milling cutters, find that although the cutting speed can be only slightly increased, so that the saving in time does not in itself outweigh the increased expense of material for cutters of high-speed steel, such cutters retain their cutting edges much longer than those made of ordinary tool steel; and this fact, when considering the question of economy, is nearly as important as that of high cutting speed.

In large shops, where several hundred milling cutters are in constant use, their grinding is a very important item in the expense account, and as high-speed steel cutters have to be ground less frequently, that is a distinct saving. The labor cost in the making of milling cutters is considerable, in many cases so great that the cost of material is small in comparison; and the greater the labor cost the more important it is to use material which adds to the cutter's life. The greater cost of high-speed steel becomes a heavy item in tools where the labor cost of making the tool is comparatively small; but in the case of a formed milling cutter, where the labor cost is large, the difference in the total cost between ordinary carbon steel and high-speed steel becomes insignificant.

* * *

THE GROWING RESPONSIBILITY OF WORKMEN.

Those who read the editorial on "The Growing Inefficiency of Workmen" in the December MACHINERY, will understand that we are not satisfied with the attitude of labor, particularly in the larger centers of population. We wish it were possible to find words to set forth the responsibilities and possibilities which are presented to the men in this country who make their living by the work of their hands. One often gets the impression, after listening to speeches in meetings of manufacturers' associations, industrial educational societies, etc., that it is the duty of the employer and educator to lead the American workman in the way he must go, if certain "national perils" are to be avoided.

Despite the folly often displayed by individual and organized labor, we believe that the paternal position thus taken by its "superiors" is fundamentally and absolutely false. We believe that from the workingman is coming in the present, and is to come in the future, the enthusiasm and intelligence which are to solve some of the difficulties which now seem so thickly to beset our path. He may listen to the employer and the educator, but he must think and decide for himself. Clear and honest thought devoted to the problems with which he has to deal, will convince the workman that the attitude taken by many of his fellows is wrong. As a beginning, how would it do to meditate on the matter of the truth or falsity of the following propositions:

Inefficiency and loafing—in other words, restriction of output—will not help the workman as an individual or as a class; the whole effect is injurious.

Improved machinery and processes work no harm to labor as a class, though they may temporarily injure individuals. Labor has profited from their producing power in the past, and should profit therefrom even more in the future.

These propositions touch but one side of the problem, and the employers' side at that—to judge from surface appearances. But they do not trespass on debatable ground, questionable as they may appear. A clear understanding of them is essential to an intelligent search for the still unknown, or at least unapplied, solution of the problem of the proper distribution of wealth.

* * *

FINE FINISH ON MACHINERY.

There is a growing tendency to leave off all ornamental finish on manufactured machinery. The reaction from the absurd practices of two generations ago seems to gain momentum, and perhaps it is time to call a halt before it goes too far. To illustrate, take past and present locomotive practice. In the '50's and '60's many passenger locomotives were marvels of polished brass, walnut cabinet work, bright paint and fancy striping. It gradually dawned upon railway men that though high finish meant no greater tractive power or higher speed, it did mean higher first cost and continued expense to keep it in good order, and then came the change to the other extreme. But, while the change to the present style of severely plain finish has the merit of lessened first cost and economy of up-keep, it is not without certain disadvantages. Human nature is unchanging in its love for the bright and shining; it is a trait common to all. We admire the beautiful, and the beautiful attracts and holds attention when the plain receives scant respect. The romance of the locomotive has largely departed with the coming of the severely plain styles, and with it has gone the love of the engineer for his engine. The practical is not everything, and it is quite possible that the large economy supposed to result from plain finish is more imaginary than real.

On machine tools considerable ornamental effect is possible in the finish of working surfaces. Most machine builders believe that all flat working surfaces, such as cross-rails, planer uprights, V-ways, etc., should be carefully planed, and afterwards scraped with hand tools, to surface-plates, leaving the surfaces ornamented in approved fancy designs. Now the iconoclasts argue that all this hand work is waste effort. They aver that hand scraping does not improve the accuracy of the flat surfaces but that it rather has the contrary effect, and they would have all flat working surfaces left in the condition produced by the planer. We are not prepared to accept the proposed reform yet, and there are many others of like mind.

In the first place, we believe that intelligent and careful scraping does improve the accuracy of most planed work. It doubtless is possible to produce planed surfaces that cannot be improved in accuracy by scraping, but that is not the general condition of planer work "by a long shot." In the second place, scraping changes the nature of the surface and materially improves its wearing quality. Scraping both smooths and condenses the surfaces, and a scraped surface is not so likely to scratch and cut as an unscraped surface. The unscraped surface has a "fur" of minute iron particles detached, but still clinging to the solid iron underneath. The scraper cleans this dust off, leaving a clean, hard surface ready for immediate use. In the third place, the effect of the beautiful finish on the buyer and user should be considered. We would not do away with all attractiveness, and a handsome machine tool is quite as desirable as a handsome suit of clothes. We all might wear burlap, but the resulting economy would be largely imaginary. The average man would lose more in efficiency and self-respect than he could gain by the saving in cost. In short, the utilitarian is not all of life. We must have ideals, and love for ideals is a sentiment of practical value in business as well as in art.

* * *

The value of a developed water-power is stated by Charles T. Main, mill engineer and architect, of Boston, to be as follows: "If the power can be run cheaper than steam, the value is that of the power, plus the cost of plant, less depreciation. If it cannot be run as cheaply as steam, considering its cost, etc., the value of the power itself is nothing, but the value of the plant is such a sum as could be paid for it new, which would bring the total cost of running down to the cost of steam power, less depreciation. That is, it is worth just what can be gotten out of the plant, and no more."

ENGINEERING REVIEW.

CURRENT MECHANICAL EVENTS—LEADING ARTICLES OF THE TECHNICAL PRESS.

An unusual power contract has been made by the city of New York with the New York Edison Co., for supplying power for the operation of electric pumps for the new emergency high-pressure fire mains. A penalty of $500 per minute is imposed for the failure of the electric power supply within three minutes after a fire alarm.

In the December, 1907, issue of MACHINERY, we mentioned that the German Society of Engineers had discontinued the work on its *Technolexion*, on account of the high cost. It is stated in the *Times Engineering Supplement* that the society has appealed to the Prussian Government for assistance in finishing the work, and it will depend upon the decision of the Minister of Education whether the work will proceed or not.

At a meeting of the Institution of Mechanical Engineers, of Great Britain, one of the speakers mentioned that the manager of an automobile factory had stated to him that by using distilled water as a cooling medium and cutting lubricant, in place of ordinary water, he had been able to increase the life of the milling cutters, used in the factory, from five to ten times. Condensed steam from the steam engine would serve the same purpose as distilled water.

The production of denatured alcohol for the first six months of 1907, under the new law covering its manufacture, amounted to 1,774,272 gallons. The supplemental new alcohol law will, it is estimated, lead to a production of 4,000,000 gallons for the calendar year. The operation of the law has already reduced the cost of wood alcohol from prices varying between 60 and 75 cents to 30 cents a gallon, a fact which amply indicates that a fairly efficient monopoly has been established in the wood alcohol business.

Vice-Consul-General Paul H. Cram, of Marseilles, France, in a report to the Department of Commerce and Labor, calls the attention of American manufacturers to the fact that it is of very little use to distribute catalogues, printed in the English language, in France, and also to the fact that circular matter or letters should state dimensions and weights in the metric system, and prices of goods, delivered in France. Letters to France should also preferably be written in French.

New records in wireless telegraphy are constantly being established. A despatch from Berlin states that the Wireless Spark Telegraph Co. has transmitted a message between its station near Berlin and the Hamburg-American liner, *Cape Blanco*, off Teneriffe, a distance of 2,290 miles. Wireless communication has been established between the coast of Morocco and Paris, France, the Eiffel tower station communicating with war ships on the coast of Northern Africa, a distance of nearly 1,200 miles.

Experiments have been carried on for several years at the Oerlikon Machine Works, in Switzerland, with electrical trains for the purpose of ascertaining the best methods of electrically operating main line railroads with heavy traffic. The experiments are now closed, and, according to the *Railroad Gazette*, the system adopted is single-phase alternating current of 15,000 volts, with 15 periods per second, using overhead conductors. The experiments are said to have determined that there is no danger in employing high voltage, *provided proper precautions are taken*. The question is: "What are they?"

In the discussion of one of the papers presented before the December meeting of the American Society of Mechanical Engineers, it was stated that the limit of superheating desirable for Corliss engines is 500 degrees F. If the steam is used at a higher temperature, the valves warp and bind, due to their unsymmetrical form, and in some cases, cylinders have been known to change their shape sufficiently to cause difficulties. In engines fitted with ordinary slide valves, no difficulty is experienced, except with lubrication, but this has, in some cases, been overcome by direct oil connections to the valve seats.

It is stated that, at the present time, there is a large demand for machinery in China. The imports of machinery are constantly increasing, being, in 1906, nearly three times as high as the average for the previous five years. Great Britain supplies the greatest amount of the demand, Germany, the United States, and Belgium coming next, in order. Industrial undertakings are, at the present time, favored to a great extent by the Chinese, and there is undoubtedly an opportunity for firms who are able to supply considerable quantities of the machinery demanded.

A short description is given in the *Practical Engineer* of a number of "rail-less tramways" now in operation in different parts of Germany, for the conveyance of both passengers and goods. The cars consist of dirigible vehicles, propelled by electric motors, which receive their current from an overhead conductor, supported on trolley poles. The cars have sufficient freedom of movement to enable them to turn aside about 12 feet in either direction from their wires. When two cars, traveling in opposite directions, meet, the contact rods of one are removed from the wires, and replaced when the other car has passed by. The first tramway on this system was constructed in Saxony, in 1901.

It is stated in *The Times* (London) that the Danish Government is considering a project to construct a railway tunnel under the Great Belt. The total length of this tunnel would be about 17 miles, of which 12 miles would be under the sea. The estimate of the cost is put at slightly more than $7,000,000. At the present time, there is a train ferry service across the Belt, but it is often handicapped by bad weather, and it is calculated that the tunnel service would be profitable, even if the cost were considerably more than the estimate given. Test borings have shown that the condition of the materials in which the tunneling work would have to be carried out is favorable for the work.

It is mentioned in the *Mechanical World* that an English firm has lately been experimenting with the object of producing a file which will do more work and last longer than files made from ordinary tool steel. The outcome of these experiments is a new special chrome-steel file. These files have recently been tested at Sheffield, with excellent results. The total number of strokes made with the file tested was 270,000, the strokes per minute being 51, and the number of hours 88¼. The amount of filings removed during this time was 10½ pounds. The makers, W. Atkins & Co., Ltd., Sheffield, England, claim that this is far in excess of any result known at the present time, and that it represents a marked advance in the cutting power and ability of files.

The German navy has ordered one of its ships to be fitted with an electric propulsion system of the Siemens-Schuchardt type. According to this system, the power generated in the engines—in this case steam turbines—is converted into electric energy, and part of it is stored in accumulators and is utilized as occasion may require. It is not stated what advantages are expected to be derived by this system, excepting, possibly, greater flexibility of the power. The steam turbine alone, of course, drives the propellers at too high speed for economical working, whereas if the steam turbine is used at a high speed of revolution, and corresponding high efficiency, and electric power transmission, with low rotating speed of the propellers, is employed, greater economy is obtained. The propellers can be controlled directly from the bridge by this method, which, of course, would be a decided advantage.

As a result of a two years' trial of a four-cylinder, balanced, simple locomotive, on the London and South Western Railway of England, says the *Railway and Engineering Review*, a number of ten-wheel locomotives of this type have been designed and built by the railway, and put into service as a standard for heavy passenger service. The boilers of these locomotives have a tube heating surface of 2,210 square feet, a fire-box heating surface of 160 square feet, and 357 square feet of additional fire-box heating surface, secured from cross water-tubes. The grate area is 31.5 square feet. No injectors are used, these being replaced by two duplex feed-pumps, and the feed-water is heated by the exhaust steam from the pumps. All the cylinders are 16½ x 26 inches, the exterior being coupled to the middle drivers, and the interior to the forward drivers. The exterior valve motion is Walschaerts' and the interior, Stephenson's, both handled together by a steam-hydraulic device. All the cylinders exhaust through one pipe. The drivers are 72 inches in diameter, and the engines weigh 52 tons on the drivers, and 75 tons complete.

The passage of the free alcohol bill by Congress last year did not carry with it such enormous immediate changes in its use in the industries as was predicted, nor did the price of denatured alcohol fall to anything like the figures intimated. There are, however, strong indications that alcohol finally will become cheap enough to enter into active competition with gasoline and kerosene for a variety of power purposes. It has been shown by a congressional committee investigating the matter that the total cost of producing a gallon of 90 per cent alcohol at a large distillery in Peoria, Ill., is 18.4 cents. This, however, was when producing alcohol directly from corn. A far cheaper price may be reached by producing alcohol from potatoes, or even from the stalks of corn and corn cobs. In Cuba alcohol is now made from a cheap grade of molasses, which ordinarily is a waste product, at a cost of 10 cents a gallon, and there is no good reason why we may not ultimately expect the same low level of price to be reached in the United States. If the price were right, alcohol would, for many reasons, be far preferable to any of the common liquid fuels for power purposes.

In an article in the *L'Electricien*, a system of winding magnet coils, using bare wire, is described. The reason for the possibility of using bare wire in winding is that when two adjacent turns of the wire come in contact, they only make a line contact, and the resistance of this contact will be so great compared with the resistance of one turn of wire, that the current will flow through the wire rather than across the contact. If then the coil consists of but one single layer of wire, it is not necessary to insulate this wire, as the resistance of the contact will be sufficient to prevent short circuit. Of course, this does not apply to the second layer of wire, since the latter will come in contact with the layer below, and the resistance of the contact will be small compared with the total resistance of the intervening turns of wire. Consecutive layers, of course, have to be insulated from one another. The system is evidently limited by the diameter of the coil of the wire. If the diameter of the coil is large, and the wire is small, the current may pass across from turn to turn easier than by passing around the coil. Therefore the system is suitable for large coils only in cases when these are wound with fairly large wire. It is claimed that magnet coils wound in this way have proved satisfactory.

The automobile situation abroad seems, in some respects, not to be any more promising than that in the United States. The stocks of some of the French automobile companies have declined heavily, and although the year just closed has been one of greater sales and greater activity than in any of the previous years in the automobile industry, the future is not promising. One German automobile firm has issued a statement, in which it is claimed that a great deal too much has been spent by automobile manufacturers on exhibitions of all kinds, and that it would remove a great burden if the manufacturers would free themselves from excessive demands made upon them in this direction. The German automobile manufacturers at their annual meeting, voted not to take part in any German automobile show before September 1, 1909. This tendency undoubtedly is one which must be considered as indicating a new and healthy development of the automobile trade. The automobile shows have been largely devoted to exhibiting luxurious cars, for pleasure purposes, the commercial vehicles having been almost totally neglected. There are strong indications in Europe, as well as in the United States, that this condition will cease, and the tendency toward that firmer basis on which the industry will be placed when attention is given to vehicles that will be actually useful, is the most hopeful sign of the present time.

Should aerial flight ever become an accomplished fact so far as humanity in general is concerned, the exhibit of Mr. Henry Farman in Paris, January 13, will become of considerable historical interest. Mr. Farman sailed nearly one mile in a circle with an aeroplane flying machine heavier than air, and won the Deutsch-Archdeacon prize of $10,000. The flight was made at a height of 25 feet from the ground, and the speed averaged 34 miles per hour. The machine in plan is somewhat like that of a bird, the two wings being duplicated by two aeroplanes, one above the other on each side, with a third double aeroplane trailing behind to form the tail. The propulsion is effected by a propeller driven by a 50 H.P. gasoline engine of extraordinary power in proportion to its weight, which is approximately only 175 pounds. To enable the machine to rise from the ground, it is necessary that it be mounted on wheels so as to gain sufficient speed to balance its weight on the air before rising from the earth. These wheels are of very light construction, similar to those used on bicycles. The successful trial demonstrated that it is possible to build machines heavier than air which can raise themselves from the earth and sail in any direction, under favorable atmospheric conditions. For brief review of recent dirigible balloon exploits, see MACHINERY, January, 1908, page 281, Engineering edition.

The results obtained from some interesting experiments undertaken to ascertain the bursting strength of malleable iron pipe fittings, were published in *Power* some time ago. These experiments were undertaken by the Pittsburg Valve and Fittings Co., and the tests were made on 4-inch standard threaded malleable iron tees, both black and galvanized. The metal of all the fittings was ¼ inch thick on the body portion. It was found that the average bursting pressure for the black fittings was 2,900 pounds per square inch, and for the galvanized fitting, 2,833 pounds per square inch. The working pressure recommended by the manufacturers for these fittings is 150 pounds, giving thus a factor of safety of about 19. One of the interesting facts proved by these experiments is that the galvanized fittings can stand practically the same pressures as the black, which is contrary to the expressed belief of many users of malleable fittings, who have been very positive in their statements that galvanizing greatly weakened the strength of the pipe, because the dipping of the fitting in a bath of molten zinc, and then suddenly cooling it by immersing in cold water, would have a tendency to bring the castings back to the unannealed state, making them hard and brittle. That this theory is not correct is conclusively shown by these tests. As compared with experiments undertaken with cast iron tees, the strength of the malleable fittings is more than 50 per cent greater than that of cast iron fittings. In most cases the malleable fittings developed leakage through minute "pin holes" at pressures ranging from 1,000 to 2,500 pounds. In no instance were these pin holes visible below a pressure of 1,000 pounds with the black fittings, or below 2,000 pounds with the galvanized fittings, while two of the galvanized fittings sustained a pressure of 2,500 pounds before pin holes developed. It is therefore evident that galvanizing is very effective in closing small imperfections or pin holes in the malleable iron.

ELECTRIFICATION OF THE SWEDISH STATE RAILWAYS.

More detailed information regarding the electrification of the Swedish State Railways has now been published. As will be remembered, we have several times referred to the plans for the electrification of the Swedish State Railways, which

proposition has been given thorough consideration by the Swedish government, particularly because of the abundance of water power available in the country, and because of the fact that coal must be imported at high cost. For some time past the government railway administration has carried on various experiments with electric power on a part of the State Railways, outside of Stockholm, and the estimates for the cost of power of installations necessary have been founded on the results of these experiments. The length of the railways which would ultimately be electrified is about 1,300 miles, the total length of track, including double track and sidings, being somewhat more than 1,800 miles. Five water falls of great capacity, located at various parts of the country, will give the required power. Power transmissions will conduct electric current of 50,000 volts, which will be transformed to 15,000-volt current in the contact conductors. The transformers will be located about 30 miles apart. The total cost for conductors and transformers is estimated to be nearly $10,000,000, and for the power stations, about $6,500,000, to which would be added $400,000 for special buildings required. The estimates show that at the present time, the saving of electrification over steam traction would amount to $120,000 a year, but when the traffic increased about 60 per cent, as it is estimated that the traffic will by 1920, the saving would amount to about $400,000 a year. The estimates have been

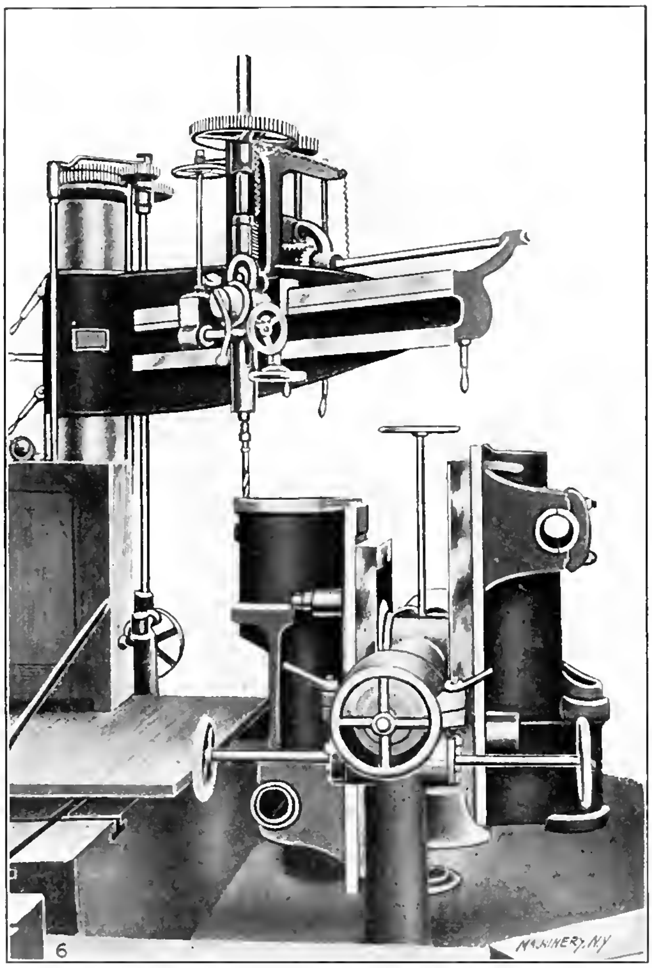

Fig. 1. Universal Table for Machine Tools.

carried out carefully into details, and it is believed that this is the most thorough scheme for the electrification of railways that has ever been worked out anywhere. A complete official report regarding all the experiments which have been carried out by the Swedish Government Railways, and the results obtained, is to be expected in the near future.

That these plans are not merely to be made on paper, but are intended to be actually carried out, is indicated by the fact that the Swedish Government, at the present time, is building its first large power station which ultimately will be capable of developing 100,000 horse-power, and has possibilities for being increased to 180,000 horse-power through the purchase of some additional water rights. This power station will not be completed to this enormous extent all at once, but, at the present time, four generators, to be driven by water turbines, have been ordered from the General Swedish Electric Co., in Västeras, Sweden. These generators will be the largest that have so far been made in Europe. They will be made of the horizontal type, and will have an outside diameter of 27 feet. Each will generate 10,000 horse-power, normally, the maximum load being 12,500 horse-power.

UNIVERSAL TABLE FOR MACHINE TOOLS.

Zeitschrift des Vereines deutscher Ingenieure.

The accompanying half-tones, Figs. 1 and 2, and the line cut Fig. 3, show the design and application of a universal table, the principles of which may be applied to many different classes of machine tools. It is primarily intended for

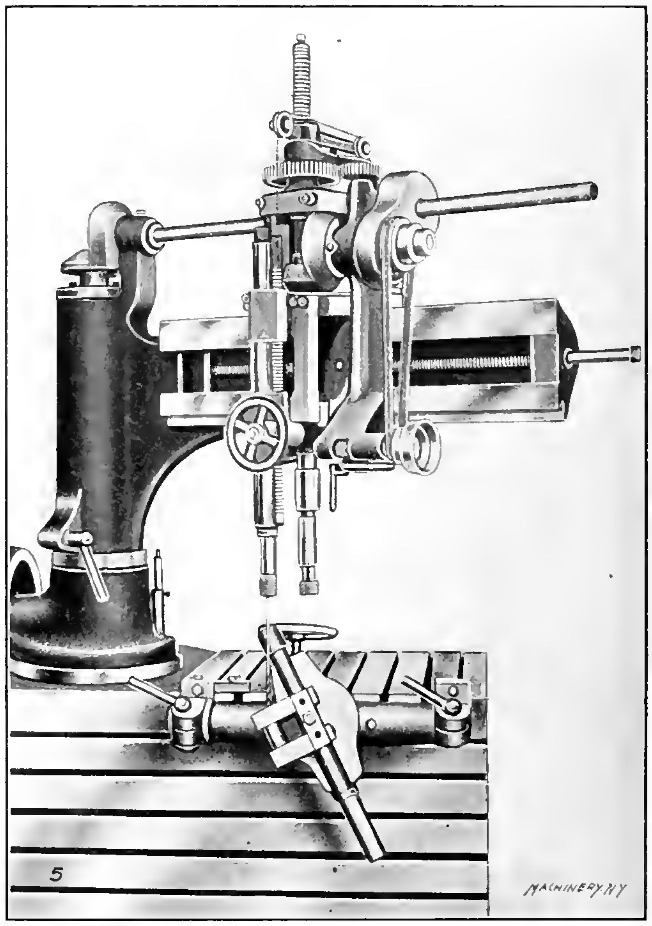

Fig. 2. Type of Universal Table used for Small Work.

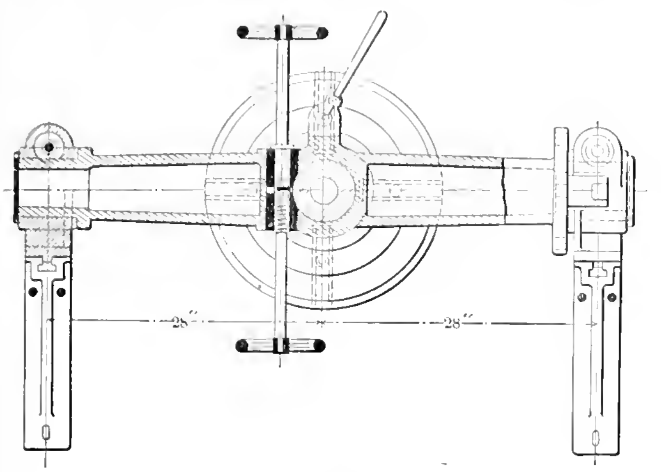
pieces of work which have to be held in several different positions in drilling machines, or in special milling machines, permitting, as shown in the cut, the turning of the piece being worked upon to almost any position. The usefulness of the device in the radial drill press is most apparent from Fig. 1. The device may be mounted in different ways. In Fig. 3, for instance, it is mounted on two brackets, which are bolted to the side of the removable square table usually furnished with radial drill presses. These two brackets are provided with T-slots to which the device is clamped. This permits the device to be moved in and out along the ways on the brackets.

The device itself consists of a rotating arbor having trunnions mounted in bearings immediately over the brackets. By means of a hand-wheel, and a worm and worm-gear connection, the device can be turned to any position around the axis of the arbor. The table to which the work is clamped, is mounted at the center of this arbor, and can be swung around its own axis. The combination of this swivelling table and the rotating arbor make, of course, a perfectly universal device. The table, as well as the rotating arbor, is provided with suitable means for clamping, as will be seen in Fig. 3. There is one table provided for each side of the arbor, thus permitting work to be clamped on both sides. The half-tone, Fig. 1, shows the usefulness of this arrangement. The design of the device, as shown in Fig. 1, is not

exactly the same as that shown in the line cut, Fig. 3, but the principles applied are exactly the same. In the half tone, however, the tables are square, and are also capable of a longitudinal movement. In the cuts shown, two gas engine cylinders, cast integrally with their frames, are bolted to the tables. The half-tone, Fig. 2, shows the same kind of a device, but of the type used for small work. In this case, the whole device is clamped to the side of the drill press table, and a case of angular drilling is shown. We under-



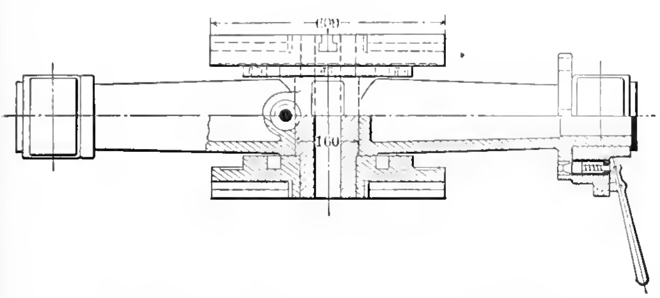


Fig. 3. Plan and Elevations of the Universal Table.

stand that this device is, at the present time, used with great success in the works of Gasmotorenfabrik Deutz, of Köln-Deutz, Germany.

NOTES ON THE MANUFACTURE AND UP-KEEP OF MILLING CUTTERS.

H. T. Ashton, before the *British Institution of Mechanical Engineers.*

Although the system of manufacture of milling cutters, detailed below, is suitable for general application, it has been developed more particularly to meet the difficulties of extending the use of high-speed steel to milling cutters of complicated shape. It is believed that these difficulties have been commonly met with, and that, owing to them, the general

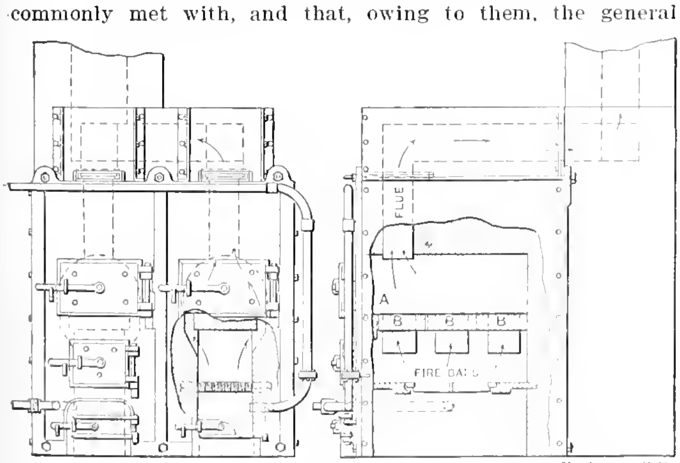

Fig. 1. Front and Side View of Hardening Furnace.

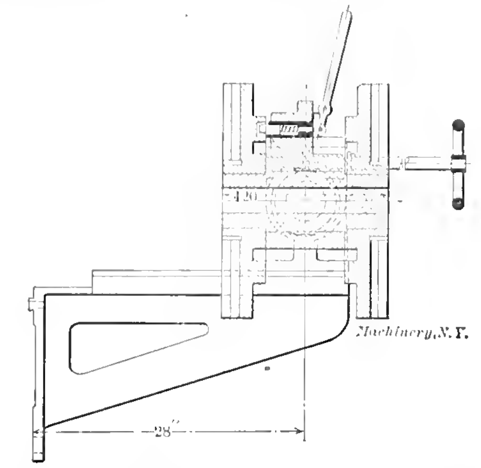
introduction of high-speed steels of the Taylor-White class has, so far, generally proved of less value for milling cutters than for any other form of cutting tool used in the shop.

Perhaps the advantages to be obtained by the use of high-speed steel; for such cutters are also not so obvious as they are for the heavy lathe or planer tools, where the almost red-hot chips, that they can be made to produce, appeal to the least observant onlooker. When, however, it is considered that this class of steel not only has the property of keeping a cutting edge for a reasonable time, when taking very heavy cuts at a previously unattainable speed, but also keeps its cutting edge when used with a moderate cut and speed for a far longer period than was previously obtainable, its advantages, if applicable to complicated milling cutters, are clearly just as great as for the simpler tools taking the heavy cuts.



For, although the nature of the work upon which the cut is taken and the finish required from the cut may not allow, in the case of the milling cutter, any great increase of speed or feed by the use of high-speed steel, and consequently little direct saving upon the time occupied in doing the work, as in the cases of the other classes of tools, yet an equally important saving is effected in the cost of supply of the tools themselves. The milling cutter is the most expensive of all the tools used in cutting metals. In the simplest milling cutter, the cost of workmanship so largely exceeds the cost of material that a moderate increase of life obtained by improvements in the raw material far outweighs a considerable increase in

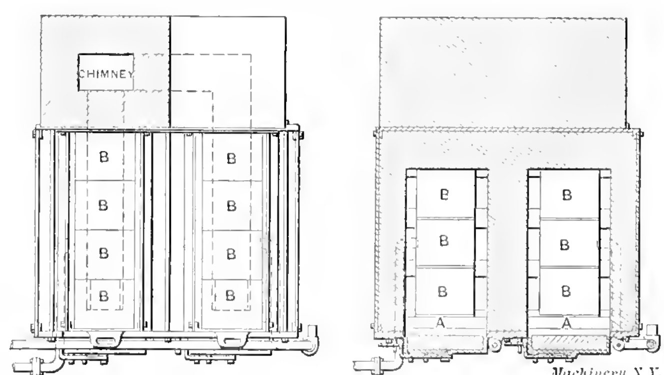


Fig. 2. Plan and Section of Hardening Furnace.

its original cost, provided that there is sufficient work in sight for the cutter to insure its being fully employed for its maximum possible life. Perhaps it is this ruling condition which has led to somewhat less attention being paid to the application of these steels to milling cutters in general machine shop practice than to other cutting tools. For in ordinary shops, with the exception of a few simple cutters generally useful for roughing out or for finishing simple profiles likely to recur, it has perhaps generally been more economical to make the cutters from ordinary qualities of tool steel, or even in some cases from specially case-hardened mild steel; hence the preparation of an elaborate milling cutter from high-speed steel has not received quite the same general attention as the preparation of other cutting tools of maximum endurance.

The case, however, is different in a number of shops where the interchangeable parts of many classes of apparatus and fittings depend very largely upon the use of formed milling cutters, and where the accuracy of the work so produced is directly dependent upon the accuracy with which the form of the cutter can be maintained for a prolonged period. It is desirable also that the cutters should have as long a life as possible in actual service, in order to minimize the first cost

and up-keep, and also to keep the output of the machines as continuous as possible, by reason of freedom from delays in changing the cutters. These points depend chiefly upon:

1. The quality of steel from which they are made.
2. The method of hardening adopted.
3. The care and accuracy with which the new cutters are made.
4. The facility and correctness with which the cutters can be ground when they have become dull or lost their accuracy.

The Steel Used.

There is, of course, nothing to compare with the recently developed high-speed steels as a material for cutters which are required to work at a high cutting speed and have the maximum possible life; and no difficulty is now experienced in obtaining work with a sufficiently satisfactory finish, provided care is exercised in the grinding and finish of the cutters, in the manner which will be described, and also if the cutting speeds and feeds are suitably arranged. Any of the best-known makes of this class of steel can be used in conjunction with the system to be described.

The steel is annealed by packing in spent powdered charcoal and steel turnings in cast iron pans with covers which are luted down. These are placed in the annealing furnace the first thing in the morning, and are gradually heated up to 1,300 or 1,400 degrees F.; this heat is usually reached by 1 o'clock and is maintained until about 5 o'clock, when the dampers are closed and the furnace is allowed to cool gradually for forty-eight hours. It is found that some makes of high-speed steel are satisfactorily annealed by the makers, but it is not the universal practice. Annealing in this manner is found to give thoroughly satisfactory results.

Method of Hardening.

The furnace used for hardening cutters is shown in Figs. 1, 2, and 3, and it has been found specially adapted for obtaining a soaking heat, together with the high temperature necessary in treating this class of steel, and freedom from oxidation. The furnace is coke fired, and has a forced draft, and temperatures up to 2,300 degrees F. can be obtained.

In using the furnace, the cutters are packed closely in powdered charcoal in sheet steel boxes about 6 inches by 6 inches by 3 inches. These boxes take from 2¾ to 3 hours to reach the necessary hardening temperature, the time taken varying with the weight of metal to be heated. The hardening temperature varies somewhat according to the class of steel being used, but may be said to be between 2,000 degrees F. and 2,100 degrees F. The exact temperature necessary for satisfactorily hardening any particular class of steel is previously determined in the laboratory by exact experiments, and the temperatures obtained in the furnace are checked by means of a Fery radiation pyrometer—also shown in Fig. 3. This pyrometer is itself tested against a standardized Callendar pyrometer, and has so far given extremely reliable results.

The cutters, when sufficiently heated, are quickly removed from the charcoal in which they have been packed, and are at once placed upon the hardening table shown in Fig. 4. This table is of a type frequently used in workshops for heating tools by gas, but when used for hardening cutters, air only is supplied through the two nozzles. These can be moved, as required, about vertical pivots, so as to cause the air blast to impinge upon the periphery of the cutters at any required points and simultaneously upon the vanes of the spindle upon which the cutter is placed, causing the whole arrangement to rotate and thus equalizing the cooling and hardening effect. The air delivered upon the cutter is drawn from a culvert which passes under the floor of the workshop and through which a stream of water continually flows; hence at all times of the year a supply of cold damp air of maximum cooling effect is available. The temperatures used in hardening are such that the edges of the cutters are almost fused, and although different makes of steel have been found to vary somewhat in this respect, the general statement remains true of all of them. At the same time, it is found that this fusing effect for a given heat is considerably minimized by the method of heating in closed boxes, as compared with the ordinary method of heating tools either in a muffle or directly in a gas flame, and even the scaling, which, with the latter systems, is frequently marked, is, with the method now described, so slight that the cutters can be wholly freed from scale by placing them momentarily under a revolving scratch brush.

All difficulties as regards the expansion of the hole through the cutters in hardening are met initially, leaving the bore slightly smaller than is ultimately required—on the average about 0.010 inch less than the finished diameter; the expansion

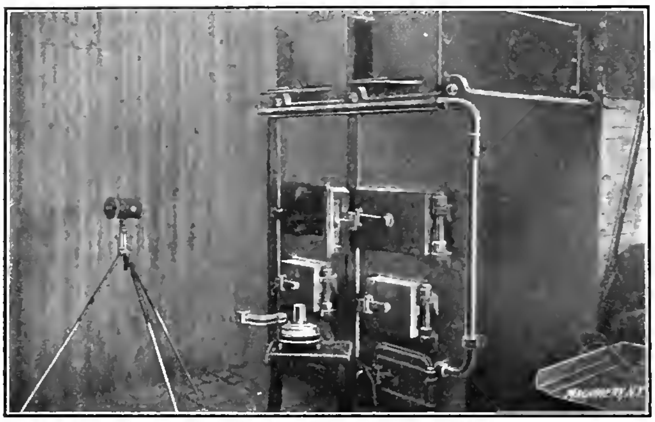

Fig. 3. General View of Hardening Furnace.

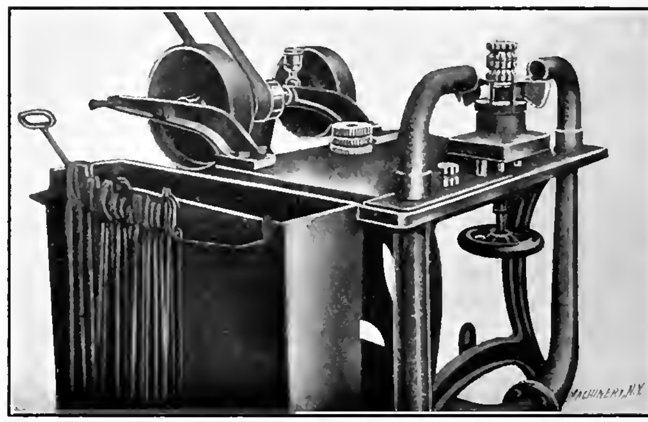

Fig. 4. Method of Hardening by Air Blast.

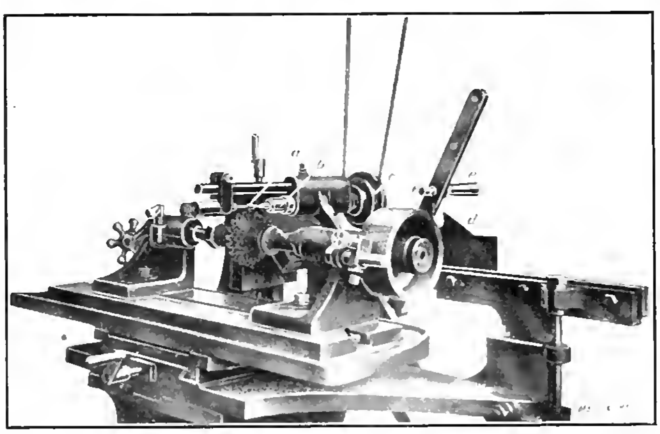

Fig. 5. Milling Teeth of Formed Cutters.

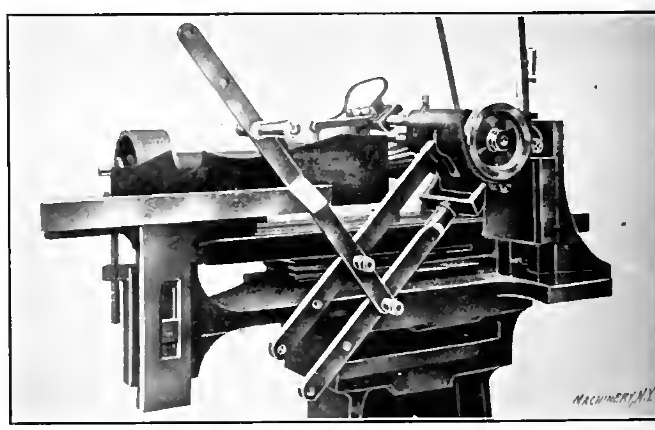

Fig. 6. Front View of Machine for Milling Teeth of Formed Cutters.

is usually about 0.003 inch to 0.005 inch, the average diameter of the mandrel being 1 inch. After hardening, the milling cutters are first chucked truly with the outside diameter in a self-centering chuck, and the internal bore is ground up truly to the finished diameter. After this, the hardened cutters are chucked upon mandrels and the teeth are finished upon the special machines to be described.

Forming Cutter Teeth.

Accuracy of form of the cutters is secured, both when being cut in the first place, and also when subsequently re-formed, by turning the blanks and milling out the teeth in the ordinary manner, and then backing them off in the machine shown in Figs. 5 to 8. In this machine, the cutter to be formed is carried on a dividing head, so that one tooth at a time can be presented to the small milling cutter *a*, Fig. 5. This is mounted upon the cutter spindle *b* driven by a pulley *c*, from which cat-gut cord runs through an overhead gear, allowing the spindle to be moved within the necessary limits. The small cutter spindle-frame forms part of a system of adjustable pantograph links, so that its movement is an exact reproduction in miniature of the movement of the tracing pin upon are either clutched together or clamped together upon plain faces, from which, after a particular grinding or series of grinding operations, the same amount is ground off as that by which the radial cutting edge has receded. Where the edges of the teeth are parallel or nearly parallel to the axis of the cutter, the profile is, of course, not appreciably affected by grinding back the faces of the teeth. A further means of avoiding such errors is also to be found in grinding the tops of the teeth in the manner subsequently described.

As it is found advantageous, in order to obtain a fine finish, to use helical teeth upon milling cutters, a fitting consisting of a sleeve with spiral slot—see Figs. 7 and 8—can be mounted on the same spindle as the milling cutter. A pin on a hinged arm centered above the backing-off cutter spindle is arranged to slide in the slot in this sleeve so that, as the frame carrying the copy and the cutter spindle is moved backwards and forwards along the axis of the cutter being backed off, the helical teeth are maintained in correct relation to the backing-off cutter, while at the same time they are backed off to the correct profile. Theoretically, of course, in such cases, the axis of the cutter being operated upon could be inclined to the axis of the backing-off cutter spindle at

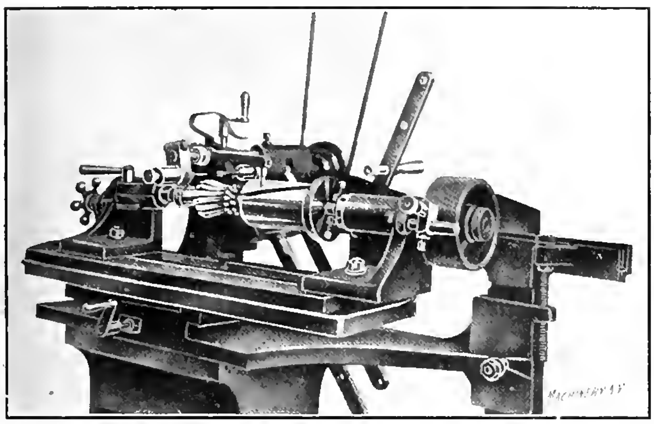

Fig. 7. Milling Spiral Teeth by means of Guiding Cam.

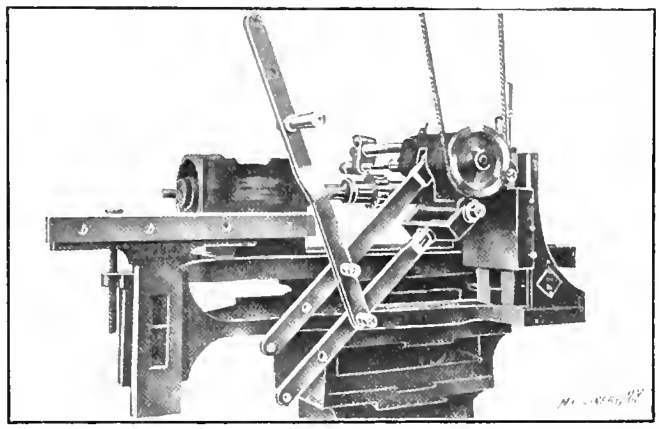

Fig. 8. Front View of Machine rigged up for Milling Spiral Teeth.

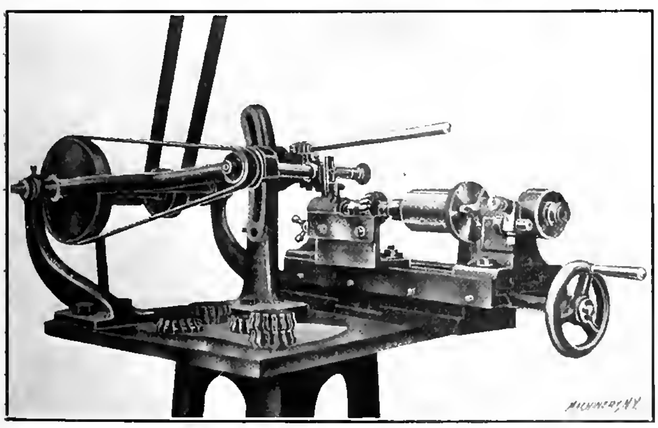

Fig. 9. Grinding Formed Cutters.

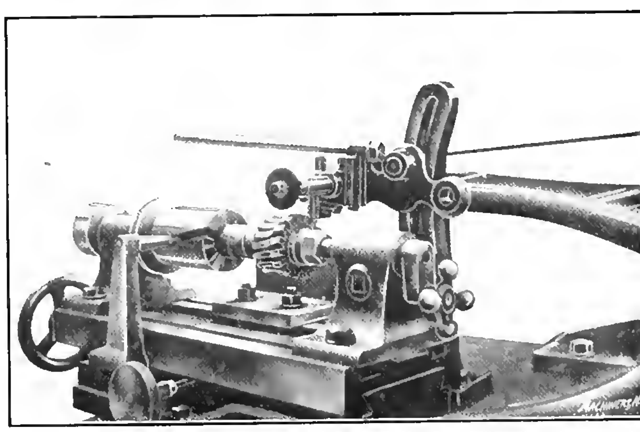

Fig. 10. Front View of Grinding Machine.

the former *d* fixed in front of the machine. The operator, by means of the handle *e*, moves the pin *f* lightly along the former, and consequently also moves the cutter over the tops of the teeth to a similar but smaller shape. The small cutter is enlarged in diameter toward one end, so that it cuts away the back of each tooth upon the cutter to the necessary extent. Commonly a conical backing-off cutter is used, the angle of the cone being 20 degrees, and the setting being such as to give an angle of relief of 10 degrees, that is, the axis of the cone is at right angles to the radial face of the tooth being backed off. It will be seen that this characteristic enables the machine to produce teeth of any form, upon a cutter backed off in every direction from the cutting edge, so that a clean cut can be taken with the sides as well as with the tops of the teeth.

In the case of those milling cutters in which grinding back the faces of the teeth so backed off might cause serious inaccuracy, owing to its throwing back the radial cutting edges of the teeth, the cutters are built up of annular sections which an angle equal to that of the spiral of the cutter being produced, but in actual practice it is found that this adjustment is very seldom necessary, as the cone angle of the backing-off cutter, and also the amount of material which can be removed from the cutting edge of the cutter being produced, are both, comparatively speaking, small.

This machine has been found not only capable of backing off satisfactorily cutters of a shape which could not be backed off along the whole length of their profile in an ordinary relieving lathe in one operation, but it has been found possible to do the backing off in, approximately, one-third of the time required on a relieving lathe, while at the same time a less expensive class of labor may be employed, and the finish of the teeth is found to be better.

Grinding Cutters.

Figs. 9 and 10 show the machine used for sharpening the cutting edges of the hardened milling cutters and subsequently regrinding their faces or edges as required from time

to time. This machine has a grinding wheel mounted upon a spindle suspended on a swinging frame, and follows the work by the use of a former, the profile of which is of the same magnitude as the one to be ground. In an ordinary way, this former would not have the exact outline of the shape desired on the finished cutter, corrections having to be applied for the diameters of the tracing roller and also of the grinding wheel, the latter item being, of course, itself, variable. This difficulty is overcome by using grinding wheels of special fast-cutting artificial stone, which will perform a considerable amount of useful work before being appreciably reduced in diameter, and by making the diameter of the tracing roller equal to the diameter of the grinding wheel; there is in addition, of course, an adjustment for raising or lowering the former.

The milling cutter being ground is, as before, mounted upon a dividing head, in the case of straight cutters, or upon a dividing head provided with helical sleeve in addition, in the case of helical teeth cutters, and all the teeth are first ground along the tops to profile and afterwards in the usual manner down their faces, the grinding wheel being, of course, set over to the angle of the spiral. The cutter thus finished has edges both of the maximum keenness and also of the maximum endurance due to correctly hardened high-speed steel, as only the thin skin partially oxidized in heating before hardening is removed.

Hitherto the apparatus employed for sharpening profile cutters for milling machines in repetition work, such as is produced in small arms factories and elsewhere, has required the handling and attention of men with considerable training and skill. The provision of simple machines, such as those described, now enables an unskilled man to regrind correctly all cutters brought to him with considerable rapidity and the minimum possibility of error. By standardization of the pitches of the teeth and their angles, and by the provision of suitable templets for each of the cutters commonly required, the use of these machines has been found to result in distinct economy, both in the up-keep of cutters and also in the quality of the work turned out.

Considerable advantages result from being able to re-form accurately the contour of the teeth, in addition to grinding the face. In ordinary use, the teeth of milling cutters are damaged not only on the face, but to an even greater extent on the top, and it has frequently been found that removing, say, 0.002 inch from the top has as beneficial an effect as removing 0.006 inch from the face, and with this additional advantage that, when a tooth has been ground to its fullest extent from the face, it can be further sharpened on the top while still retaining its correct figure, until the tooth is too short through not allowing the necessary clearance; and this consideration will, in many cases, lengthen the life of a cutter by 10 per cent.

The life of some milling cutters prepared by the methods indicated above has been extraordinary; for example, a cutter working in an automatic cross milling machine and operating upon the bodies of a service rifle at an average cutting speed of 69 feet per minute, with a feed of $1\frac{3}{4}$ inch per minute and a depth of 0.08 inch, and taking a cut of an average width of 1 11/16 inch and $7\frac{3}{8}$ inch long, has produced 39,170 bodies, and is still good for about half as many more. This particular cutter has been reground across its face twenty-five times. The composition of the steel upon which it operates is 0.5 to 0.6 per cent carbon, with an ultimate tensile strength of not less than 35 tons per square inch.

ELECTROPLATING IN QUANTITIES IN DRUMS.

Deutsche Metall Industrie Zeitung

In the last few years there have been made quite a number of apparatus for electroplating small articles in quantity. In most of these, the pieces to be plated are placed in rotating drums with perforated walls. The drums are partly constructed of non-conducting materials, and the objects to be plated are held by metal strips, which are put in electric connection with the source of current, in different ways. As such apparatus are now in very extended use, a few hints as to their practical employment should not be out of place.

Almost every one who works for the first time with a drum apparatus experiences more or less trouble therewith. As a rule, the apparatus is not to blame therefor; it is the fault of the operator, who is not familiar with its working. The greatest difficulty in using a drum apparatus is when the tension is not high enough. Ten to fifteen volts are necessary in order that the currents shall flow through the electrolytes in the drum. The reason for this is the resistance which the drum makes to the passage of the current. This is just the same as when a non-conducting substance comes between the anode and the piece to be plated. The current will not flow through the solution; and if this does not take place, no metal will be deposited.

For some kinds of work a six-volt dynamo will suffice; but the results obtained therewith are, however, not especially good; also, the deposit does not take place so rapidly as with higher voltage. In such case only a small number of articles can be placed for plating in the drum. Where there are too many, the deposit takes place too slowly, and with great irregularity. With higher tension, the desired amount of metal is deposited in a short time on the articles.

Of equal importance with the current voltage is the strength of the solution. It is useless to try to electroplate with a weak solution. The resistance of the solution, in combination with that of the drum itself, prevents the passage of the current. For instance, a nickel solution of 5 to 6 degrees Beaumé, which is strong enough for ordinary electroplating, is not suitable for drum work. In the latter case, either the articles will not be covered, or only their edges will be plated. If, however, a solution of 8 to 9 degrees Beaumé, or a saturated solution, be used, the deposit will be made with success. The same is the case with brass and copper solutions. Electroplaters who get the best results with the drum apparatus, always employ strong electrolytes.

The rotation speed is of no very great importance. It is only necessary to keep the articles in motion. If the speed is too high, however, the objects have a tendency to fly to the walls of the drum and lie there, where their entire surface is not subjected to the action of the current. Special care must be taken to have all the electric connections perfectly clean and properly arranged. If this is not the case, it will be impossible to pass the necessary current through the solution; and the deposit of the metal will in such case be irregular. The same is to be noted in connection with the drum; the holes or slits therein must be kept free from salt crystals and foreign substances. It is often found that imperfect deposit is caused by stoppage of the holes through which the electrolyte and the current pass.

In plating with copper, bronze or brass, there are no conducting salts which can be added, but none are needed; it is only necessary to have the solution as strong as possible. In nickel-plating, it is recommended to use two conducting salts, as for instance ammonia, with either ammonia sulphate or common cooking salt. These salts increase the conductivity of the electrolytic solution. No definite quantity of these can be mentioned as necessary, but the electrolyte will need only a small quantity of these salts. The usual rule is to take as much as the nickel solution will dissolve.

The surfaces of the anode in a drum apparatus should be large, and so arranged that they surround the drum on all sides. In this manner the solution can work the best. A nickel solution requires constant watching. If the electrolyte is too acid, as is often the case, there must be added, to reduce this acidity, nickel carbonate. Boracic acid is used in the drum apparatus in the same way as with other nickel solutions.

In the regular drum apparatus, bars, chains, etc., cannot be plated with advantage, because, by reason of the rotation of the drum, they bend and tangle so as to make a knot that can hardly be loosened, and the regular plating of which is impossible, and they also may cause short-circuiting in the drum. For such articles special apparatus should be employed, of the so-called swinging type, which do not cause these difficulties. These latter have a half-drum of non-conducting material with a swinging motion, and a fixed anode, and permit the articles in the bath to roll from one side to the other, which prevents tangling. R. G.

THE A. C. A. AUTOMOBILE DYNAMOMETER.

The accompanying illustrations show a very interesting apparatus recently installed by the Automobile Club of America on the eighth floor of its new reinforced concrete garage and club house at 247-259 West 54th Street, New York, for testing the tractive power, speed and internal resistance of automobiles. The need of a reliable and official testing apparatus for demonstrating the power and speed of motor cars has been keenly felt. The claims of agents and builders, in many cases, have been open to suspicion, and buyers have felt with good reason that their purchases by no means fulfilled the promises made. The apparatus shown in the illustrations was designed under the direction of Dr. Schuyler Skaats Wheeler, president of the Crocker-Wheeler Co., Ampere, N. J., who is vice-president of the Automobile Club of America. In 1904 Dr. Wheeler was requested to design and build a testing apparatus which would meet the practical requirements of automobile testing and at the same time be so designed as to avoid criticism of the captious-minded. The requirements were scientific accuracy, convenience of use and the indication of the results in terms that the ordinary layman could understand. For the past four years the engineers of the Crocker-Wheeler Co. have been working on the problem, and the result apparently leaves little to be desired.

The general appearance of the testing floor is indicated in Fig. 1. The automobile is driven in facing the large horse-power chart shown on the wall, and to such position that the rear wheels will stand on the rollers or drums sunk in the floor. It is then hitched to stops fastened in the floor both front and back, the stop in front showing directly underneath the brake horse-power chart. The construction of the testing apparatus is similar in principle to that employed in locomotive testing machines such as are in existence at Columbia University, New York, and in the Pennsylvania R. R. testing plant at Altoona, Pa., so far as the absorption of power is concerned, but in addition it has apparatus of unique design never before applied to such use.

The rotation of the rear or driving wheels of the automobiles drives the drums, which are mounted on a shaft below the floor, as shown in Fig. 2. Upon this shaft are mounted an Alden absorption brake and a pendulum having a weight of 1,600 pounds. The traction of the wheels transmitted through the absorption brake rotates the weight-arm to an angle dependent upon the force exerted. This is indicated diagrammatically in Fig. 3. In line with the same shaft is mounted a motor which can be connected to the traction shaft by a clutch. The object of the motor is to determine the power consumed by internal friction of the engine and driving apparatus, the consumption being indicated in amperes and volts on the indicating electrical apparatus. Right here it may be said that the internal resistance of most automobiles is high, being about 25 per cent of the indicated horse-power. Machines have been tested wherein the resistance was much higher, being, for example 18 horse-power in the case of a supposed 50 horse-power car. The section of the shaft on which the weight-arm is mounted is fitted with two dash-pots connected by bell-crank levers, as shown at the left in Fig. 2. The object of these, of course, is to prevent violent fluctuations of the weight-arm under the influence of unsteady driving.

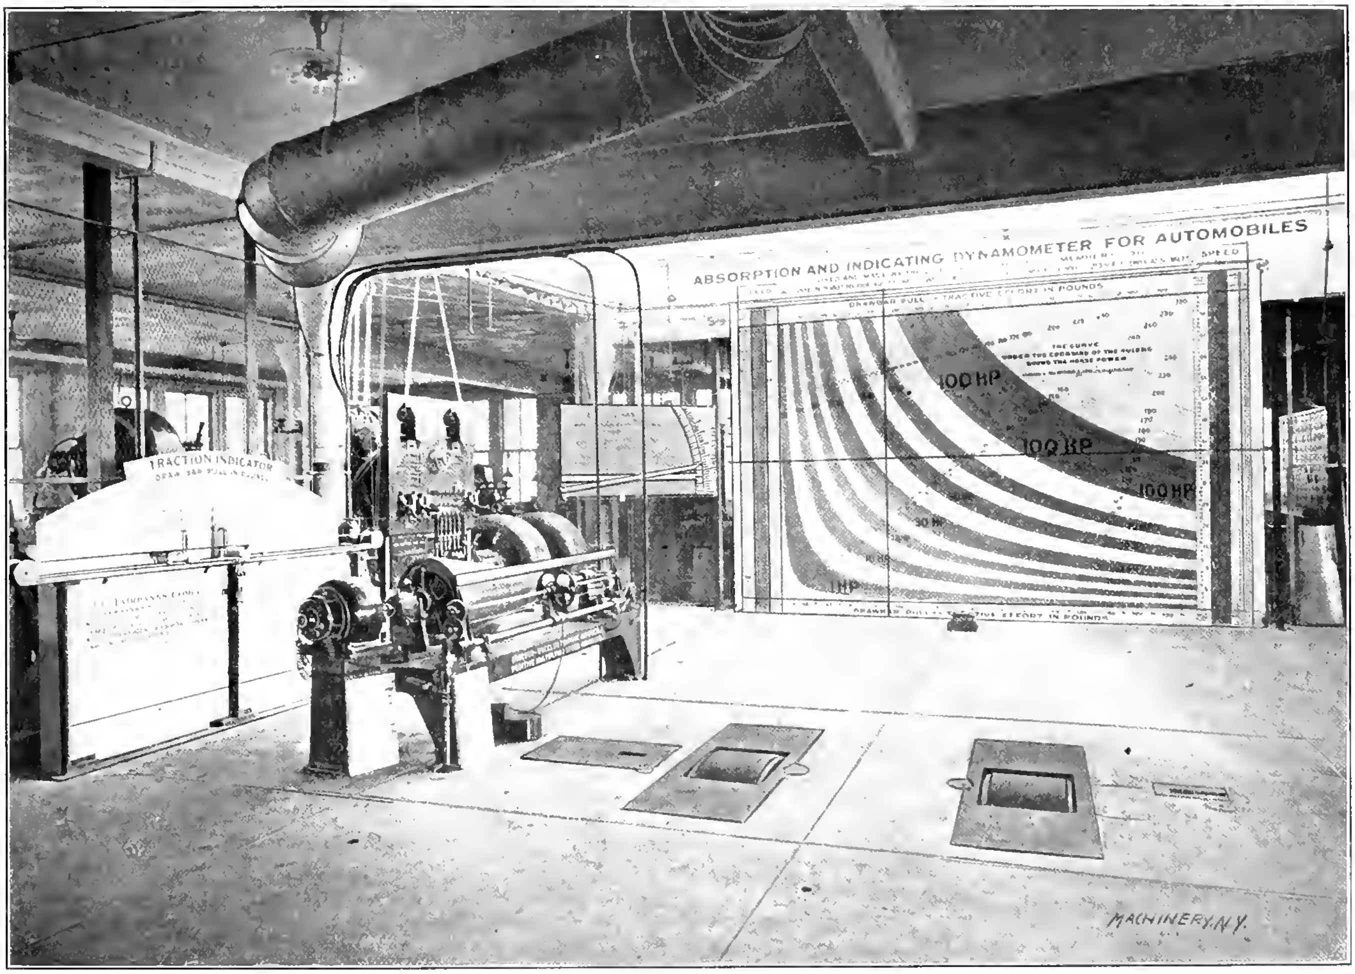

Fig. 1. General Appearance of the Testing Floor of the Automobile Club of America, New York.

The results of the tests are plainly evident to the driver, being indicated by the horizontal and vertical rulers, plainly visible on the horse-power chart in Fig. 1. This chart is ruled with hyperbolic lines and these sections are alternately shaded white and green, thus making the readings at intersecting points of the rulers plain. The horizontal ruler indicates miles per hour, and the vertical ruler gives the draw-bar pull or tractive effort in pounds. The horse-power is the component of the speed, generally computed in feet per minute in engineering calculations, and the draw-bar pull in pounds, but the chart is figured to indicate the horse-power by the more convenient formula:

$$\text{H. P.} = \frac{\text{pull, in pounds} \times \text{speed, in miles per hour}}{375}$$

The capacity of the apparatus is from 1 to 75 miles per hour and from 0 to 213 horse-power at 50 miles per hour. The chart was ruled by plotting the curves with the apparatus working under known conditions, the traction pointer arc being graduated at the same time in accordance with calibrations made by the Fairbanks Scales Co.

The tractive force of the automobile being indicated by the angular displacement of the weight-arm, it becomes very desirable that it shall encounter no other resistance than that due to gravitation. If the friction of the indicating apparatus were added, it would produce a variable and, therefore, uncertain resistance that could not be accurately predicted. To overcome this the apparatus is so arranged that it provides the force to move the traction indicator (horizontal bar on the chart) entirely independent of the displacement force exerted by the automobile drivers. As the vertical pointer shown at the left of the half-tone, Fig. 1, moves along the graduated arc it makes an electrical contact on one of the small slides or carriages shown on the horizontal track, whereupon a small motor (beyond the traction chart) called "traction follower motor" winds up a thin steel wire cable causing the carriage to follow the pointer and at the same time moving the traction ruler on the large chart to the correct position. The moment it reaches this position, the electrical contact is broken, and if the motor over-travels, another contact is made which reverses it, thus keeping the carriage in constant attendance to the vertical pointer. When testing an automobile, in backing, the vertical traction pointer moves in the opposite direction and a twin carriage is provided which acts in the same manner in the opposite direction. To prevent injury to the apparatus because of violent fluctuations that the dash-pots cannot control, the vertical pointer is provided with a spring connection to the brake shaft which unhooks in case of a violent jerk and permits the pointer to fall behind the angular position of the weight arm and to catch up with it under the influence of a coiled spring. Thus the follower motor is given time to traverse its carriage and indicator without causing undue stress. The resistance of the drum shaft to rotation in its ball bearings is about 25 ounces, starting from rest without load of the automobile superimposed.

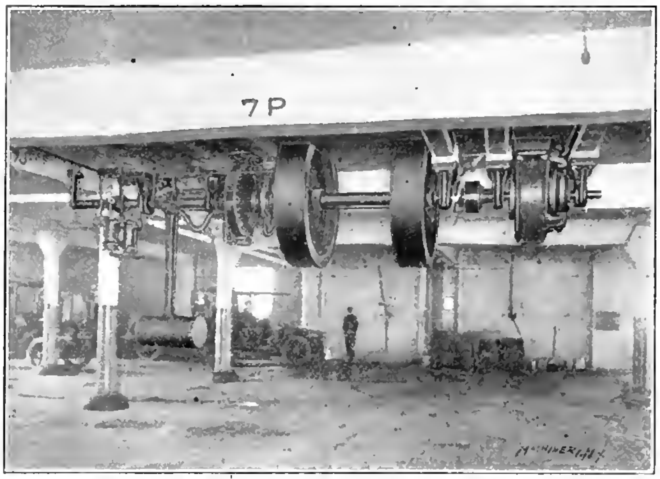

Fig. 2. Drums, Drum-shaft, Electric Motor, Alden Absorption Brake, Etc., underneath Testing Floor.

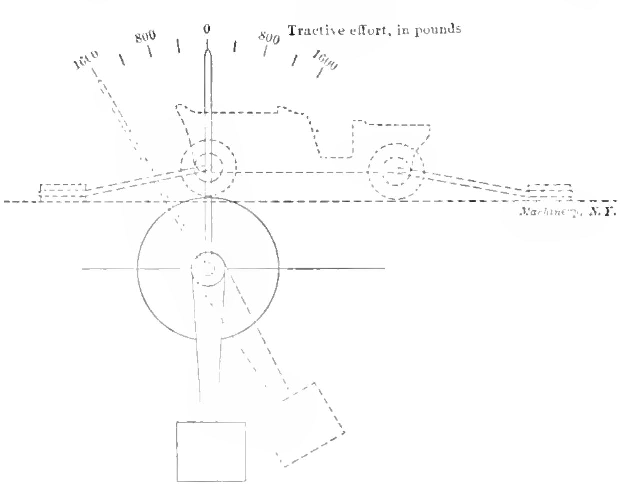

Fig. 3. Diagrammatic Elevation of Automobile on Testing Apparatus, showing Traction Indicator.

The same general principle as just described is employed to indicate the speed in miles per hour, but as the element of time enters, the apparatus is somewhat more complex. The machine shown in Fig. 4 is solely for this purpose, and has been ingeniously worked out. It consists of a conical drum driven by a constant-speed motor at the rate of 200 revolutions per minute. The rate of rotation is fixed by a sensitive centrifugal governor mounted in the large end of the cone, and a timing bell is provided which rings each half-minute, or at each one-hundredth revolution. Thus, a stop-watch can be used to check the timing bell and the speed of the cone. Parallel with the cone surface is mounted another shaft called the speed shaft, upon which is mounted a thin friction disk. The disk is not firmly held to the speed shaft, but, between the limits of the stops formed by electrical contacts, it is driven by the friction caused by the pressure of a small coil spring forcing it against a shoulder on the splined bushing upon which it is mounted. Thus, within the narrow limits of oscillation permitted, it tends to run at the peripheral speed of the cone shaft at the section with which it is in contact. The speed shaft is driven from the drum shaft, which is beneath the floor, by a chain, bevel gearing and a vertical shaft not very plainly shown in Fig. 1. At the right of the machine is a small motor designated as the "speed follower motor." The function of this motor is to traverse the disk and its mounting on the speed shaft to such position on the cone that the disk peripheral speed is the same as the cone peripheral speed at the point of contact. If the disk runs either faster or slower, the difference in speed causes the disk to shift relatively to the speed shaft and make an electrical contact, front or back. These contacts actuate the motor which shifts the disk either to the right or left as is required to make its peripheral speed the same as the cone peripheral speed. The shifting of the disk actuates the vertical ruler on the horse-power chart shown in Fig. 1. Therefore, this ingenious arrangement also imposes no additional load on the dynamometer shaft; it simply follows up the indication of the speed shaft substantially as does the vertical traction ruler follow the vertical traction pointer over its graduated arc.

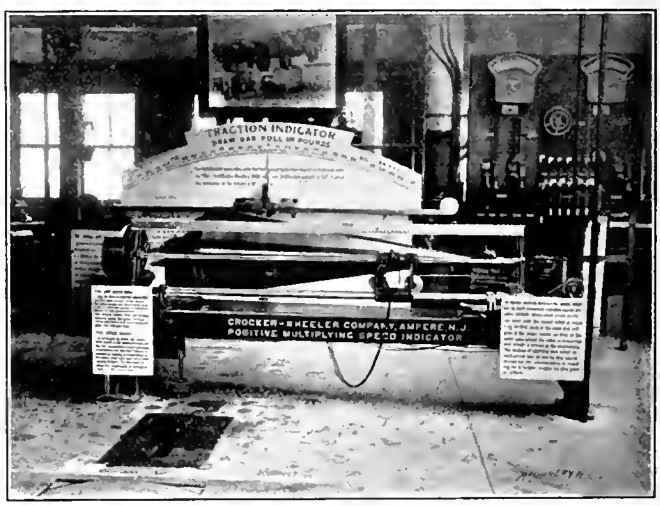

Fig. 4. Crocker-Wheeler Multiplying Speed Indicator.

At the left of the horse-power chart, Fig. 1, is a grade meter indicator, the object of which is to show the angle of inclination of grade that the car would climb if there was no wind resistance, slipping or track resistance. To use the grade meter, the sliding poise is set upon its beam at the point representing the weight of the car. This change of the sliding poise changes the point of contact of the beam with a horizontal ruler (between it and the board backing) that is raised and lowered by small wire cables from the traction indicator. The grade as indicated is proportional to the tractive effort, being expressed by the formula:

$$\text{sine of grade angle} = \frac{\text{tractive effort}}{\text{weight of car}}$$

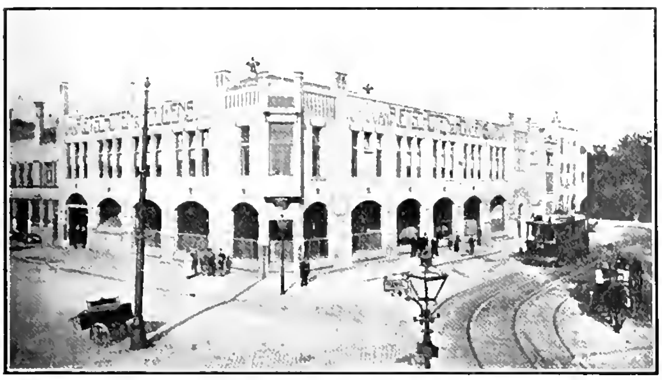
The indicator also shows the grade in per cent, the formula being:

$$\text{Grade in per cent.} = \frac{100 \times \text{pull}}{[(\text{weight})^2 - (\text{pull})^2]^{\frac{1}{2}}}$$

* * *

HANDSOME MACHINERY HOUSE IN ROTTERDAM.

The accompanying half-tone shows the handsome building recently constructed by Van Rietschoten & Houwens, Rotterdam, Holland, for a machine tool depot and showroom. The attractive appearance of the building is in decided contrast with the usual American structure built for such purposes. It was designed with much taste, and is a creditable ornament to any commercial district. It is built of hard pressed brick of light tint, the name of the firm being picked out near the top in dark-colored brick. Incidentally the half-tone shows the remarkable cleanliness of city streets in Rotterdam, this characteristic being common to Dutch cities. Holland suffered much in the depression of 1907 and money was at a high premium, consequently little business was done, and 1908 so far shows small prospects. Notwithstanding the discouraging times, the concern built these warerooms, believing that the "harder the times the stronger the push" should be. The sentiment is one well worth attention by American concerns.



New Machine Tool Depot and Showroom in Rotterdam, Holland.

* * *

Brass manufacturers are, as a rule, not very eager to use fluxes for protecting the metal, in melting, from the action of the air and the gases of the fire, because most of the fluxes used attack the crucible. The *Brass World* says, however, that there is no question about the value of the fluxes, and that glass has proved to be suitable for this purpose, and that it is used to a large extent by rolled brass manufacturers, who by this means are able to get their spelter loss considerably lower than one per cent. The reason for the excellence of glass as a flux in melting brass is that it does not become actually liquid, and therefore does not attack the crucible. It becomes pasty, and thus covers the metal, but is readily skimmed off, a difficult operation with a liquid flux. When the metal is ready to cool, the glass will be found on the top in the form of a soft "pan-cake," which may be easily skimmed off. The cheapness of glass and the fact that the crucible is not attacked, render its use attractive, and many manufacturers have been accustomed to employ it. Its good effects, however, are not generally known.

* * *

The beneficial effect of safety appliances is well exemplified by the results obtained by the constant application of means of prevention of accidents in British mines. Fifty years ago the death rate was 5 per 1,000 of the mine employes. Safety appliances, however, have gradually reduced this figure to 1.4 per 1,000 employes. While the difference between the figures fifty years ago and now may be greater in this industry than what could be effected in other less dangerous occupations, there is no doubt whatever but that nearly all of our industries could cut down their casualties to one-half, were proper appliances for safeguarding of life and limb universally used.

HEAVY SPIRAL CUTTING ON THE MILWAUKEE MILLER.

In Fig. 1 is shown a Milwaukee milling machine, built by the Kearney & Trecker Co., of Milwaukee, Wis., engaged in a milling operation on a piece of work which weighs something over $1\frac{3}{4}$ ton. This piece is the blank for a roll used for forming the tie-plate shown in Fig. 2. This tie-plate is rolled from a steel strip, and has flanges and ribs on its under side, and herring-bone corrugations on the upper surface. There is also a ledge on top for aligning the plate with the rail. All of these projections and grooves are formed by rolling. In the lower roll, of course, it is simply a matter of turning the proper shape on the surface of the roll. The upper roll is more complicated. It is shown diagrammatically in Fig. 3. The acting surfaces are composed of herring-bone projections, separated into sections by the triangular grooves which form the ledge for the flange of the rail. These grooves and projections are milled from the solid, and it was for this operation that the fixtures and attachments seen in place on the machine in Fig. 1 were made.

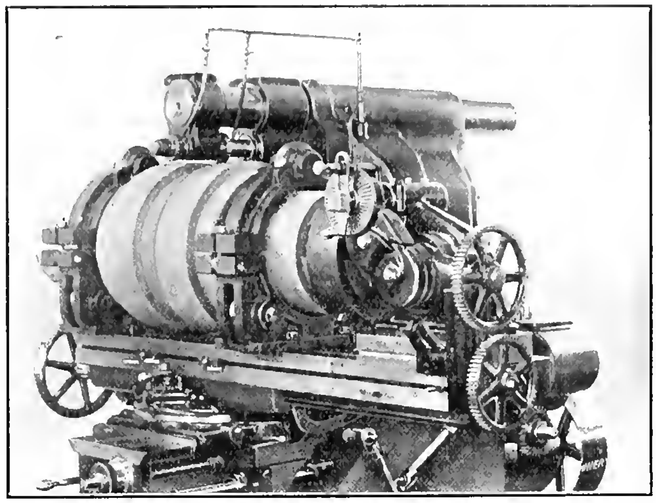


Fig. 1. Milwaukee Miller arranged for Cutting Cross-grooves in a Heavy Roll.

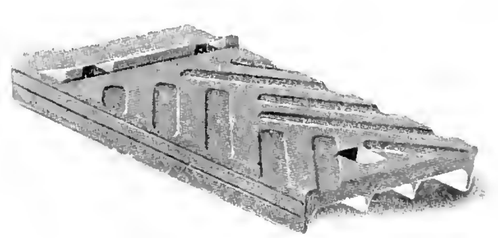

Fig. 2. The Tie-plate, which is the Product of the Roll.

It was seen that the work was so large as to exceed the vertical capacity of the machine. For this reason it is necessary to provide a supplementary cutter spindle which brings the arbor and cutter closer to the overhanging arm. This arbor is carried on special bearings clamped to the overhanging arm, and is connected by stout spur gearing with the regular spindle of the machine. As shown in Fig. 1, the machine is set with the table at right angles for cutting the straight cross grooves which form the ledge for the rail flange. The cutter for this operation is shown centered with the work.

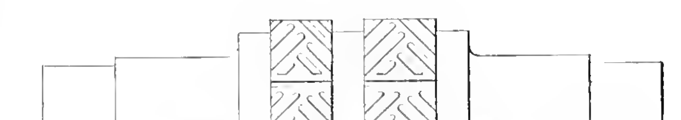

Fig. 3. Diagram of Acting Surface of the Roll.

The diameter of the roll was so great that it was necessary to block up the indexing head as shown. Owing to the great weight and size of the roll, it was, of course, impossible to support it by ordinary means. The arrangement devised for the purpose is clearly shown in Fig. 1, and in the line drawing Fig. 4. The work D is mounted in a pair of holders, built on the back rest plan, with bases E fastened to the milling machine table. The work is centered and revolved upon three rolls G on each side, two being carried by each base E, and the others by the upper portion F of each support, which is hinged so that it can be swung back out of the way for removing or replacing work. For taking the thrust in the spiral cutting operation shown later in Fig. 5, rollers H and H on each support are provided, bearing against the shoulder of the journals of the work. To obviate the necessity for accurately centering the work with the dividing head A, a flexible driving arrangement is used, consisting of a collar C clamped to the driving neck of the roll, and a fork or driver B, fastened to the nose of the dividing wheel spindle. This driver engages the block shown, pivoted to collar C. It will be seen that this arrangement allows for a slight misadjustment of the axis of the work either vertically or horizontally.

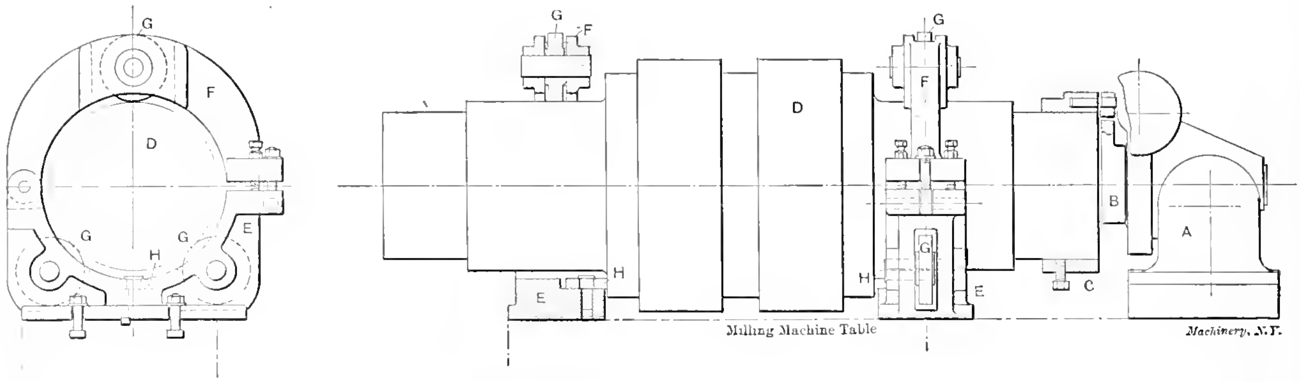

Fig. 4. Arrangement of Supporting and Driving Devices for the Roll shown in Place on the Miller in Figs. 1 and 5.

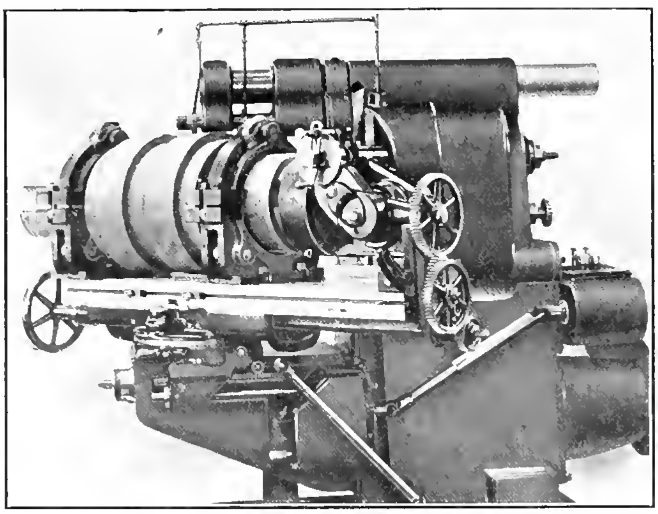

Fig. 5. Milling out the Stock from between the Herring-bone Projections of the Roll.

The device as arranged for milling the stock from between the spiral or herring-bone projections, is shown in Fig. 5. The same supplementary spindle is used as in Fig. 1, but the table is brought out to center with the work of the cutter on the opposite end of the arbor. Rollers H, shown in Fig. 4, now come into action in taking the thrust of the cut while the work is being revolved by the spiral mechanism of the miller.

The machine used is of the regular type built by this firm, which we have previously described in MACHINERY (see "New Machinery and Tools," February, 1907). The drive is through change gearing to give the required speeds and feeds, all of which are obtained from a single-speed pulley. Another feature of the tool is the provision made for constant lubrication of all important bearings by the use of an oil pump and piping system. So far as we know, this firm is the only one to permanently discard the cone pulley and back geared type of machine.

SPECIAL LATHE AND TOOL EQUIPMENT FOR TURNING CONE PULLEYS.

WM. F. GROENE.*

Perhaps some of our friends, who advocate all geared heads or single pulley drives, may consider the subject of this article an antiquated one. Still, here at the R. K. Le Blond Machine Tool Co., we yet have some faith in the cone pulley, and expect that this style of drive will continue to be preferred by most of our customers for some time to come. For this reason, we have been induced to design a machine for doing certain operations in our cone pulleys, and this machine we have recently installed in our shop.

The accompanying half-tones and line engravings, together with the following paragraphs of description, will make clear the construction and operation of this machine, and the tools used with it. The general principle of using multiple tools for turning cone pulleys is not a new one, by any means, but we believe we have embodied in this scheme features and details which are entirely new. The great aim was to produce work of a very high degree of accuracy and truth, at a reasonable labor cost.

The machine used (see Fig. 1) was one of our 30-inch lathes, with head- and foot-stock, "raised in the sand," to swing over the carriage the largest cone pulley we use. This includes all the milling machine cones, and all the lathe cones from 12 to 20-inch swing. The only alterations in the lathe consist in providing a forming attachment for crowning

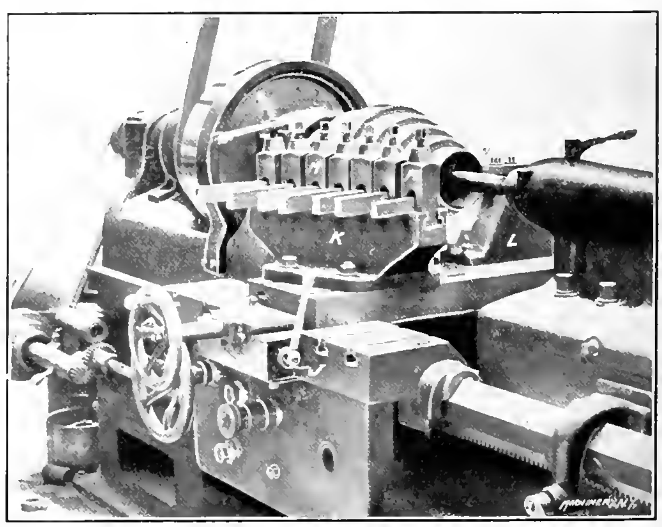

Fig. 1. Lathe with Special Forming Attachment and Tool-holder for Turning Cone Pulleys.

the pulleys, and a multiple tool-holder for finishing the various steps, together with means for holding and driving the work.

The forming attachment will be best understood by reference to Fig. 1, in connection with Fig. 2, which shows a plan and cross-section of the carriage. The cross slide screw A is not mounted in the carriage, as usual, but in a square sliding bar B, which is seated in a corresponding rectangular recess in the carriage dove-tail, over which the cross slide fits.

* Address: 1311 Delta Ave., Cincinnati, O.

This square bar B carries at its rear a pivot, on which is mounted a grooved pulley C, which, by a wire rope and a system of idlers, supports the weight D, which constantly tends to draw B toward the rear. A bracket E is fastened to the rear of the lathe bed, having a planed top with a T-slot, in which is clamped former F, which has an outline agreeing with the outline of the crown it is desired to turn in the pulley.

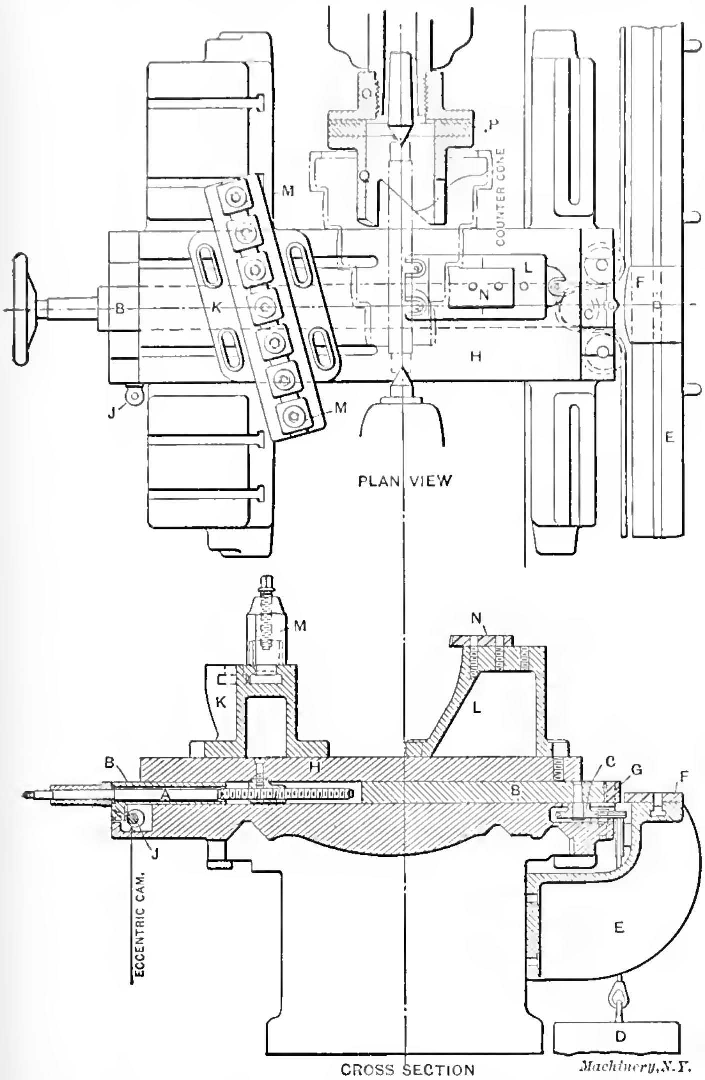

Fig. 2. Plan and Section of Carriage of Special Forming Lathe.

A finger, G, screwed to the rear of sliding bar B, (see also Fig. 4) is pressed in contact with this former by the weight D, so that B is moved in or out to agree with the contour of the former, as the carriage is operated to the right or left, carrying with it, at the same time, the cross feed screw A, and through A the cross slide H, carrying the tools. An eccentric cam J, whose handle is plainly seen in Fig. 1, bears on a downwardly projecting lug at the front of bar B, and is used to withdraw it against the pressure of the weight from contact with former F.

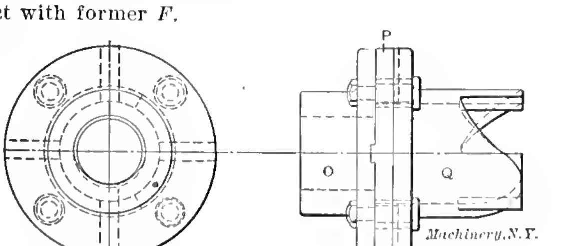

Fig. 3. Equalizing Driver used for Ribbed Counter-shaft Cones.

Two tool-holders are provided; the one in front, K, is set at an angle approximately corresponding to the angle of the cone. It carries a T-slot in its upper face, in which are placed a series of tool-posts M, each carrying a tool for one of the steps of the cone. The other tool-holder L is mounted at the rear of the work, and carries a forming tool N for finishing the steps.

The cones are first chucked true with the inside, in one of our 24-inch chucking lathes, and are then bored out with the turret tools. Then, while the outer end of the pulley is supported by a pilot held in the turret, the outside surface of the cone is scaled off all over, with tools held in the turret tool-post on the cross slide. No attention is paid to dimensions, the operator merely following the contour of the casting, taking off about 1/32 inch all over. The pulleys are then hand reamed, after which they are ready for the finishing machine.

The method of turning the counter-shaft cones is shown in Fig. 1, and is also indicated by the dotted lines of Fig. 2. The work is mounted on a plain lathe arbor, as shown, and driven by an equalizing device from the spindle. This compensating driver, shown in detail in Fig. 3, consists of a face-plate O, threaded to the nose of the spindle, an intermediate plate P, and a driver Q having three jaws, adapted to engage with corresponding ribs in the cone. The intermediate plate P has horizontal tongues, fitting loosely in corresponding grooves in O, at the left. At the right, it has vertical tongues, loosely fitting in corresponding grooves in the flange of Q. The clamp bolts which hold O, P and Q together fit loosely. It will thus be seen that Q adjusts itself horizontally or vertically, until all three of its driving faces are bearing with equal pressure on the three ribs of the cone, which is thus rotated absolutely without eccentric strain.

Seven tools are shown in place in the tool-holder, turning the five steps of the counter-shaft cone in Fig. 1. Of these seven, five are used to turn the five steps, while the other two are employed to finish the edges of the rim at the largest and smallest steps. The tools for turning are set to a master cone. The slide is raised from the former by eccentric J, the tools are set central with the face of the pulley, and the former is set central with the finger, this being done for each new piece of work. The carriage is then moved to the left, the eccentric released and a cut taken over the pulleys.

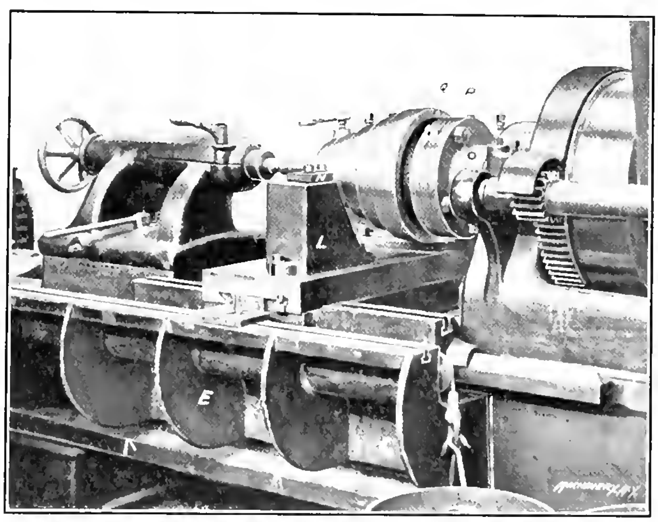

Fig. 4. Rear View of Carriage, showing Form Tool Holder and Form Copying Mechanism.

The next operation consists in scraping the surfaces of the steps with the flat forming tool N, mounted at the rear. This tool is ground to exactly fit the previously turned face of the pulley, and takes off about 0.005 inch, enough to remove the tool marks and give a fine finish. It will be seen that this forming tool also has a small lip formed on its left side. This is used for undercutting the sides of the cone steps for belt clearance. By moving this tool slightly sidewise, the proper clearance is cut. This tool, together with the former F, and the finger G bearing against it, are best seen in the rear view of the lathe in Fig. 4.

In turning the head cones, practically the same turret lathe operations are gone through with as in the case of the counter-shaft cones, the work being chucked and then roughed all over the outside to remove the scale. In addition, the inside is turned, and the step for the cone pinion is bored. The cone pinion is then pressed in, and the pulleys are ready for the finishing machine.

As shown in Fig. 5, the head cones, with the cone pinions

in place, are mounted on the shoulder arbor *R*, and held there by nut *S*. This arbor has a shank at one end fitting the tapered hole in the spindle, while in the other is driven a bronze taper bushing, running on a special hardened center *T* in the tail-stock spindle. The cones are driven from the face-plate *U*, screwed to the spindle, and provided with three driving pins, fitting accurately jigged holes in the inner flange of the cone. These holes are the ones made for the lock plungers.

It will be seen in Fig. 5 that only the four larger steps of the five are turned by the tools in the multiple tool-post. The former does not have to be set centrally with the work for each new piece, as in the case of the counter-shaft pulleys,

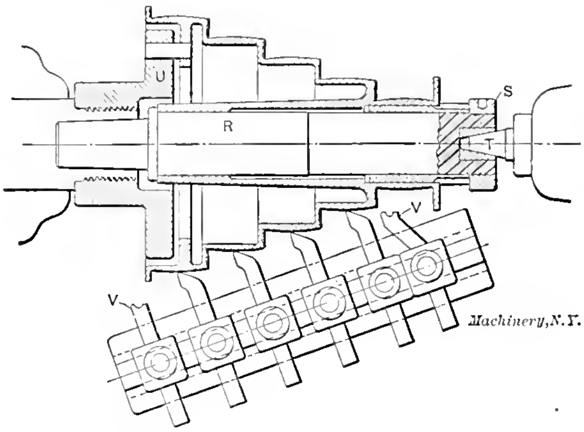

Fig. 5. Method of Driving Head Cones, and Layout of Tools.

since the work is located endwise by the shoulder on arbor *R*. Two extra tools, *V* and *V* are used for finishing the large and small end flanges of the cone. The forming tool *N*, in Fig. 2, is used as before, to finish the crowned surfaces and recess the sides of the steps for the belt clearance. In addition, it turns the periphery of the smallest step, the work being supported stiff enough at this point to allow this heavy forming cut to be taken.

The cones come true to within 0.002 inch, leaving an excellent finish; they require absolutely no filing and practically no polishing.

* * *

Work was begun on the first Hudson tunnel in November, 1874, and continued intermittently until the Hudson Tunnel Co. acquired the franchise and other valuable franchises for tunnels under the Hudson and contiguous shores. The first tunnel projected is rapidly nearing completion, and the opening to traffic from Hoboken to Hudson street took place February 25. Notwithstanding the fact that work was begun on the first tunnel under the waters surrounding Manhattan Island over thirty-three years ago, the first bore to be opened to the public is that under the East River joining Bowling Green with Borough Hall, Brooklyn. This tunnel was opened January 9, and is run in connection with the New York subway. Certain subway trains continue their trips into the Brooklyn district. The new service has to some extent relieved the Brooklyn Bridge congestion, and is the first step in providing more adequate transit facilities between New York and Brooklyn.

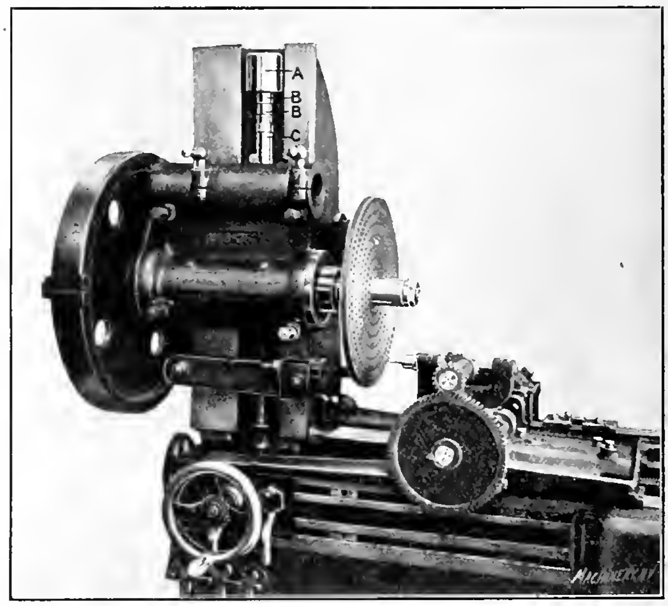
* * *

More than ten years ago, experiments were undertaken by the firm Gabellini, in Rome, Italy, to make boats out of reinforced concrete. Since that time, the firm has built a number of boats for different purposes from this material, these boats having a displacement of from 100 to 150 tons. The frames of the boats are constructed from reinforced concrete, and are covered on the outside and inside with a concrete covering, reinforced with wire netting, water-tight compartments being thus formed between the two layers of concrete. The outside is covered with pure cement, giving a highly finished surface. It is claimed that boats made in this manner have the following advantages over boats built in the usual manner: They can be built quicker and cheaper; the maintenance becomes smaller; they have a high capacity for withstanding outside forces; and, as compared with wooden boats, they are fireproof.

AUTOMATIC FEED-PLATE DRILLING ATTACHMENT.

The accompanying half-tone shows an interesting use for a Brown & Sharpe automatic gear-cutter, it being transformed into an automatic indexing and drilling machine. The scheme is in use in the new shop of the Mueller Machine Tool Co., Cincinnati, Ohio, and is employed for drilling the feed-plates of the variable speed box of the Mueller radial drill.

The drilling fixture is bolted to a No. 3 Brown & Sharpe gear-cutter, the cutter spindle of the latter having a large spur gear, mounted as shown, which drives the small pinion and the drilling shaft at high speed, through the medium of miter gears. The drilling fixture travels automatically back and forth with the machine carriage, in the usual manner, the same as when cutting gears. A lot of 50 or more feed-plates is usually drilled, all in the same circle, and then the index is changed to suit the next concentric circle of holes. The method of making the change is novel. The dial for elevating the dividing head is not used, but instead the exact measurements are obtained by the use of collars or bushings of the exact width required between the concentric rows of holes. A five-pound weight *A* is loosely fitted on top of the elevating screw, and when it rests upon the end of the screw it, of course, turns with the screw when the head is raised or lowered. Between this weight and the elevating screw nut there



Automatic Feed-plate Drilling Attachment.

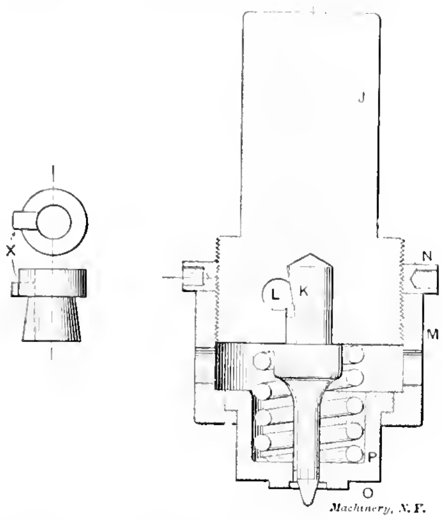
is placed a long collar or bushing *C* having a narrow space knurled. This collar has the exact length required for the elevation of the lower face of the five-pound weight above the elevating feed screw nut when drilling the largest circle of holes. When the next circle is to be drilled in a lot of plates, a collar 0.834 inch in length (which is the distance between the concentric circles) is placed between the long collar and the weight. The method of adjustment is as follows:

The operator holds the knurled collar with one hand and turns the hand-wheel with the other in the direction to lower the dividing head and work spindle. This causes the weight which is supported by the collar and the elevating screw nut, to descend until it touches the end of the elevating screw. The moment it comes in contact it begins to turn, thus notifying the operator that the limit of travel is reached. The same procedure applies for drilling the next concentric row of holes, one of the narrow collars then being interposed between the weight and the long collar. The illustration shows two of these collars on top of the long collar supporting the five-pound weight. It will be observed that the drill is in position for drilling the third row of concentric holes. This method of gaging the width between circles has been found to be close, it being easily possible to space them within 0.001 inch of exactness. It has the advantage of eliminating the mistakes which are always possible in reading graduations on a dial plate.

LETTERS UPON PRACTICAL SUBJECTS.

PUNCH PRESS FORMING JOB.

The accompanying cut shows a rather interesting piece of work done on the punch press. The work to be made is shown in an enlarged scale in Fig. 1. The operation performed with the tool shown consists in forcing the metal out on one side of the piece to form a key, as shown at *X*. The die of the device with which this is done consists of a cast iron block *A*, Fig. 3, bored to receive the tool steel ring *B*, which is tapered on the inside to fit spring collet *C*. The



Figs. 1 and 2. Enlarged View of Piece to be made, and Punch for Forming Key.

set-screw *D* acts as a key and allows the collet to move up and down, but prevents it from turning. The plate *E*, on the top, acts as a stop for the collet, which is forced upward by the spring *F*. Finally, four screws *G* fasten the ring *B* and the plate *E* securely to the die block. The plunger *H* is used for ejecting the piece, being actuated by the spring *I*.

In Fig. 2, the punch-holder is represented by *J*. Into this, tool steel punch *K* is fitted, the punch being driven into its holder, and secured by the taper pin *L*. The sleeve *M*, made

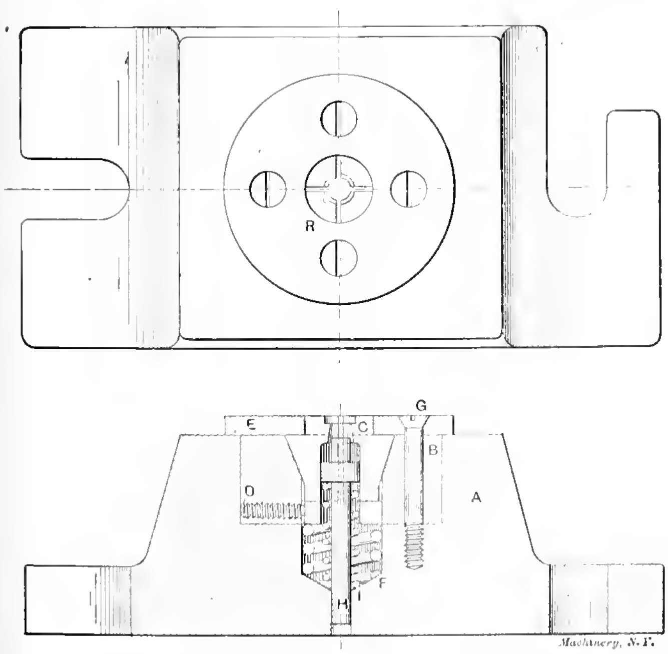


Fig. 3. Die for Forming Key on Piece shown in Fig. 1.

of machine steel, is threaded on the punch holder for adjusting the spring *O*. This sleeve is locked in position by the nut *N*. The cup-shaped piece *P* acts as a stripper, and also closes the collet *C*, Fig. 3, when the punch descends.

The operation of this punch die is as follows: The piece or work, as received from the automatic screw machine, is set into the collet, which is sufficiently open to admit the large end of the tapered part of the work to be put in. The press is then operated. The point of the punch enters the piece, bringing it concentric. The part *P* then strikes the collet, forcing it into the taper ring *B*, and thus the work is held securely while a shoulder on the punch strikes the metal on one side of the piece, forcing it out into the pocket *R*, in the collet, and by this means forms the desired key.

Candiac, Canada. S. A. McDonald.

WEIGHTS NOT THE EQUIVALENT OF SPRINGS.

Your editorial in the February issue reminds me of the experience of a friend who builds many kinds of hydraulic presses and who, one day, discovered a place in which a weight was by no means the equivalent of a spring.

Some of his presses are equipped with a by-pass valve designed to open when the maximum pressure is reached, and thus prevent accidents. This valve had always been held to its seat by a weighted lever, and had always "functioned" without trouble.

But one day he put to the shop test a press which he had built for a leather-belt manufacturer. It had a large platen for wide belts, and was designed to press together the cemented joints of leather belts in process of manufacture.

In such work the pressure in the cylinder would go up from practically nothing to the maximum, in something like half a stroke of the pump, and then the by-pass valve had to open quickly. It did this by bending the lever on which the weight was placed, the weight itself offering too much resistance to the very quick acceleration required.

The weight was replaced by a helical spring, which was the equivalent of the weight so far as holding the valve to its seat was concerned, but was a very different affair when there was a call for quick opening of the valve, because the mass of the spring was so small as to offer only a negligible resistance, and the valve, though held to its seat by the same pressure, was permitted to open as quickly as was necessary.

On the paper-perforating machine which forms a part of the "monotype" outfit for setting type, there is a suspended weight, which, by its descent, operates certain mechanism intermittently, as the keys of the machine are manipulated. But to the eye, the weight seems to descend, not intermittently, but with a perfectly steady motion when the keys are played rapidly. This is because a portion of the weight-suspending member is a helical spring, which, when the mechanism is released, contracts, and when the mechanism is stopped, expands. Thus the pull is practically uniform, instead of being very small at the beginning of motion and very heavy at the end of it, as it would be if the suspending member were rigid.

The result is another very pretty example of the fact that a weight and a spring are by no means equivalent. I think, generally, when the claim is made that they are equivalent it is meant for the particular case under consideration only; not that the one is broadly the equivalent of the other.

Center Bridge, Pa. Fred J. Miller.

DRILLING AND REAMING IN THE LATHE.

Your shop operation sheets Nos. 16, 17, and 18 show the old reliable way of drilling and reaming a hole in the lathe. Allow me to offer a quicker, more modern, and even more reliable method of performing said operation.

Take a lathe with a large hole through the spindle and fit to it an up-to-date 3 or 4-jaw geared scroll chuck. These chucks have been wonderfully improved in strength and wearing qualities, and are at present infinitely superior to the old style ring-and-pinion universal chucks. Fit a No. 2 or 3 Hartford or similar drill chuck to the taper hole of the tail-stock spindle, and we are ready to go ahead.

Put the work into the large chuck and face it true. Put a large combination center drill (one with a 7-16 inch body) in the drill chuck and run it in as far as possible—easily at first to make sure it runs true. Follow this with a 1/4, 5-16, or 3/8 inch drill, according to the size of hole wanted. By thus removing the stock which would otherwise have to be almost

pushed away by the point of the large drill, it is a comparatively easy matter to enlarge the hole to reaming size by means of a twist drill held by the same drill chuck in the tail-stock.

Now about the reaming: I have been told lots of times that a reamer held in the chuck would cut larger than standard, but my experience in this line has taught me that if everything is in line, as it should be, the hole will be straight, true, and as near to size as it is possible to get it by any method. The work may now be turned to size on the outside if required without further adjustment, and if you are one of those fortunate ones who know how to use a cutting-off tool without breaking it, you can finish the piece in one operation without rechucking or placing on a mandrel.

The one point which I would like to bring out most clearly is the utter fallacy (in my estimation) of feeding a drill, reamer or any boring tool into a revolving piece of work by holding it against a pointed center. H. J. BACHMANN.

New York.

LINING LOCOMOTIVE GUIDE BARS FOR LATERAL WEAR.

While visiting several railway repair shops during the past summer, I was particularly struck with the various ways in which the same job was performed. For instance, the manner of fastening liners to steel guide bars, for taking up lateral wear, was accomplished in some places by drilling clear through the guides, and then riveting the liners in place. This takes considerable time, and when a bar requires a liner on each side, some difficulty is met with in getting them both

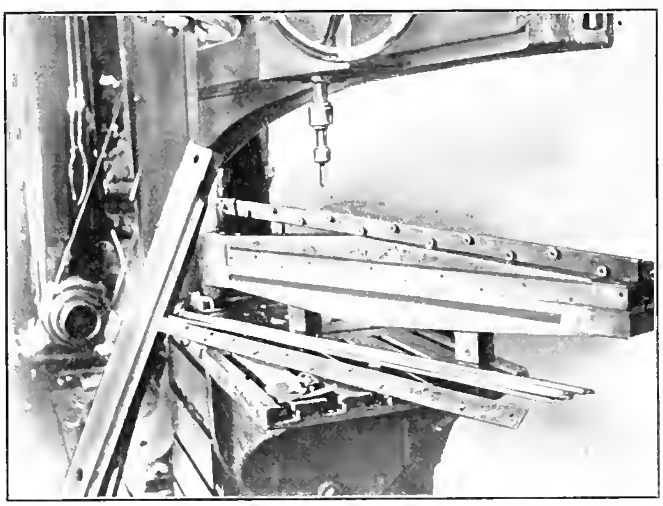

Fig. 1. Guide Bar planed for Liners, and Jig for Drilling the Liners.

tight when using the one rivet for both sides. Others drill and tap holes about one inch deep, then fasten the liner in place by screwing into these holes a length of threaded iron, which is cut off to proper length and then riveted. This does not always make a tight job, and frequently a tap is broken in a hole. Then again, others used countersink screws for holding the liners in place, or, instead of using liners, babbitted the sides of the guides. Of course, in all previously mentioned methods the bars had first been planed certain depths to make room for the liner. I was informed that the babbitted liners wore much longer than the original bar did, and were quickly put on and machined. If this is correct, I am inclined to think this method is better than the others mentioned.

After considerable experimenting, I find the method illustrated in the accompanying cuts to be very satisfactory. In Fig. 1 is shown a bar which has been planed for liners on both sides, the planed surface being 7/32 inch deep and 2 inches wide. Steel liners, 1/4 x 2 inches, are drilled to the jig shown, then clamped to the guide bars and the bars drilled with a 3/8-inch twist drill to a depth of 3/4 inch. A short twist drill that has been ground so that it is much smaller 1/8 inch back from the point than at the point, and also ground off the center, is inserted in the hole already drilled, and the hole drilled about 1/4 inch deeper. A drill ground in this way will produce a hole similar to the one shown in Fig. 2. After countersinking the liners with a long taper countersink, a 5/16-inch steel ball is dropped in the hole and either a brass or soft iron rivet is driven in. While riveting up the top end, the ball is forcing itself up into the slot, which has been sawed in the end of the rivet, causing the rivet to spread and fill the enlarged part of the hole. These liners, if of common rolled bar stock, should be planed after being riveted on; if cold rolled stock is used, this is not necessary, and the recess in the bars should be planed the proper depth

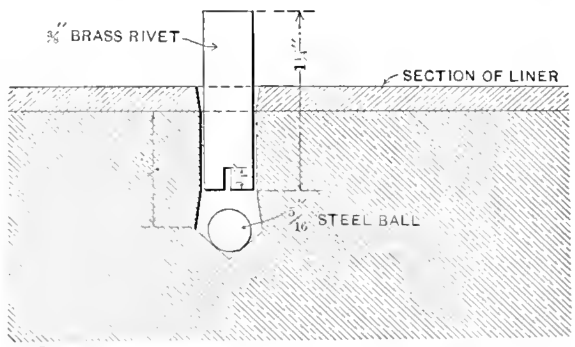

Fig. 2. Method of Fastening Liners to Guide Bars.

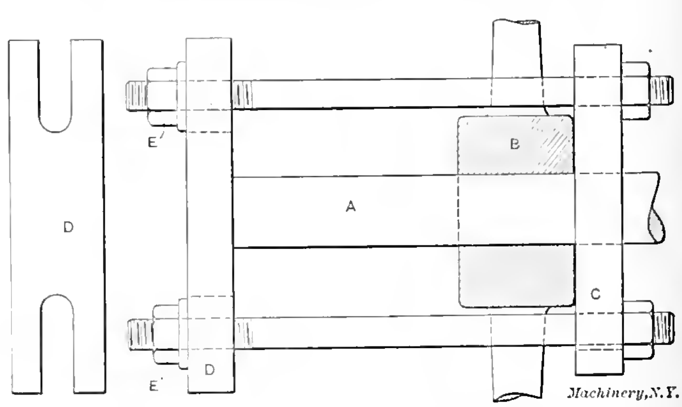
to suit the thickness of the liners. This is an inexpensive method ,as the steel balls used do not cost over one-half cent apiece, and there is no tapping of holes or turning and threading bolts or rivets. One end of the liner should be made to butt up against the cylinder head, and the other end to bear tightly against the end of the planed recess in the bar, thereby preventing any shearing strain being put on the rivets. While these liners are not so tight that they cannot be taken off by driving a flat chisel between them and the bars, still, properly fitted endwise, they have held for two years to my knowledge, or until they have had to be removed through wear. M. H. WESTBROOK.

Port Huron, Mich.

TO REMOVE PULLEYS FROM SHAFTS.

The first thing to do when pulleys are to be removed from shafts is, of course, to loosen the set-screws, if there should be any. These are sometimes rusted in, and in such a case it is necessary to use a wrench and pull with a steady pull to avoid breaking off the heads. If the heads of the screws should break off, the only thing that can be done is to drill out the screws. Should the screws be hardened, they can be annealed by means of a blow torch. To remove keys, procure a short, stiff key drift and a heavy sledge. Strike with as heavy blows as possible; light blows are likely to upset the end of the key and make it harder to remove. If it is found impossible to remove the key by this process, a key gun, such



Device for Removing Pulleys from Shafts.

as described in the December issue of MACHINERY, may be used to advantage. If nothing of this kind is at hand, a swinging ram, if there be room to work it, may be used. This may consist of a piece of round iron or steel about six inches or more in diameter, and two feet, or more, long. There should be two eye-bolts in the upper side of this bar, by means of which the ram is suspended from above by a rope, or chain, in such a position that it can be drawn back and swung against the drift. If the key cannot be driven out in this

manner, on account of lack of space, but it can be reached with a drill. It is then necessary to drill it out.

When the key is removed, if the pulley is not very large, or does not stick too hard to the shaft, it may be driven off with a swinging ram. Larger pulleys often have to be pulled off by means of a jack and a long chain; in such a case place the bottom of the jack on the end of the shaft, put the middle of the chain over the top of the jack, and hook the ends around two opposite arms of the pulley, provided these are strong enough to stand the strain; otherwise, place a heavy strap back of the hub, and attach the chain to this. When enough pressure is brought to bear on the jack, a blow with the sledge is likely to start the pulley.

Sometimes a more elaborate rig is required, such as is shown in the cut. In this, *A* represents the shaft; *B*, the hub of the pulley to be removed; *C* is a heavy U-strap; and *D* is another similar strap made as shown in the end view. The size of the bolts and straps used for this rigging, of course, depend upon the size of the work. Three-inch bolts are, as a rule, large enough for any ordinary work, and a wrench may be used, say 10 feet long. The outer ends of the bolts should have a long threaded portion, and suitable washers should be used under the nuts. It is plainly seen from the cut how the pulley is removed, the nuts *E* being tightened up until the hub of the pulley gives away from the shaft. If, however, the hub cannot be started by tightening up the bolts, it may be necessary to heat the hub. Waste dipped in kerosene, charcoal, or blow torches may be used, when necessary, for heating. The rim of the pulley may be protected from the heat by pieces of sheet iron, and the shaft should be kept cool with water.

When a heavy pressure is secured on the shaft, a jar with a heavy sledge is most likely to start the pulley. If, however, the pulley is still fast on the shaft, and no appliances for removing it can be easily secured, then the hub had better be split, and the hole wedged open far enough to let the pulley come off. The pulley can afterward be made "as good as new" by shrinking bands around the hub.

Portland, Me. H. K. GRIGGS.

DRIVING AXLE CENTERING TOOL.

The accompanying cuts illustrate a centering device which may be of interest to the readers of MACHINERY. This attachment is used in the Sedalia shops of the Missouri Pacific Railway. The idea is original, and I do not believe that this device is in use elsewhere. On account of heavy wheel lathe service, we are required to put a 60-degree center, measuring

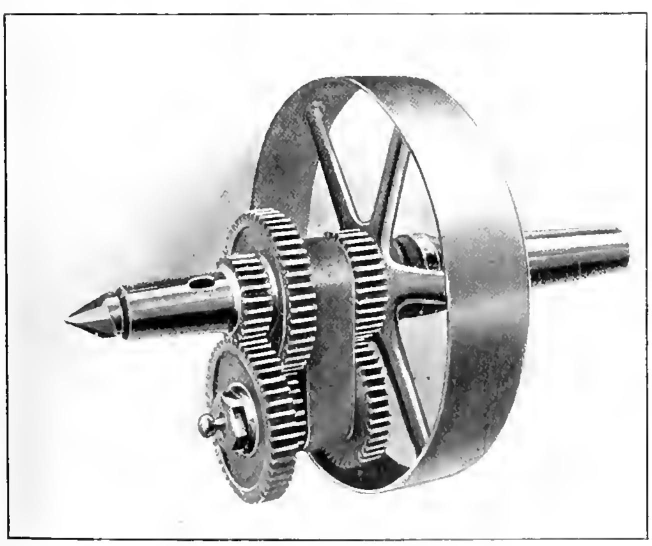


Fig. 1. Lathe Attachment for Centering Heavy Work.

1½ inch in diameter, in all locomotive driving axles. The process of drilling them in with a ratchet was too slow and laborious, and not having a regular centering machine, the attachment shown in Fig. 1 was devised. This attachment works perfectly, producing two large smooth-cut centers in fifteen minutes. The way in which this device is attached to a lathe is clearly shown in Fig. 2. The lathe center is removed, and the spindle of the machine is inserted into the tail-stock of the lathe. A separate counter-shaft is provided with a "Sim-Pull" starting device, and by changing the posi-

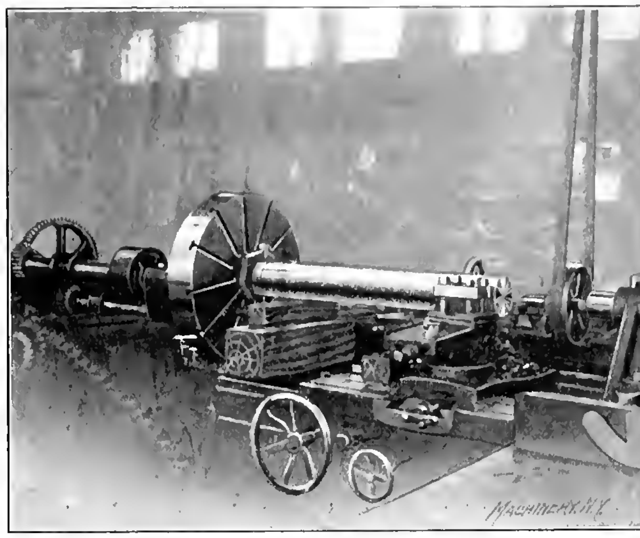

Fig. 2. Centering Tool attached to the Lathe.

tion of the pin *A*, shown in Fig. 3, two speeds are obtainable, one giving 75 revolutions for the countersink, and the other 300 revolutions for a ⅜-inch drill which precedes it. A 2½-inch belt is used for driving, and as there is but four inches

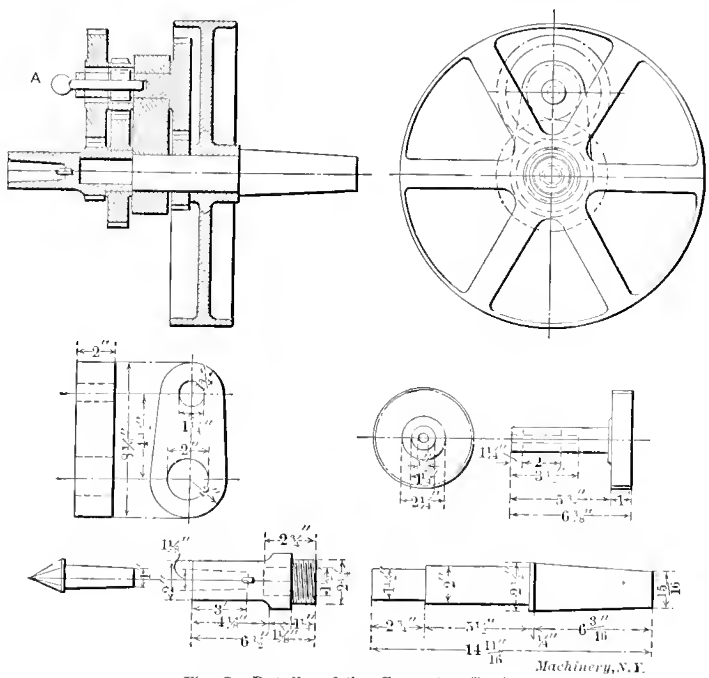

Fig. 3. Details of the Centering Tool.

difference in the length of all the axles in use here, a 10-inch face fully on the counter-shaft gives ample room for the variations. W. W. WILLIAMS.

Sedalia, Mo.

MAKING A SLEEVE WITH AN ACCURATE KEYWAY.

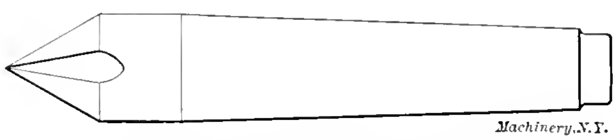
One day a job came up requiring the making of four high-percentage chrome nickel-steel sleeves, 9 inches long, having a 1¼-inch bore, with keyways 3/16 inch wide by 3/32 inch deep. The sleeves must be made so that they would slide on the shaft freely, and yet have no play. The bore was to be within 0.0005 inch of the correct size and the key way to be exactly parallel with the bore. This job was completed in the following manner. The bar steel for the sleeves was held in a chuck near the end and rough-turned on the outside, and provided with a 1 3/16-inch drilled hole. It was then taken out of the chuck and a 1-inch bore collet was fitted to the taper in the spindle of the lathe, and a cast iron boring bar holder fitted to the carriage and bored with a 1 inch drill, held in the chuck,

so as to be parallel with the head-stock. A piece of cold rolled 1-inch shafting was then provided with a square cutter held in place by a set-screw on the side and fed out by a set-screw on the top of the bar, acting on the end of the cutter. The sleeves were then rechucked and bored to 1.240 inch diameter, and then the cutter bar was inserted in the boring bar holder and brought carefully to the center, and the carriage clamped to the gib screws. A slotting cutter, ground to gage, was inserted in the bar, and the set-screw on the side was tightened just enough to hold the cutter firmly in place and yet allow it to be pushed out by the adjusting screw after each cut to provide for feed. The carriage was then run forward and back by hand, each cut taken being about 0.003 inch deep, using lard oil on the cutter. The sleeves were then placed on a mandrel and finished on the outside. The bore was lapped to size with a lead lapping bar cast on a tool steel mandrel, turned to about 1.180-inch in diameter. This procedure resulted in a perfect job.

Schenectady, N. Y. ROBERT MAYHEW.

CENTER USED WHEN FACING THE ENDS OF WORK.

I have been greatly interested in the letters in MACHINERY regarding the squaring of the ends of work on centers, and it may be of interest to some readers of MACHINERY to see the simple center that I use for this purpose. This center may not be new to everybody, but I have never seen this idea published in any trade paper before. On the side of the center is a half round groove as indicated in the cut. This groove



Center with Groove to receive Point of Tool.

is made by a round file, and while the efficiency of the center for ordinary work is hardly impaired at all, it is possible to use a tool that is quite blunt on the end when facing work; by feeding the tool to the bottom of the groove, the work can be cleaned perfectly at the end. The edges of the groove should be slightly rounded, so as to prevent all tendency for cutting or reaming the center hole of the work.

Newburyport, Mass. R. H. MARSH.

NOTES ON CENTERING.

The remarks by "Allan" in the October, 1907, issue regarding centering work for turning has just caught my attention, and I would like to add a few words. What "Allan" writes is all very good as far as it goes, but in my estimation "the half has not been told." The balance of the story is this: Keep handy a punch ground accurately to 60 degrees and fairly long and stout. After the center has been reamed, clean out the hole thoroughly, then set in the punch so that it stands vertical, and give it a hard blow or two with a fairly heavy hammer. To prove that this method is necessary, center a shaft, omitting the punching. Take a heavy cut half way over the piece. Turn it end for end and start another cut. Where the cuts meet, it will be shown that two ends of shaft are not concentric in nine cases out of ten. Now, take another piece and punch as described above, turn as in the other example, and you will find the result more satisfactory.

Another kink I always use and which I believe is not widely known (having been asked by different foremen more than once, "Now, what are you doing that for?"), is to grind a fine, narrow groove lengthwise on the dead center. Set the center with the groove on top or a little to the rear. This prevents disagreeable happenings in the shape of pieces dropping down between the lathe ways when you are loosening the center to oil it, or when the center gets hot. With this groove you can oil the center at any time and its life is much prolonged.

As "Allan" aptly remarks, the centering is of the utmost importance. The angle of centers must be perfect because of the extensive use of the grinding lathe in modern manufacturing, and the attendant changing of the shaft from one machine to the other. Where there is a grinder it is best to have a special collet or bushing in which to grind lathe centers. Some argue that a center should be ground while in place in the spindle, but in modern lathe building practice it is waste of time, for the center will invariably run true without having to be scratched or center punched to correspond to a certain place on the lathe spindle.

PLODDER.

[We are impressed by "Plodder's" faith in the absolute concentricity of lathe spindle taper holes with their bearings, but think that it is wise to demonstrate the fact on each lathe before accepting it as the gospel. In a later letter "Plodder" explains that the use of the special 60-degree punch is to condense the metal around the center hole and thus prevent rapid wear. If the practice is followed it is obvious that great care should be taken to set the punch perfectly in line with the piece being centered so as not to distort the center.—EDITOR.]

FACING WORK ON CENTERS.

Having noticed, recently, several suggestions relative to the facing of work on centers, it has occurred to me that a method I have used for some time may be of interest to the readers of MACHINERY. After drilling the centers and before countersinking, put the piece in the lathe and face as close to the center as is convenient with an ordinary side tool; then finish the center, cutting off the thin shell that is left around the drilled hole with the countersink. By this method one avoids using an extra center, and the work is square on the end before the countersinking is done, which is a considerable advantage, since, if such is not the case, the high side tends to push the countersink out of line with the drilled hole. Another way is to face the ends while the piece runs on punched centers, before they are drilled, and sometimes this does very well, saves a little time, and makes an end square enough for the purpose, but it is not as accurate as the former method, since it is not at all certain that the center, when finished, will have the exact location of the punched hole.

C. H.

A RULE FOR OBTAINING THE HEIGHT OF THE MIDDLE ORDINATE OF AN ARC.

In the December issue a correspondent asked how to obtain the height of the middle ordinate of an arc, having given the chord and the angle at the center. Here is my rule:

Divide half the chord length by the sine and by the tangent of half the angle at the center. The difference between these

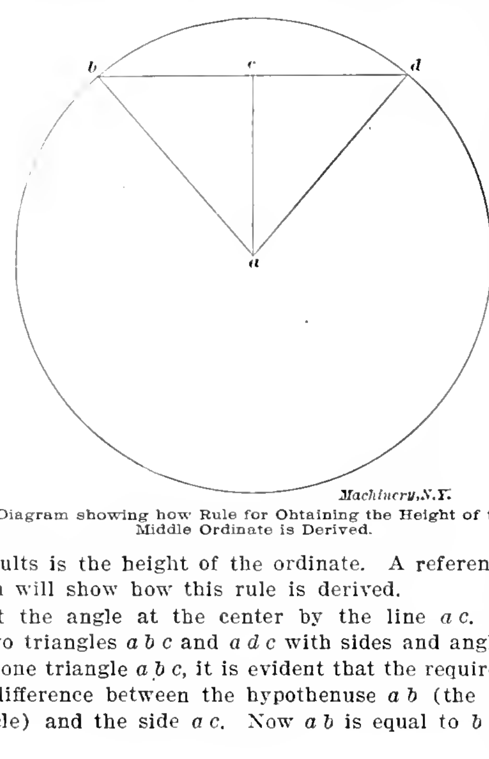


Diagram showing how Rule for Obtaining the Height of the Middle Ordinate is Derived.

two results is the height of the ordinate. A reference to the diagram will show how this rule is derived.

Bisect the angle at the center by the line $a\,c$. We now have two triangles $a\,b\,c$ and $a\,d\,c$ with sides and angles equal. Taking one triangle $a\,b\,c$, it is evident that the required height is the difference between the hypothenuse $a\,b$ (the radius of the circle) and the side $a\,c$. Now $a\,b$ is equal to $b\,c$ divided

by the sine of the angle $b\,a\,c$. And $a\,c$ is equal to $b\,c$ divided by the tangent of the angle $b\,a\,c$.

In the problem which you used as an illustration, the chord was equal to 10 feet and the angle at the center 36 degrees. Using these values, $b\,c$ equals 5, and angle $b\,a\,c$ equals 18 degrees. Now 5 divided by 0.30902, the sine of 18 degrees, equals 16.1801. You obtained 16.55 for this value. This was erroneous, the error being made in solving the equation $0.30902\,R = 5$. Dividing 5 by the tangent, 0.3249, we have 15.3892 as the length of the side $a\,c$. Subtracting, 16.1801 minus 15.3892 equals 0.7909 foot, the height of the ordinate.

F. M. S.

[The method given by F. M. S. is undoubtedly the more elegant of the two, although the operations are the same in number, *i. e.* three. It is generally easier to multiply numbers than to divide them, especially when the divisors contain five or six figures, part or all of which are decimals. For this reason some may prefer the method given in December.—EDITOR.]

SHADING DRAWINGS.

To what extent it is desirable to shade the curved surfaces shown on working drawings, giving more or less resemblance to the appearance of a wood engraving, is a question occasionally calling for a decision in the drawing-room. The question is usually decided by the chief draftsman in favor of no shading at all, in view of the appreciable amount of the draftsman's time required to do the extra work, involving an additional labor cost. The additional advantages of a judicious amount of shading is entirely lost sight of in the light of the extra drawing-room expense incurred. While it is important for commercial reasons that labor cost should be kept at a minimum, it is questionable economy to keep down this cost at the expense of absolute clearness, especially so when the resulting drawing may go distances varying from 300 feet to 300 miles, or more, away, passing into the hands of unknown workmen, with more or less doubtful ability to properly read and comprehend all of the details involved. There are many to whom the lines and details of a working drawing are a meaningless mass of confused lines and figures, entirely beyond comprehension, while a wood engraving is clearness itself, instantly presenting the object in an unmistakable manner, with the least possibility of misunderstanding. It is unquestionably a fact that the major part of all machine drawings would be a great deal clearer, easier and more quickly read were a judicious amount of shading properly done in their preparation. The slight extra cost being many times offset by the saving in correspondence and time used in asking questions, and in running about making the necessary explanations, which, were proper shading done, would be, to a large extent, eliminated.

Being in charge of drawing-room on a class of work requiring many complicated assembled drawings, which are distributed among men of varying degrees of ability in the quick and accurate reading of drawings, the need has been felt for some means of bringing out more clearly the forms of the various parts, which has been done with very satisfactory results by the adoption of a generous amount of shading of curved and irregular surfaces. This resulted in a very marked decrease in the number of inquiries received, and explanations necessary to be made, and also in a considerable saving in the time of a high grade man, which was formerly used to an appreciable extent in running around a large factory in the capacity of a walking encyclopedia. While it is not practical to duplicate a wood engraving in its completeness, yet there is undoubtedly a point between this extreme and that of the ordinary working drawing which it is economical to reach, notwithstanding the extra drawing-room cost incurred.

H. D. PENNEY.

Pittsfield, Mass.

[The time required in the drafting room to make simple shade lines to indicate the lower and right-hand edges of solids is time well spent. When a drawing is properly dimensioned, every distance that the workman will need to know being given, there can be no objection to such shade lines other than the time required to make them. The time dwindles into insignificance when the clearness and attractiveness of drawings properly shaded is taken into account. In the course of a year we see a great variety of drawings made by all kinds of draftsmen trained under all sorts of conditions. The difference in clearness is amazing, and it is easy to see that simple shading and proper cross-sectioning are really very important. The drawing that possesses snap and life is an inspiration, and it is a real pleasure to work from it. The unshaded drawing has a weakness and dullness that is discouraging. It requires more mental effort or concentration to understand it, and the chances for error of interpretation are greater, we believe, than with shaded drawings. As to shade lines for rounded surfaces, however, we doubt that they are generally advisable. Unless such shading is *very well* done, the result is decidedly amateurish in appearance. If it is well done the effect is, of course, pleasing and the subject stands forth clearly, but unless for some very special cases, we would not favor it.—EDITOR.]

GERMAN MANUFACTURERS HELPED ONLY BY REDUCED FREIGHT RATES ON EXPORTS.

In your leading editorial in the November issue, 1907, entitled "The French Machine Tool Trade," you claim that the German tool manufacturers receive an allowance from their government on all machinery sales for export. This statement is certainly not based on fact, and it seems to have emanated from certain sources which constantly endeavor to create ill feeling against the nation that is one of America's best customers.

The only way in which the German government favors export is by allowing a slightly more favorable *freight* rate on goods exported than on those imported, which, however, is quite a negligible quantity, and it certainly does not handicap the American builders. The import of American machine tools in Germany and other continental countries is, as you must be aware, more handicapped through the excessive American duties which have made treaties on a mutually fair basis practically impossible. The result is that American machinery has lately been deprived of the very advantageous tariff rates ruling under the "most favored nation" clause, and pays now here in German nearly double the former rate. I note that the National Association of Machine Tool Builders lately decided to maintain prices regardless of the falling-off demand; while such a move may be practicable in the United States, it is essential for the maintenance and development of the American machine tool trade in Europe that such artificial prices based on an excessive tariff and resulting high cost of material and labor, are not imposed upon the European market.

FAIRPLAY.

Charlottenburg, Germany.

WRITING TO GERMANY.

Referring to item on page 232, engineering edition, in regard to foreign postage for replies; why not use a postcard with paid reply (cost 4 cents), or get, at your local post-office, an international reply coupon for six cents, which will buy a 20-pfennig or a 25-centime stamp in the country of the receiver? United States stamps are of no use to Germans. What would Americans do with German stamps? If Americans would pay full postage on their sendings, it would be better. Many a letter containing an offer is refused because the addressee will not pay 40 pfennigs on a sending of unknown contents.

ROBERT GRIMSHAW.

Dresden, Germany.

HARDENING SPRING COLLETS.

In reading an article by Mr. J. J. Voelcker, in the December issue, regarding the making of spring collets, it occurred to me that it might be of interest to some of the readers of MACHINERY to know how the writer hardens them. I have been hardening tools of this character for the past eight years, and have had no trouble with breakage, which I attribute to slow and even heating.

In the first place, the collets are heated evenly all over, using a section of pipe closed at one end, if heating in a forge. I then take the collets, one at a time, put them on

end, and insert a taper plug in the hole, pressing it in until I get the required expansion, in a manner as shown in the half-tone, Fig. 1.

Sometimes one slot will not open as readily as the others, the reason for this being that the collet is slightly cooler in one portion than in other parts, making it somewhat stiffer. To overcome this, I insert a thin chisel in the narrow slot, carefully pressing inward until I get the slots about equally open. I then leave the plug in the collet until the latter is cold. When I heat them for hardening, I set them on end in the furnace. If heating them at the forge, I make a small taper piece of iron, about one inch long, and insert this in the hole at the jaws, previously having taken out the expanding taper plug. This small piece keeps the sections of the collet from closing up, which they naturally would do if placed on their sides in the forge. They should be frequently turned around in order to heat them evenly. When the collets are hot, the plug is easily and quickly pushed out from the back end with a rod or wire; then the collet is dipped into the bath.

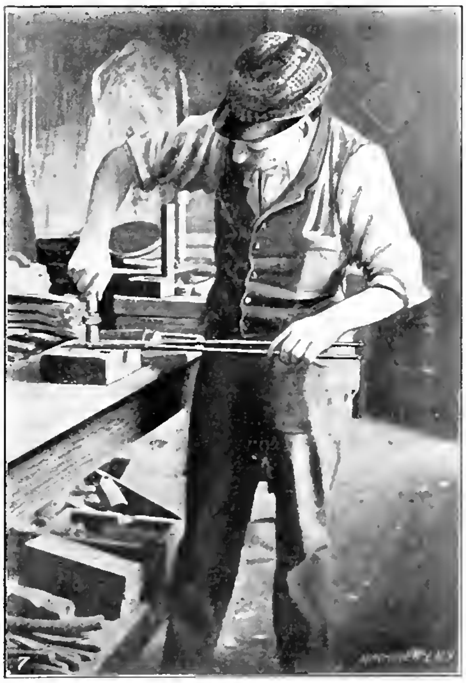

Fig. 1. Inserting Taper Expander into Collet.

When dipping, the collets should be immersed in the bath up to the shoulder or a little more, and when cold enough to have secured the necessary hardness, they should be withdrawn quickly from the bath and plunged in lard oil. When cold, they are polished from the shoulder to the back end, and then drawn to 400 degrees F. in the oil furnace; finally, the back end is drawn to a dark blue on a heated plate, running this color about half way up on the collet. Then the collets are cooled in oil.

Machine steel collets are expanded in the same manner, and then packed in a suitable box, as indicated in the line cut, Fig. 2, the packing consisting of a mixture of No. 2 raw bone and burnt bone, that is, bone that has been used once. The collets are packed in pairs, about one-half inch apart, and there should be about one inch of packing between the collets and the walls of the box. The cover is then put on the box, and luted with fire-clay. The box is then put in the hot furnace and heated slowly to 1300 degrees F., and kept at that temperature for about three hours. It is then removed from the furnace, the cover taken off, and the jaws of the collets plunged first in water and then in lard oil. When cooled off, the collet is polished, drawn to a deep blue, leaving the jaws as hard as when they came from the bath. Care should be taken that the heat does not exceed 1300 degrees F., as it makes the collets brittle if subjected to a higher heat. If the collet is a long one, the color is drawn to about 1½ inch above the end of the slots. The writer's experience indicates that machine steel collets give fully as good satisfaction as tool steel collets when the cost and the greater ease of making is considered.

It may be somewhat difficult to get the right heat when case-hardening the collets. A good method is to drill two or three holes in the top of the box and insert some nails long enough to reach to the center of the box. These nails can be withdrawn when it is estimated that the box is heated all through, the heat of the nails observed, and the heat inside the box estimated accordingly.

The box used may be made very simply and inexpensively from sections of 3, 4, 5, or 6 inch pipe, as the case may be, and should always be two inches longer than the work to be hardened. A cover is welded on one end, and the other end has a cover with a lug or eye riveted to the center, making it easy to handle. These pipe boxes, if flattened, as shown

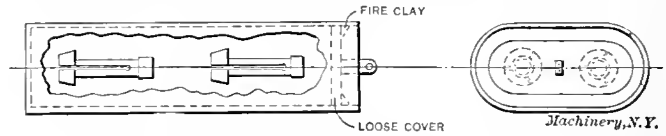

Fig. 2. Method of Packing Machine Steel Collets for Case-hardening.

in Fig. 2, become somewhat more useful. It is well to pack the collets with the back ends toward the open end of the pipe, as it makes it easier to take them out and dip them. Care should be taken, when pulling out the collets not to uncover those still remaining, but if one of them becomes exposed, cover it with hot bone dust, so as to keep the heat until ready to remove the next collet. GEO. T. COLES.

Decatur, Ill.

KILLING MEN AND FINING EMPLOYERS.

As to killing men and fining employers, referred to in the December issue on page 233, engineering edition, the majority of fatal accidents are caused by the men. As a boy I lived near a gunpowder works. The men were forbidden to enter a grinding mill before stopping the machinery from the outside; to wear boots with iron-pegged soles; or to use iron hammers in coopering up the powder. They did all three (smuggled iron hammers in under their blouses) and caused many explosions. They wrecked part of 15th Street, Wilmington, Del., by smoking in one of three eight-mule wagons loaded with gunpowder. I have known workmen in rubber-mills to put pennies on the rolls and bet 10 cents that they could get them out before they went through. Sometimes they didn't, and lost an arm. ROBERT GRIMSHAW.

Dresden, Germany.

DIE FOR BENDING COLD ROLLED STEEL PIECES.

The tools shown in the cuts herewith are designed for bending ⅜-inch round cold rolled steel pieces to the shape shown at *E*, Fig. 1. The chief consideration in the manufacture of these parts is the reduction of the cost, and the elimination

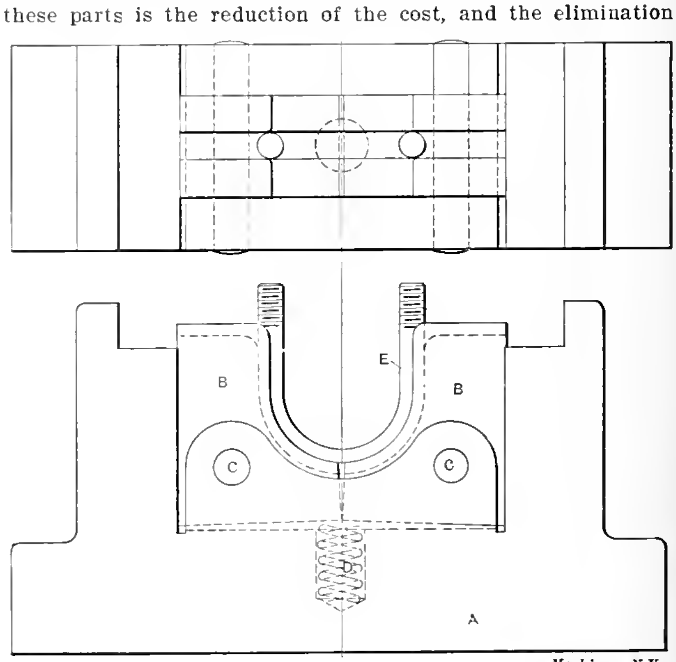

Fig. 1. Die with Completed Work in Place.

of as many operations as possible, yet maintaining the accuracy required, which, in this case, is very close, the opposite sides of the work having to be almost parallel, the ends not to be spread more than 0.002 inch. The type of die shown, for bending the piece in one operation, is being applied with great success, and can be highly recommended for its pur-

pose. While the tool was devised primarily for the purpose of bending the work mentioned, it can be used to advantage for flat work of similar shape, especially for metals of an elastic nature, when it becomes necessary, in order to obtain desired results, to make allowance for the spreading of the ends after bending.

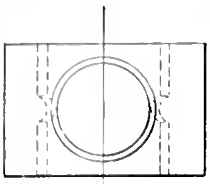

Fig. 1 shows the die, consisting of the cast iron holder *A*, the upper parts of which are machined to act as a gage for the stock, the steel jaws or dies *B B*, which are made of tool steel, hardened, and ground to dimensions, and have the holes lapped to an easy fit on pins *C C*; and the spring *D*, which is required to open the die as the punch ascends. The holder should be machined to permit the opening of die sufficiently to release the work, and permit the easy removal of the finished piece by the operator. Fig. 2 shows the punch, made of high carbon steel and hardened, and having a groove on the sides and lower end, of a radius to accommodate the work. The cuts show very plainly the construction and action of the device. It may be further stated, however, that, in adjusting the press ram, it should be brought down sufficiently to tip the die members, and bend in the ends of the work a certain distance. This is required to compensate for the springing back of the metal when the punch ascends.

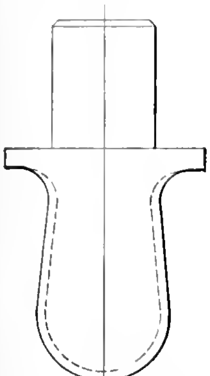

Machinery,N.Y.

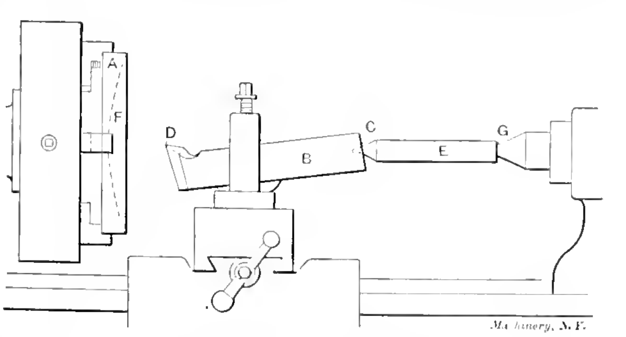
ENGINEER.

FACING CONCAVE WORK IN THE LATHE.

It is quite often necessary in machine shop practice to turn out concave disks for various purposes. This work of course, can be done on turret lathes with the aid of forming tools, but the manufacture of an outfit for this purpose is too expensive when only a small number of pieces are to be made. The following method will be found to be very satisfactory and cheap, as the apparatus, if constructed properly, will finish the work so closely that it will require little or no scraping to fit it to gage: Chuck the piece *A* in the required position, and after centering the tool *B* at a point *C*, set the tool so that points *D* and *C* are in line with the head- and tail-stock centers. Take a piece of cold rolled steel *E* the same length as the radius of the concaved surface *F*, and point one end the same as a center, and center-drill the other end. Move carriage of lathe so that tool *B* is close enough to the work to take a cut of sufficient depth. Place the point of the piece *E* in the center *C*, and draw up the



Machinery, N.Y.

Facing Concave Work in the Lathe.

tail-stock bringing the center in *G*. Clamp the tail-stock securely. Start up the lathe and feed the cross-slide either by hand or power. The piece *E* may be made in two parts by using a right- and left-hand union nut with check nuts to hold the union nut in position. This will allow of adjustment in the piece *E*.

W. J. SANSOM.

Madison, Wis.

[Of course it will be seen that if the lathe has a compound rest it is not strictly necessary to place the radius piece between the end of the tool shank and the tail-center, although this is the most convenient position, no doubt. We, therefore, venture to suggest a variation of this ingenious scheme that has an obvious advantage. If we make the radius piece pointed at each end, and support it in prick-punch marks in the cross-slide and tail-stock base, it will guide the tool point in exactly the same arc as though used in the manner illustrated, provided it is properly aligned to begin with. This being so, the same plan may be followed in turning convex surfaces, by simply placing the double point radius piece between the cross-slide and the head-stock. It will not work so well because the pressure of the cut will tend to push the carriage from the radius piece, whereas on concave facing the pressure of the cut is against the radius piece. However, for light finishing cuts it should work fairly well.—EDITOR.]

CONSTANTS FOR FINDING SPEEDS OF DRILLS.

The accompanying table contains constants which have been figured for facilitating the calculation of the speeds of drills. These constants will be found useful for finding the speed in feet, when the number of revolutions is given, or the number of revolutions, when the speed in feet is given. Thus, the figure in the column opposite the size of drill will, when multiplied by the number of feet per minute, give the required number of revolutions for the given speed in feet for this size of drill. Used in the reverse order, when the number of revolutions is given, dividing by the number opposite the size of drill will give the speed in number of feet per minute. Suppose, for instance, that it is wanted to run a 3-inch drill, at 40 feet per minute; then, multiplying 40 by the constant 1.27, given opposite the size of drill in the table, gives us 50.8 revolutions per minute. In the same manner, if it were known that a drill was running at 51 revolutions per minute, by dividing by the constant 1.27, for a 3-inch drill, we would get the running speed as 40 feet per minute, approximately.

TABLE OF CONSTANTS FOR FINDING SPEEDS OF DRILLS.

Worcester, Mass. PETER PLANTINGA.

COMMENT ON UNIVERSAL VISE.

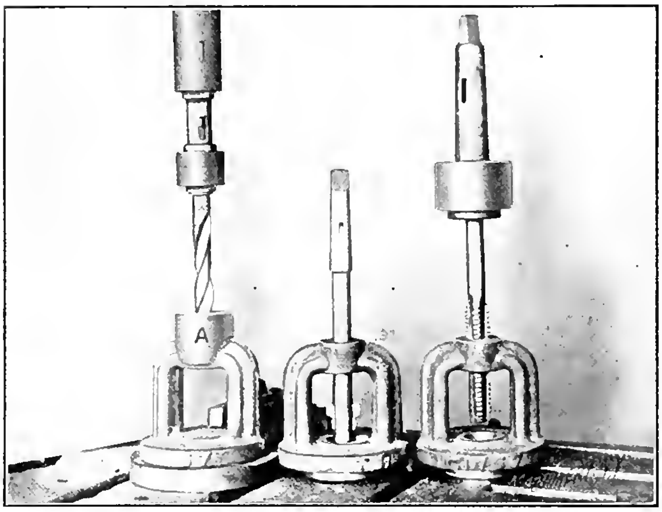
A machine vise having a ball and socket joint like that illustrated in the January issue of MACHINERY was used by the writer in 1887 in Battle Creek, Mich. The vise was employed principally in drill press work, and while the idea was apparently all right from a theoretical standpoint, the thing did not work satisfactorily in practice. In leveling up work, a blow of the hammer in one direction nearly always caused the vise to go down in a slightly different direction, making it a tedious job to get a piece of work properly adjusted. The trouble was probably due to some irregularity in the ball. In making such a vise, the ball should be turned in connection with the compound rest, or with a ball-turning attachment. If neither of these is available, the gage that is used to test the ball should be bored true in the lathe rather than filed to marks. The bearing in the socket may be made by pouring babbitt around the ball, and probably it would be a good idea to tighten the clamping bolts slightly while the babbitt is cooling.

W. S. LEONARD.

Atlanta, Ga.

DOING LATHE WORK ON A DRILL PRESS.

The accompanying cut illustrates how a cast iron hydrant yoke, which was formerly machined in the lathe, is done on a drill press with a great saving in time and money, the cost being reduced from fifty cents to five cents each. By referring to the cut, the method of doing the work will be readily understood. First a cast iron plate was turned to fit the hole



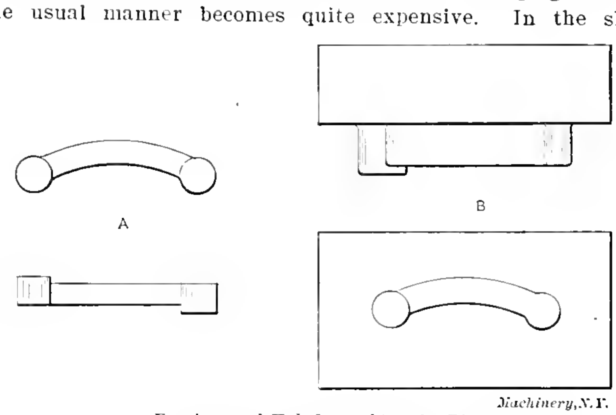
Method of Drilling, Boring and Tapping Hydraulic Yokes on the Drill Press.

in the drill press table, and the upper surface of the plate recessed to receive the projecting bottom of the yoke. When a yoke is to be machined this casting is driven into the table, and the yoke securely bolted to it. The steel cap *A*, which fits around the boss on the yoke, is then placed on it as shown, and a hole drilled central for threading. A bar is then put in the spindle and passed through the hole, and a high-speed steel cutter is inserted into the slot, and the stuffing-box bored. Next, the special tapping socket is put in the spindle, and the hole tapped, the tap being taken out through the hole in the table. The base-plate and table are securely fastened in one place during the operation, and it is not necessary to move the drill spindle sideways after once starting the job. The castings were afterwards placed on a mandrel and the bottom faced off in a lathe. This is but one of many instances where I have found that by paying attention to special devices, I have been able to do good every-day lathe work on the drill press at less than one-fourth the cost.

Port Huron, Mich. M. H. Westbrook.

HOB FOR FORGING DIES.

In the accompanying cut, a forging of which a great number is to be made, is shown at *A*. As dies for making this forging, it being produced in such great quantities, have to be renewed quite frequently, the making of forging dies in the usual manner becomes quite expensive. In the shop



Forging, and Hob for making the Die.

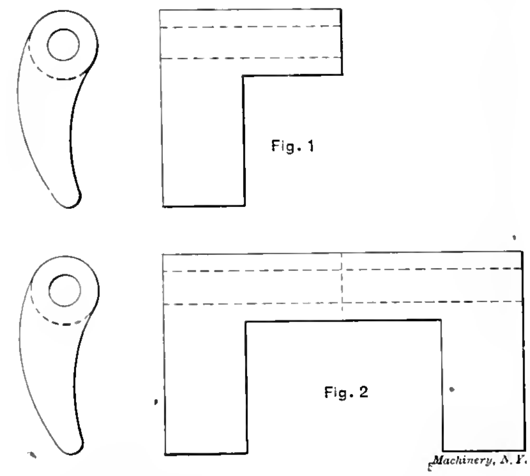
where these pieces are manufactured, however, the expense of making new dies is greatly reduced by making a hob, such as shown at *B* in the cut. This hob is made of tool steel and hardened, and has a projection of exactly the same shape as the piece to be forged.

The block for the forging die, in which the shape of the piece to be made is to be formed, is placed, together with the hob, in correct relationship in a hydraulic press, and the hob forced into the die block the required depth by hydraulic pressure. By forcing the hob into the die block, the metal displaced is thrown up around the side of the hob. This surplus metal is removed, and the die is hardened. By making dies in this manner, it is possible to renew the dies at a fraction of the cost of dies made in the ordinary way. For irregular shaped forgings it is sometimes necessary to make two hobs, one for the top and one for the bottom die. Fred R. Carstensen.

Montreal, Canada.

AN EXAMPLE OF MISPLACED ECONOMY.

The accompanying cut shows an example of how the mad rush to try to accomplish a saving in the cost of a product, when accompanied with too little forethought, often plays a trick on its originator and causes an additional, rather than a reduced expense. Things of this kind, perhaps, do not happen very often, but the case in hand has actually taken place



The Piece to be made, and the way the "Saving" was accomplished.

in one of the largest machine shops in the country. A little detail, such as shown in Fig. 1, was required to trip a lever on an automatic machine. The foreman of the department detailed to make these pieces, who, by the way, receives a liberal allowance on the contract price for the work carried out, provided he can cut down the expense of producing the work to a low limit, conceived a brilliant idea of making these pieces "two in one." The pieces were first to be drop forged, being finished only on the portions that worked against other surfaces, and he placed an order for drop forging dies to make pieces such as shown in Fig. 2. When cut apart in the middle, on the dotted line, there would evidently be two pieces made practically at the cost of one, if the price of material is not considered. Enormous quantities of these little details were drop forged, machined, drilled, cut apart, and case-hardened, when it was finally detected that one-half of the number of pieces became left-handed, and therefore, by necessity, had to make a bee-line for the scrap box. T. O. Olmaker.

TOOLS MADE FROM FILES SHOULD BE ANNEALED.

Among the "Practical Don'ts for Machinists" published in the January, 1906, issue, we found one that said: "Don't forget that a fairly good center-punch can be made from a piece of round file." This statement should be qualified by the caution that the end which is to be struck with the hammer should be annealed. The danger of striking hardened steel with a hammer is well known. Three machinists with whom we are acquainted here in Waterbury each lost an eye by striking hardened steel with a steel hammer.

Waterbury, Conn. Henderson Bros.

[The above caution applies to almost all tools made from old files. The temper should always be drawn before they are used, if subject to hammering, like a center-punch, chisel or other percussive tools, and preferably for any purpose, on account of the brittleness of the tool if left "file hard."—Editor.]

FINISHING PISTONS AND PISTON RINGS ON THE GISHOLT TURRET LATHE.

The making of pistons and piston rings for gas engines, particularly for automobiles, is done on so large a scale that the expenditure of considerable thought and time is warranted in designing the tools, fixtures and machines by which the work is done. Figs. 1 and 2 show the operations developed by the Gisholt Machine Co. of Madison, Wis., for doing this work in its turret lathe. As will be seen from the engravings and the following description, the tools used are simple and inexpensive, and the operations comparatively few.

As is often advisable with work done in large quantities, the rough castings are made with extra projections so arranged as to assist in holding the work, these extraneous parts being removed when the piece is completed. In the case shown (Fig. 1), a ring, about 1¼ inch long and of a diameter a trifle less than that of the piston itself, is formed at the head end of the piston. The piston *A* is held in suitable chuck jaws *B* by the inner diameter of this ring. The set-screws in these special jaws are then set down on the work, clamping it tightly between the points of the screws and the jaws, in such a way as to make it safe to take heavy cuts on the outer end of the long piston without loosening it. It will be seen that this method of holding, besides being secure, also permits the whole exterior of the piston to be turned, since all of it projects beyond the chuck jaws. This is the object aimed at in providing the piston with the ring by which it is held.

The first operation, which is shown in action in Fig. 1, consists in rough-boring the front end of the piston. The double-ended cutter *N* is held in boring-bar *M*, which is in turn supported by a drill holder, clamped to one of the faces of the turret. This bar is supported in a bushing in the drill support shown, which is attached to the carriage, and may be swung into or out of operating position as required. After this cut is completed, the turret is revolved half way around and the piece is finish-bored in a similar manner, with double-ended cutter N_1 held in bar M_1, the drill support being used as in the previous case. The support is then turned back out of the way to allow the turning tools in the turret tool-post to come into action.

The outside diameter of the piston is next rough-turned with tool *K* in the turret tool-post, which is revolved to bring this cutter into action. The post is then turned to the position shown, in which the outside diameter of the work is finish-turned by tool *J*, which takes a broad shaving cut. The turret tool-holder is again revolved to bring form tool *L* into position for action. This cuts the grooves in which the piston rings are to be located. Suitable positive stops are, of course, provided for both the longitudinal and cross movements of the turret tool-post.

In the second operation, the work *A* is reversed and held in soft jaws, which are used in place of the hardened jaws *B* shown in the illustration. These jaws are bored to the outside diameter of piston *A*, so that when closed, they hold the work truly with the first chucking. In this operation, the chucking ring by which the piston is previously held is cut off, and the end of the piston is faced. If the crank-pin hole is to be finished, still a third operation is necessary, a self centering chuck-plate and the necessary boring tools being used for this. These are not here shown, however.

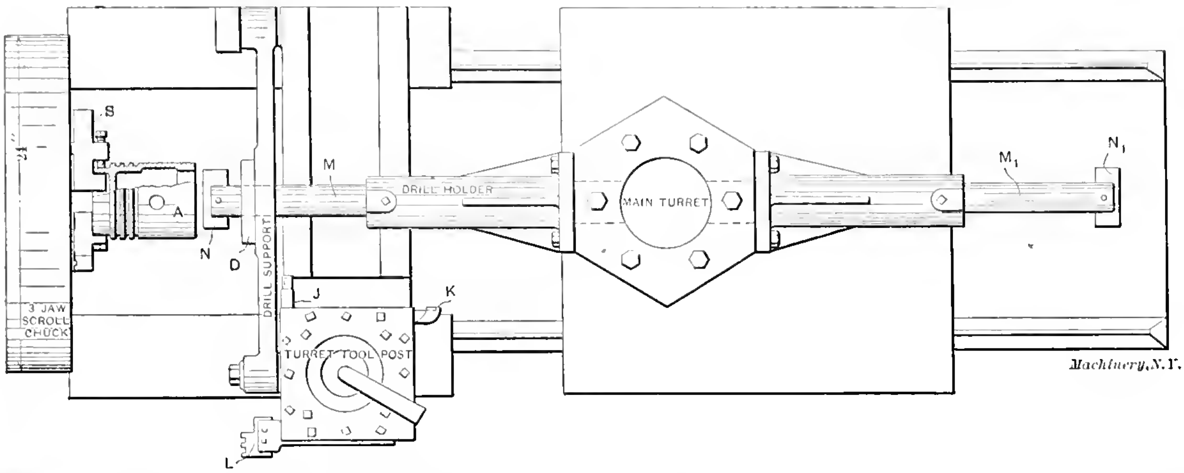


Fig. 1. Method of Boring and Turning Pistons in Gisholt Lathe; note the Ring cast to the Work, by which it is held, and the Special Chuck Jaws used.

The method of making piston rings is shown in Fig. 2. In this case, as in the previous one, the casting is one having a special form to facilitate holding it in the turret lathe. The piston rings are cut from a cast iron cylindrical piece which has three lugs (seen at *B* in Fig. 2) cast on one end and so arranged that they may be held by these in a three-jawed scroll chuck. This cylindrical piece is about 10 inches long, and when the rings are to have their inside and outside surfaces concentric, the casting is held by them in the regular jaws furnished with the chuck. The arrangement used for eccentric turning and boring, which is that shown in the illustration, will be described later.

The casting *A*, from which the rings are made, is first rough-bored with double-ended cutter *N* in boring-bar *M*, after which it is finish-bored with cutter N_1 in bar M_1. While taking these cuts, the bars *M* and M_1 are supported by their for-

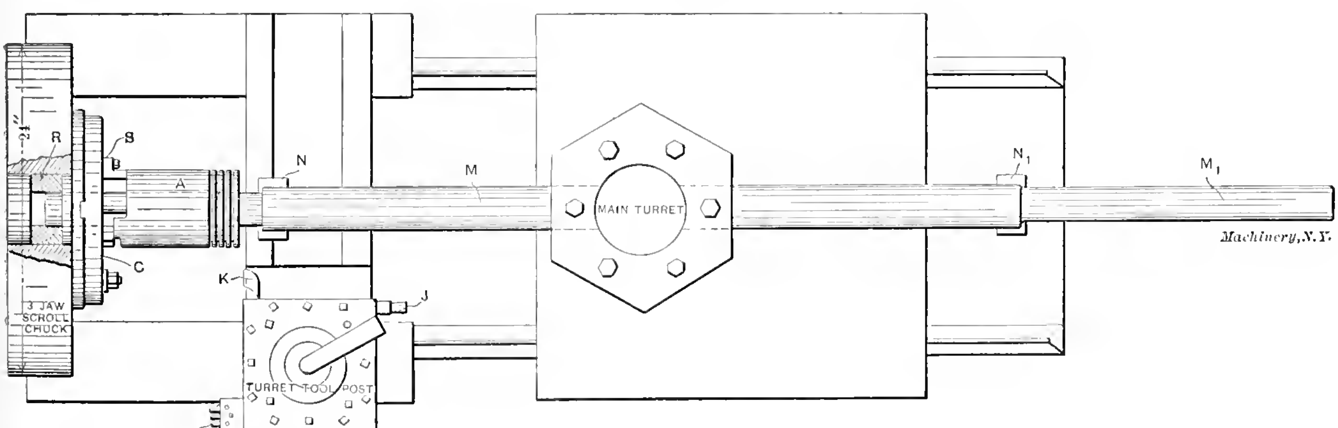

Fig. 2. Special Chuck and Tools for Turning, Boring and Cutting Off Eccentric Piston Rings in the Gisholt Lathe.

ward extension in bushing R, located in the central hole of the chuck. This furnishes a rigid support for the cutter, so that a heavy chip can be taken.

The periphery of the piece is next rough-turned with tool K, held in the turret tool-post. This tool-post is then revolved to bring tool J into action, by which the outside of the work is turned true to size, a broad shaving chip being taken. The turret tool-post is again swung around, to bring the cutting-off tool-holder L into use. This, as shown, contains four blades set the proper distance apart to give rings of the desired width. Each blade is also set a little ahead of the preceding one, so that the rings are cut off one after the other, each ring supporting the cut being taken on the outer side of it, until that cut is completed. After the first four rings are cut off, the carriage is moved ahead again to a second stop, and four more rings are severed, the operation being continued until the casting A has been entirely worked up into rings.

When the bore of the ring is to be eccentric with the periphery, the holding arrangement shown in the cut is used. The casting A is bolted to a sliding chuck-plate C, and the periphery is rough turned with tool K in the tool-post. Finishing tool J is then brought into action, and the outside diameter is turned accurately to size. Then the sliding chuck-plate C, carrying the work, is moved over a distance equal to the eccentricity desired, and the work is rough bored with cutters N and N_1 as in the previous case. The turret tool-post is next revolved and the cutters L brought into play, when the rings are cut off, as before. The reason for finishing the periphery first in this case is apparent. To secure good clean work in cutting off, this operation should evidently be done when the work is running concentric with the bore, rather than with the exterior surface.

It will be evident that this method gives a far greater out put of rings than is possible by finishing them in the more primitive way on engine lathes. The faces of the rings may be finished in a second operation if desired, or they may be ground, depending on the method in vogue in the shop where the work is being done.

SHOP ELEVATORS, AND OTHER THINGS.

CON WISE.

A few months ago I went into two shops in the same city. At the first one I found a sign at the door "Blank Mfg. Co. upstairs." At the top of the first flight I found another just like it and so on till at the top of the fourth I read the welcome one, "Blank Mfg. Co., one flight up." Needless to say the discounts that I had planned to offer grew less at each sign, and if I had been buying instead of selling, I would have given up the climb altogether. When I arrived, I tried to get a chance to look around the factory. I was not refused, but it was painfully evident that it was an unusual thing for them to see a visitor in the works. The workmen acted as if we were a lot of wild animals on exhibition, and it was almost impossible to pick our way around among the piles of work and rubbish.

At the second shop I asked at the office downstairs for permission to look around, and was promptly given a pass card, shown the shop door and told that I would probably meet one of the proprietors somewhere. I found it a rambling place full of odd corners and turns, but I wandered around rather aimlessly for an hour without a question or look of inquiry from anyone. After a time I saw two men in overalls get off an elevator. The sight was so odd that I sauntered over and asked the boy who engineered the thing—where he went to when he went down. "The engine room," he said. "Nice plant there; don't you want to see it?" Needless to say I did. Another man in overalls got on too. I looked at my pass to see if there was anything about talking to the help, and then asked him how it happened that they were allowed to ride on the elevator, and how they liked it. "It's all very nice," he said, "but it is all the same to us whether we ride or not. If we ride and save any time we have to get out enough more work to make up. They don't let you blow your nose but just so many times a day here, and they calculate to get us just so tired at night. It pays them all right, but we don't ask about elevators when we are out looking for jobs."

I could not help comparing the two places, and then inquiring about both. It turned out that in the first shop they never expect to see a customer from one year's end to another. They go out to buy their stock themselves and they can carry a full line of samples in an overcoat pocket. They are not bothered by agents or solicitors to see their help. They pay their workmen by the piece and never have any trouble getting all the help they want. They are making money, and the proprietor thinks that if he can stand the stairs, no one else has a right to complain.

In the other shop they seldom sell to a new customer who does not come and look them over. Consequently they are always on exhibition. They are accustomed to visitors and they know that it will not do to walk a silk-hatted, short-winded customer up and down stairs long enough to see the plant; hence the elevator. The elevator being there, why not make it pay dividends? Man power costs more than steam power every time, so why not let the men ride and then get enough more work out of them to make it pay? It is fine advertising to show the silk-hatted fraternity what philanthropic citizens they are and how thoughtful of the welfare of their humble brethren. And it takes all right because the "silk-hat" never thinks of approaching a workman from a point of view that gives him a chance to feel that he can talk freely.

These chaps in the shops care precious little about but two things. One is, how much money they can carry home pay night as compared with the time they spend away from their wives and children to get it, and the other is whether their work is congenial.

This latter does not have as much to do with flower gardens and ambulance corps or any such things, nor does it have much to do with labor-saving devices which are only used to save the employer on his production cost. It does have a great deal to do with means of lightening the actual brute strength required from an operative in a day, and a great deal more with the decency with which the foremen treat the help. A great many foremen do not know that it is possible and profitable for them to be gentlemen and yet get the work out, and a great many employers do not realize that it pays to get gentlemanly foremen, nor that such foremen attract the best help.

The average employe understands perfectly that he has no legal right to share in the profits brought about by another man's brain work, but he cannot see why all men are not as brotherly toward him as he is toward his neighbor on the next lathe. Did you ever see a rich man that would do as much for famine sufferers or neighbors in distress as a $15-a-week machinist will, in proportion to his means?

A man in the shop cannot see and cannot be made to see, and I am glad of it, why a man, as soon as he gets more money than he needs for his own daily use should not look around for some one in need to help a little; not to insult him with money, or to patronize him, but to help him carry his burden easily.

Now all this does not mean that I nor the men in the shops do not believe in the uplifting influences of all the flower gardens or pleasant homes, nor that we are looking for the dollar to the exclusion of everything else. Not at all! What we would like would be to feel that all these uplifts were ours, that if we wanted to lie down on the grass we could do so, and that we could have a feeling of proprietorship in the cosy cottages that are held out to us as inducements to move. But in almost every case we find that these things have strings on them, and even when we feel that we are paying for all the extras, we find that they are liable to be yanked back if anyone in authority gets a bit on his ear at us. In a word, independence was worth fighting for years ago, and it is worth something now.

The spring convention of the National Machine Tool Builders' Association will be held at Atlantic City, N. J., Tuesday and Wednesday, May 19 and 20, with headquarters at the Hotel Chalfonte.

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

SELECTING CUTTER FOR FLUTING CONCAVE MILL.

M. E. M.—The accompanying cut (Fig. 1) shows a milling cutter having a concave surface, and it is required to find an angular milling cutter for milling the teeth in this concave mill so that the width of the land y will be the same both at the center and at the outside edges of the mill. The problem may be stated thus: If the number of teeth, the width and diameter of the mill, and the radius of its concavity are given, to find a cutter which will mill the teeth so that the width of land y remains constant for the full width of the mill.

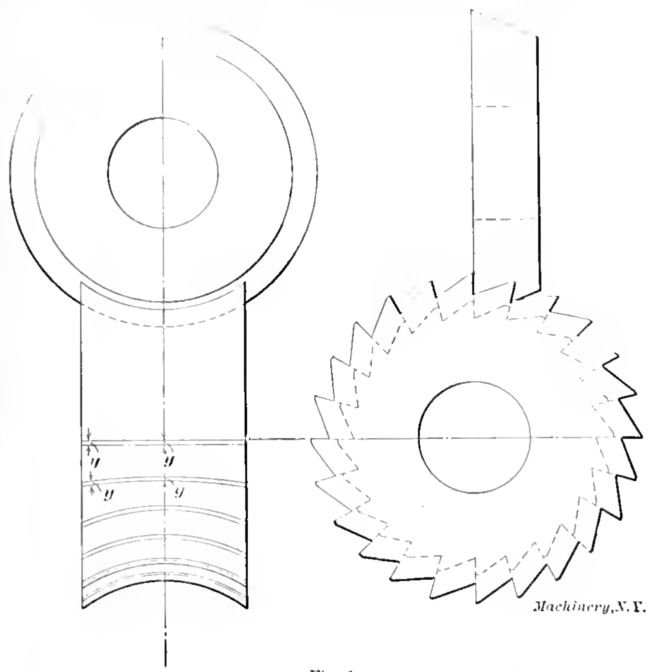

Fig. 1.

A.—Theoretically, this problem is one the conditions of which do not permit of a solution. Suppose, for instance, that the width of the land of the teeth be infinitesimal; this will make it easier to state the case in a clear manner. In Fig. 2, the cutter surface of the cutter for milling the teeth, being that of a cone, is represented by ABC, the cutter being imagined as extending out to a sharp point at the apex C of the cone. The mill to be provided with teeth is represented by the half-circles KL and MN, the latter being the line at the bottom of the circular groove at the center. Assume that DE is the pitch of the mill at its largest circumference. Then, a plane OH passed through the point E from the center of the mill produces a circular arc EFE where it intersects with the surface of the blank of the mill. The section produced by this plane in cone ABC, however, is an ellipse. As a circular arc and an ellipse never can fully coincide, it is evident that the problem contains conditions which make it impossible. If, however, the pitch DE is very small in proportion to the radius OE of the mill, so that the section FG of the cone nearly resembles a circle, then a cutter may be determined that will cut the teeth to agree *approximately* with the conditions given. What is then necessary is that the diameter of the cone, or angular cutter, at point F shall be as nearly equal to the diameter of the circle forming the outline of the mill blank as possible.

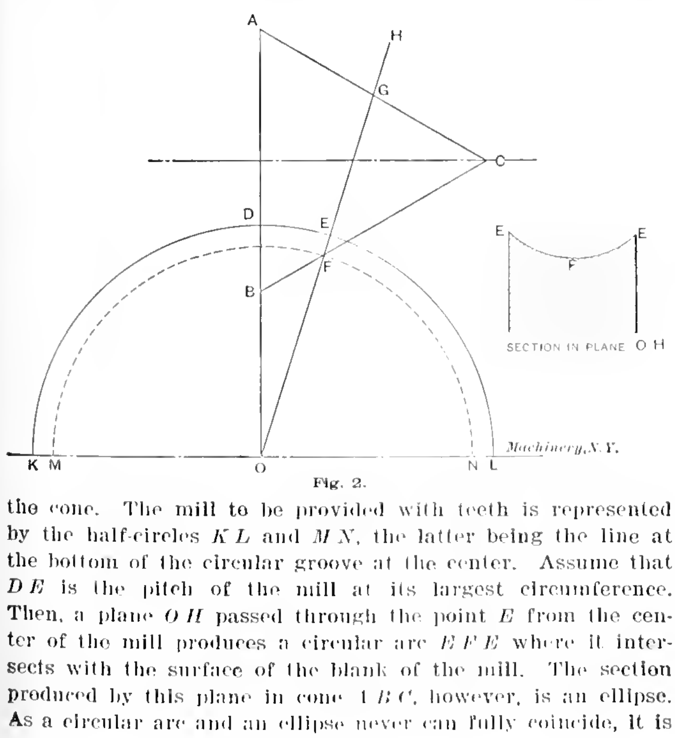

Fig. 2.

In practice the problem is usually solved by the cut and try method, approximate results only being obtained. Approximate formulas no doubt could also be worked out, and if some of the readers of MACHINERY who meet with this class of work have adopted any special rules which they follow, we would be pleased to place them on record.

TO OBTAIN FACE ANGLE OF BEVEL GEARS.

E. H.—Please tell me how to obtain the face angle, measured as shown in Fig. 1, for two bevel gears, 25 and 50 teeth, 10 diametral pitch. The shafts are at right angles.

A.—To find the face angle for a pair of bevel gears, proceed as follows, using the reference letters below in addition to those shown in Fig. 2.

N = number of teeth in gear;

n = number of teeth in pinion;

ϵ = face angle, as usually measured.

First we get the pitch cone angle of the gear

$$\tan\beta = \frac{N}{n} = \frac{50}{25} = 2.000 = \tan 63° 26', \qquad (1)$$

then we obtain the addendum angle

$$\tan\delta = \frac{2 \times \sin\beta}{N} = \frac{2 \times 0.89441}{50} = 0.03578 = \tan 2° 3' \qquad (2)$$

Adding together (1) and (2), we get

$$\epsilon = \beta + \delta = 63° 26' + 2° 3' = 65° 29'$$

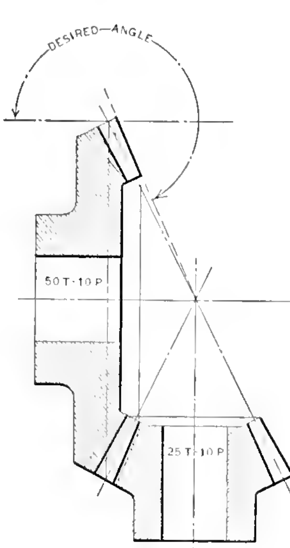

Fig. 1.

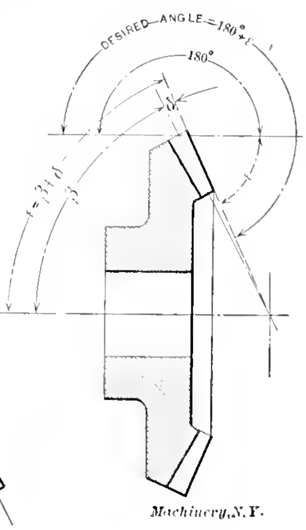

Fig. 2.

The face angle is usually measured as shown in Fig. 2; the angle you call for is 180 degrees more than this.

$$\text{The desired angle} = 180° + 65° 29' = 245° 29'$$

The pitch cone angle of the pinion is found thus:

$$\beta_p = 90° - \beta = 90° - 63° 26' = 26° 34'$$

The angle as usually measured will then be

$$\epsilon_p = \beta_p + \delta = 26° 34' + 2° 3' = 28° 37'$$

So that for the pinion we have

$$\text{The desired angle} = 180° + 28° 37' = 208° 37'$$

Rules and formulas for obtaining the various measurements of miter and bevel gears of various kinds will be found in the data sheet published with the May, 1907, issue of MACHINERY.

* * *

A speed of 44 statute miles, or 38.3 knots per hour, was attained over a mile course last December by the British torpedo boat, *Tartar*. This is the highest speed that has ever been attained by a craft of this class.

NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

WOODS ENGINEERING CO.'S UNIVERSAL TOOL AND CUTTER GRINDER.

In Figs 1 to 6 we show, performing various operations, a tool and cutter grinder built by the Woods Engineering Co., Alliance, Ohio. The machine is the result of long experience with tools of this class, and it comprises a number of useful features not found in other designs.

As may be seen, the grinding head is mounted on a stationary column rising from a broad, stiff base which is bolted to the floor. The upper part of this column is turned to a smaller diameter, and has fitting over it a sleeve which can be set at any angle throughout the full circle. This sleeve supports the knee on which the work table is carried. Clamping the sleeve to set the work table at the proper angle with relation to the wheel, does not interfere at all with the vertical adjustment of the knee on the sleeve, the movements being independent. The two bolts on the lower flange of the sleeve are used for clamping it at the desired angular adjustment. The emery wheel spindle has two speeds, is made of

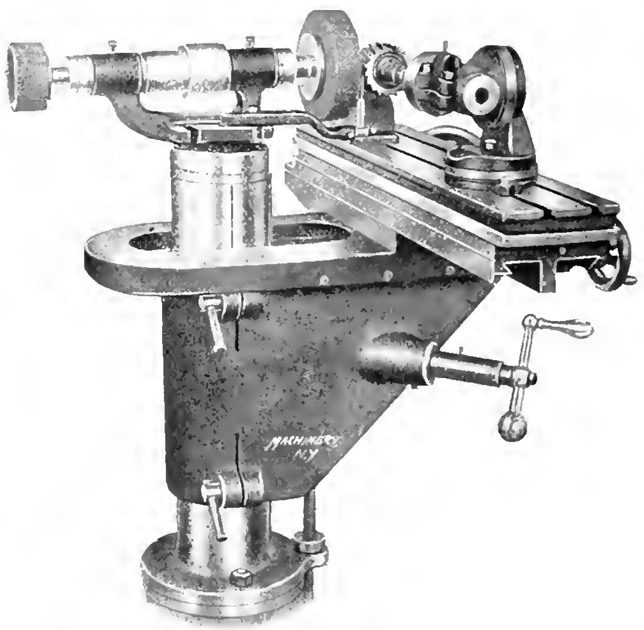

Fig. 1. The Woods Cutter and Reamer Grinder, sharpening a Spiral Mill.

tool steel, ground to size, and runs in phosphor bronze bearings which are adjustable for wear, and are as nearly dust proof as it is possible to make them.

A saddle is adjustable in and out on the knee, and the work table has a horizontal movement on the saddle, the arrangement being about the same as in the orthodox type of milling machine. These three adjustments, the vertical, cross and longitudinal, are obtained by hand-wheels and a crank which are so set as to be within convenient reach of the operator, and yet not interfere with each other in any position. The connections for the cross and vertical feeds are obvious. For the longitudinal feed of the table, the hand-wheel shaft is provided with a spiral pinion, meshing with a rack fast to the under side of the table. The bearing surfaces on which these various sliding movements take place are all carefully protected from emery. The protection for the bearing of the saddle on the knee is best seen in Figs. 1, 2, and 4. It consists of the guard which practically forms a part of the saddle and encircles the column at the rear, covering the surfaces at all times, no matter what the setting of the parts. The sides of the table are brought down below the bearings by which it is gibbed to the slide, so that these are also protected. The guards may be seen in the end views Figs. 1, 2, and 4. The slides all have 45-degree bearing surfaces. Both elevating and cross-feed screws are provided with micrometer dials reading to 0.001 inch.

The other structural features of the machine can perhaps best be understood by referring to the operations shown in progress in Figs. 1 to 6. In Fig. 1 a spiral mill is being ground. This is mounted on an arbor between the head and foot-stock centers as shown. The tooth being ground by the

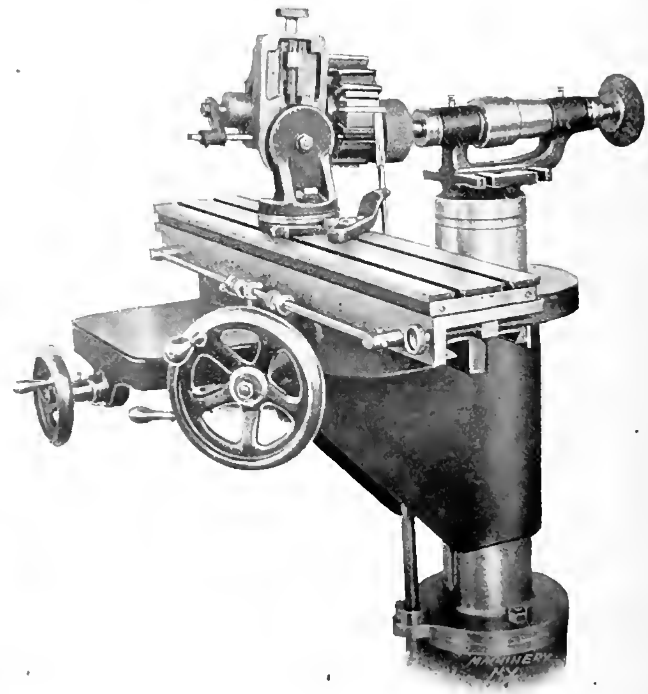

Fig. 2. Sharpening a Face Mill, whose Shank is held in a Universal Taper Holder.

cup wheel rests on a tooth support immediately beneath the grinding point. As the cutter is moved back and forth by the hand-wheel, the face of the spiral cutter is kept pressed on the tooth rest so that it is properly presented to the wheel. The tooth rest, it will be noted in this case, is clamped to a shelf at the side of the grinding head. It will be seen that

Fig. 3. The Machine arranged for Plain Cylindrical Grinding on Dead Centers.

the head-stock has a universal swiveling adjustment. This comes into play in grinding angular mills of all kinds, these being generally held on taper shanks or arbors pressed into the taper hole of the head-stock spindle. This spindle runs in dust-proof bronze bearings, and is adjustable for wear.

In Fig. 2 a universal taper holder is shown in place, clamped to the head-stock swivel, from which the spindle head has been removed. This attachment is adapted to holding taper and cylindrical shanks of larger size than can be held in the taper of the regular spindle. The face mill shown is having its teeth ground on the face, the tooth rest being in this case fastened to the table. Stops are provided for limiting the traverse of the table. These are plainly shown in this view. They consist of collars which are clamped to the rod shown extending along the front of the table. They engage a stop piece fast to the knee, which may be thrown up between them, or dropped out of the way if it is desired to run the carriage beyond the stop. Another view of this arrangement may be had in the next figure.

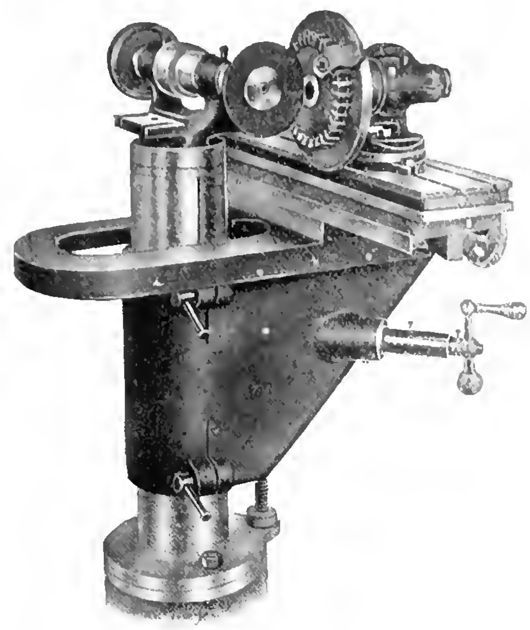

Fig. 4. Grinding the Hub of a Cutter on the Face-plate.

Fig. 3 shows the machine as arranged for plain cylindrical grinding. A center, carrying a loose pulley whose flange forms the driving face-plate, has been inserted in the taper hole of the head-stock. The spindle of the head-stock, to which the rear pulley is keyed, is locked by a plunger as shown, having a point entering holes in the rear flange of the driving pulley. When the spindle is thus locked, the work revolves on dead centers, as is usual in cylindrical grinding. The locking plunger and the holes in the pulley flange also serve as an indexing device for use when grinding broaches, punches, etc., in square, hexagonal and other shapes.

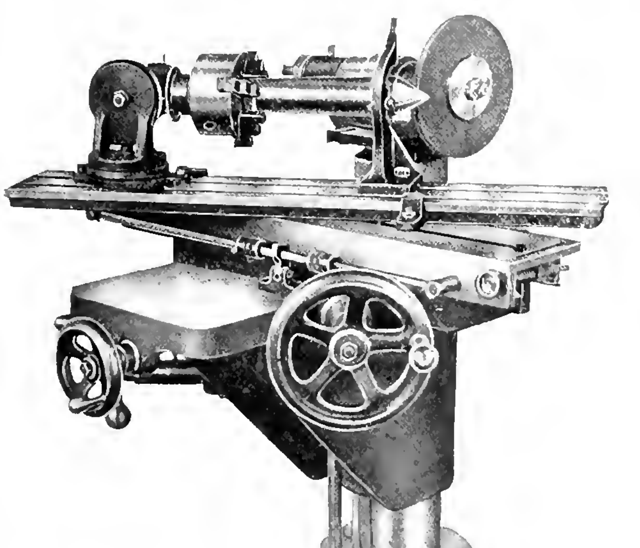

Fig. 5. Truing a Large Center, with the Table swiveled for the Angle.

The tail-stock spindle has a spring center, to take care of the expansion of the work due to heating; the center may be locked, however, for work which requires it. It will be noted in comparing Figs. 2 and 3 that the knee and table have been swung around 90 degrees between the two operations.

In Fig. 4 is shown a face grinding operation. A hardened cutter is mounted on a face-plate attached to the head-stock spindle, which is revolved by a belt from the counter-shaft. The work is traversed across the wheel by the regular table feed, and is fed in to depth by the cross slide hand-wheel in an obvious manner.

The top of the work table is pivoted, as shown in Fig. 5, to permit the grinding of tapers on centers, or in the follow rest as in this case. For comparatively small tapers this adjustment may be obtained very accurately by means of the screw and nut arrangement shown at the end of the table. This is disconnected in Fig. 5, the upper half of the platen being swung at a much greater angle than that connection allows. To clamp the platen to the table under these circumstances, two dogs are provided, as shown, one on each side. The large lathe center being ground is held at one end in a chuck which is part of the equipment provided, while the other end is held by the regular center rest furnished with the machine.

Fig. 6 shows the internal grinding attachment. This is mounted in a frame which is bolted to a shelf at the side of the grinding head. The hardened cutter on the face-plate is having its central hole ground to size. The internal grinding spindle is speeded up from the main spindle as shown, the ratio between the two pulleys being sufficient to give a suitable velocity for internal grinding. The spindle has a bearing next to the emery wheel, thus doing away with vibration due to long over-hang.

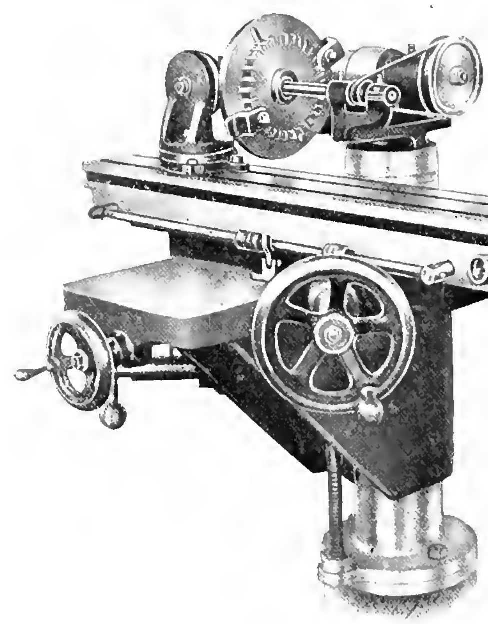

Fig. 6. The Internal Grinding Attachment in Use.

Other uses for this machine can readily be imagined from inspecting the examples we have shown here. For instance, the tool is well adapted to surface grinding. For this purpose, a universal swivel chuck is provided, which can be adjusted to any angle in three different planes, so that angular work of any conceivable shape can be ground true. When so working, the table is swung around so that its travel is at right angles with the axis of the grinding spindle. The changes from one operation to another can be made easily and rapidly, owing to the convenience of the various adjustments. The emery wheel spindle has two speeds, is made of tool steel ground to size, and runs in phosphor bronze bearings, adjustable for wear, and as nearly dust-proof as it is possible to make them.

The longitudinal travel of the machine is 22 inches, the cross feed 7½ inches, and the vertical adjustment 9 inches. It will take 22 inches between centers, and swings 9 inches

over the table. Various wrenches, dogs, tooth rests, and attachments are provided, as well as wheels suitable for the work of the machine. The weight without the counter-shaft is about 700 pounds.

LIBBY TURRET LATHE.

The turret lathe illustrated in the three accompanying half-tones is built by the International Machine Tool Co., of Indianapolis, Indiana. It is the design of Mr. Chas. L. Libby, who has had extended experience in work of this kind in both this country and Europe. It is intended for the general run of chucking and turning work for cast iron and steel parts up to 20 inches in diameter.

Spindle Driving Mechanism.

An inspection of Fig. 1 will show that the machine is built in the heavy, rigid style necessary for the effective use of modern high speed steels. The head-stock and bed are cast in one piece, and the bed is unusually deep and rigid. The spindle is of large diameter, with journals suitably proportioned, and with a $3\frac{5}{8}$-inch hole through its center. It is driven from the two-step cone pulley shown at the outer end of the head-stock, through a mechanical speed changing mechanism enclosed within the head-stock and operated by the two levers at the front of the main bearing. These levers give four changes of feed, which are multiplied by the two obtained from the driving pulley, and these in turn by the three obtained from the three-speed counter-shaft, giving 24 changes in all. The speeds vary in geometrical progression from 5 to 180 revolutions per minute.

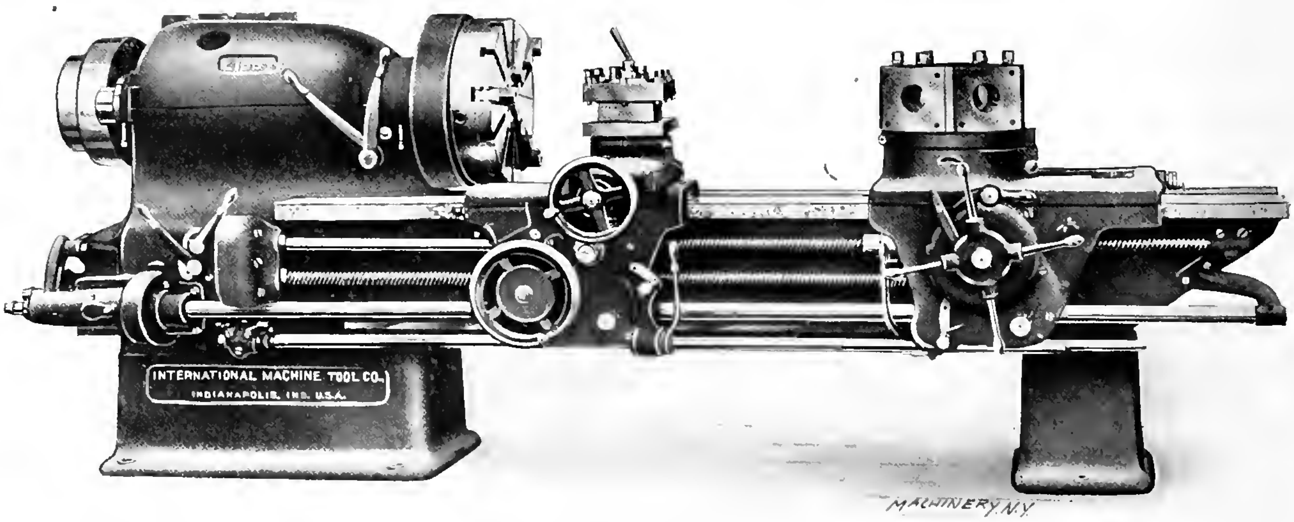

Fig 1. Libby Turret Lathe, made by the International Machine Tool Co., Indianapolis, Ind.

One of the features to which attention is called is the provision made for changing the machine from belt to motor drive independent of the builder. This can readily be done without having to rearrange the head-stock for each type of motor, thus avoiding delay and extra expense. Any motor having a speed range of at least 2 to 1 can be used. It may be mounted on the finished pads provided on the head of the machine, and connected with the driving shaft by gearing, or it may be mounted on the floor and belted to the machinery. It will be seen that the change can be made at a very low cost.

Tool-post and Turret Slides.

The tool-post carriage is of unusual construction. It does not extend across the bed, but is supported by the front way and by a V-guide at the bottom of its apron, bearing on a corresponding way on the lower edge of the bed. A long taper gib fitted to the carriage on the inside of the bed takes up the wear. As shown in Fig. 2, the tool-post carriage may be moved past the chuck toward the head-stock. This permits the use of the turret close up to the chuck, avoiding the overhanging tools usually required to reach over the tool-post cross slide. It is evident, also, that nearly the full capacity of the lathe can be swung over the carriage.

The six-sided turret is supported on a spring pivot bearing which is adjustable to its load, and takes the weight of the turret and tools off the annular bearings, thereby reducing the friction and the wear, and permitting it to be indexed easily. The clamping device acts at the outer edge of the turret, bringing it down firmly to the annular bearings after the indexing has taken place. The same lever that tightens and releases the turret clamp operates the turret locking pin. Throwing the lever in one direction releases the clamp and withdraws the locking pin. The turret may then be swung to the desired position. By throwing the same lever a little further over, the locking pin is released and the turret located. By again bringing the lever back to its original position, the turret is once more rigidly clamped.

Feed Mechanism.

The feed motion is operated from the spindle through change gearing and a quick change apparatus. Eight changes may be obtained by operating the two levers shown beneath the head-stock, and eight changes more are regularly provided for with the detachable gears furnished with the machine. Either English or metric threads can be cut without changing the screws. The feeds and screw threads obtainable vary from 1 to 200 revolutions of spindle per inch of slide movement.

The feed connections for the tool-post carriage and turret slide are entirely separate, so that the feed of either apron can be reversed without interfering with the other. Both carriages may be shifted independently by quick traversing devices. This movement can be operated at any time by the action of a single lever, the setting of the feed not interfering with this. The rate of movement of the quick traverse is about 25 feet per minute. The screw cutting and power feeds are applied to both carriages. In the tool-post carriage

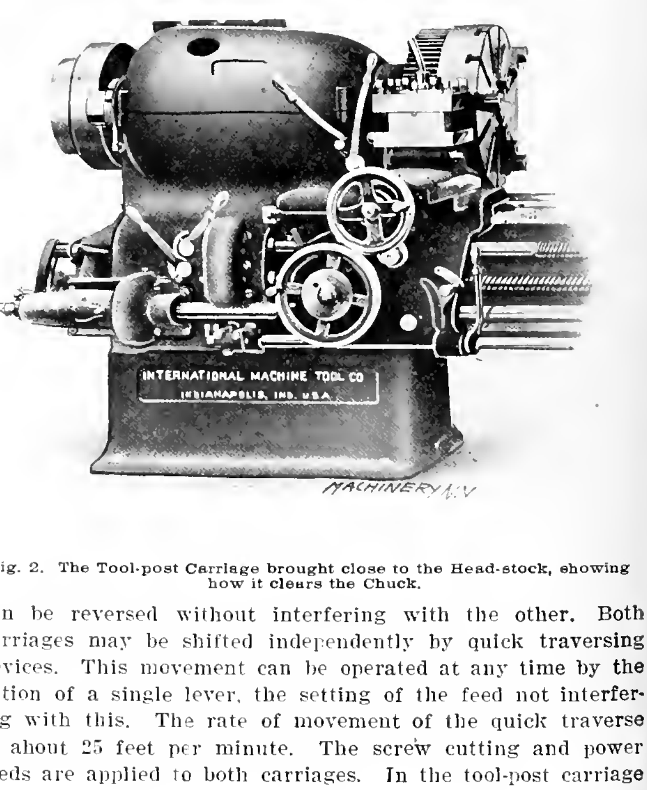

Fig. 2. The Tool-post Carriage brought close to the Head-stock, showing how it clears the Chuck.

the cross and traverse feed screws have the same lead. All the handles for operating the various changes, both of the speeds and feeds, are within easy reach of the operator, as he stands in working position. All the moving parts, as may be seen, are encased to prevent injury to the mechanism or the operator.

Automatic stops are provided for feeds in all directions. In connection with these stops, there is an indicator or moving pointer which registers the exact position of the turret cutting tools. This can readily be seen by the operator, and makes possible the attainment of duplication of work to a degree of exactness that would otherwise be difficult. The gearing of the turret apron is so arranged that one revolution of the pilot wheel gives only $\frac{1}{2}$ inch of movement to the

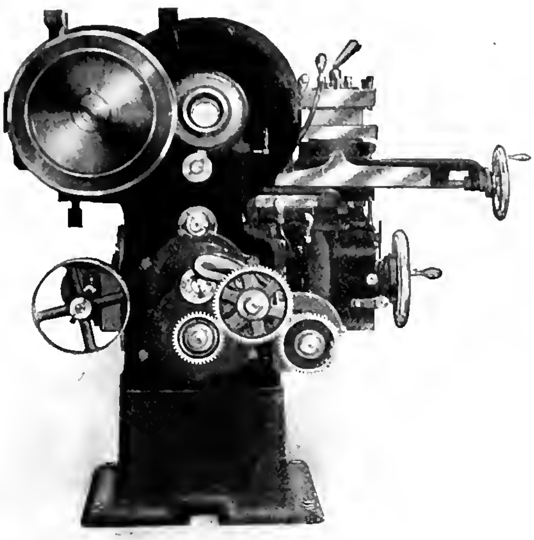

Fig. 3. End View of the Libby Turret Lathe.

slide. With this ratio, the operator has sufficient leverage to bring the tool up to a heavy facing cut without exerting himself unduly.

Method of Operation.

The makers are prepared to design and construct special tools for doing work to the best advantage. The ordinary method of procedure may be described as follows: The rough casting is grasped in the hard steel jaws of the chuck, where it is bored and reamed. Then a bushing, which fits the supporting arbors used with the facing heads on the turret, is inserted into the hole just made. The facing heads, which are made to carry a variety of tools, are next run up to the work, which is shaped to the dimensions required. In most cases two facing heads are used, one for roughing and one for finishing. Owing to the fact that the reaction of the cutting strain is taken directly in the work itself, there is very little deflection of the tools under the pressure of the cut, and heavy chips can be taken.

If a second chucking is required to finish the part complete, the hard jaws are removed and a pair of soft jaws substituted. These are set down to a little less than the size of the piece to be held, and are bored out to the exact size of the work, so that when this is again clamped in the chuck the jaws are in the same position as when being bored, and the work runs truly if the first operation is carefully done. This procedure applies to the general run of cast iron work.

The arrangement for supporting the drill or boring-bar is different in this type of machine from that ordinarily used. The support is located at the back of the machine, and is entirely independent of the carriage, so that while it is being used to guide the drill or boring-bar, the carriage can be used for turning. This often makes considerable difference in the output of a machine of this kind.

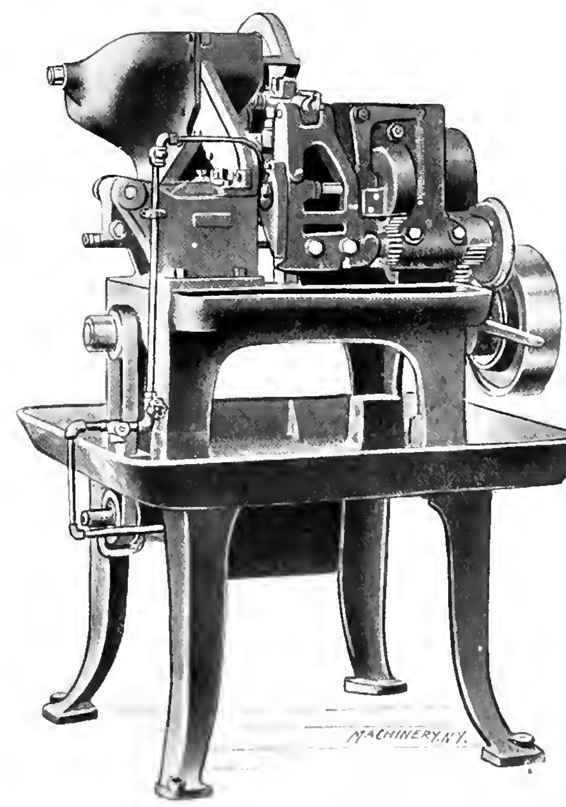
The machine is evidently suited for finishing on the interchangeable plan such parts as gear blanks, small fly-wheels, automobile cylinders and parts, couplings, rope drums and other similar work within its capacity. It will swing 22 inches over the ways, and 20 inches over the carriage. The traverse of the turret slide is 60 inches, and the hole through the spindle is $3\frac{5}{8}$ inches in diameter. The turret holes are $3\frac{1}{2}$ inches in diameter. The 2-step cone pulley has faces of the proper width for a $3\frac{3}{4}$-inch belt. The machine will be furnished with oil pan and pump, when desired, for steel work. It is 12 feet 8 inches long over all, and has a shipping weight of about 9,000 pounds.

WATERBURY-FARRELL AUTOMATIC SCREW SLOTTING MACHINE.

The tool shown in the accompanying engraving, built by the Waterbury-Farrell Foundry and Machine Co., Waterbury, Conn., is an improved automatic slotting machine for work on screw blanks for filister-head screws, stove bolts and other similar products. The experiment and study spent in the designing of this machine were directed toward obtaining accurate work at rapid rate of production, special attention being paid to rigidity, with the corresponding increase of output possible for a slotter.

A hopper feed is used, which automatically presents the blanks, as they are required, to a toggle carrier slide, which brings them into position in front of the saw. Here each blank is gripped securely between a die and a carrier slide, for the slotting operation. The saw spindle is mounted on a swinging bracket, which is well braced and guided to prevent chattering. The saw is swung on this in cutting the slot. To cut off the burr which forms on the head when the saw is dull, a chip shaver is furnished. This is a small cutting tool which passes over the head of the blank as the saw returns, and smooths off the burrs.

The machine is driven by a friction clutch pulley, through change gears which give a wide variation in the number of blanks that can be slotted per minute, thus making it suitable for varying sizes and kinds of screws.



Automatic Hopper-fed Machine for Slotting Screw Blanks.

An oil pump is provided to give a uniform flow of oil over the work, and suitable guards are furnished to keep the saw and dies clear of dirt, chips and other foreign matter. A pan under the machine collects the lubricant, strains it from the chips, and returns it to the tank and the pump. When desired, the machines can be mounted in groups, instead of on single bases as shown. When this is done, a long table is used, which also forms a drip pan, all the machines in the group being driven from a single pulley.

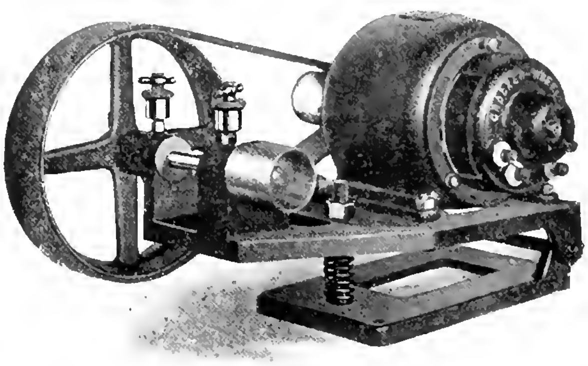
The machine shown will take screws from 3/16 to $\frac{3}{8}$ inch in diameter up to $2\frac{1}{2}$ inches long. It will operate on

thirty-five 3/16-inch blanks per minute, the saw used being $2\frac{3}{4}$ inches in diameter. This capacity may be exceeded on shallow slots and brass screws. For a single machine, the floor space occupied is about 44 x 41 inches, and the weight of the machine is 1,240 pounds. The floor space occupied by a group of six machines is 44 inches by 19 feet 10 inches, and the weight of the six machines is 7,540 pounds.

COUNTER-SHAFT BELT TIGHTENER FOR USE WITH CROCKER-WHEELER MOTORS.

We show herewith an arrangement of motor and self-contained counter-shaft which is being installed by the Crocker-Wheeler Co., of Ampere, N. J., for driving light machinery. Though designed primarily for driving the linotype, it can be used to advantage with other machinery requiring a slow speed drive.

A cast iron sub-base is used, provided with lugs to which is pivoted the cast iron base on which the motor and counter-shaft are mounted. Tension between the pulley on the armature shaft of the motor and that on the counter-shaft, is maintained by the usual plan of shifting the motor on the base, with the aid of an adjusting screw. For the belt connection between the small pulley of the counter-shaft and the driving pulley of the machine, the tension is regulated by an adjusting nut bearing on the pivoted base, which forces the front end of the latter downward, thus increasing the center distance of the pulleys over which the belt runs. A spring is provided at the front end to support the tilting base in case the belt breaks.



Motor mounted on Base Plate with Self-contained Counter-shaft.

As compared with the ordinary idler, the use of this intermediate counter-shaft avoids the usual great difference between the size of the driving and driven pulleys, so that the belts make better arcs of contact with the pulleys, resulting in a consequent decrease of slippage. The motor shown is the "L-type," made by the builders in sizes from 1-20 to 5 horse-power. It has a neat appearance and is compact in design, being especially suited for direct connection with small tools, printing presses, pumps and other light machinery. By applying covers for the openings in the frame, the motor can easily be made dust and moisture proof, for service where the open type would be out of the question.

INGERSOLL HORIZONTAL MILLING MACHINE WITH SUPPLEMENTARY VERTICAL SPINDLES.

In Figs. 1 and 2 are shown front and rear views, respectively, of a horizontal milling machine whose cross rail has been arranged to support a pair of vertical spindles, to be used in conjunction with the horizontal spindle of one of the regular line of horizontal spindle, planer pattern millers, made by the Ingersoll Milling Machine Co., of Rockford, Ill.

The vertical spindles, as may be seen in Fig. 2, can be adjusted to any position between the housings, by means of the rack and pinion arrangement with which they are provided. The spindles also have independent vertical adjustments. They are driven by spiral gearing, encased to run in grease, from a horizontal shaft which extends along the cross rail, and is connected by spur gearing with the main spindle of the machine. Cutters up to 8 inches in diameter may be used on the vertical spindle, there being no interference in any way with the action of the horizontal cutter.

This arrangement is useful in milling work in which vertical and horizontal cuts have to be taken that would otherwise require the use of expensive gang cutters, but which, in

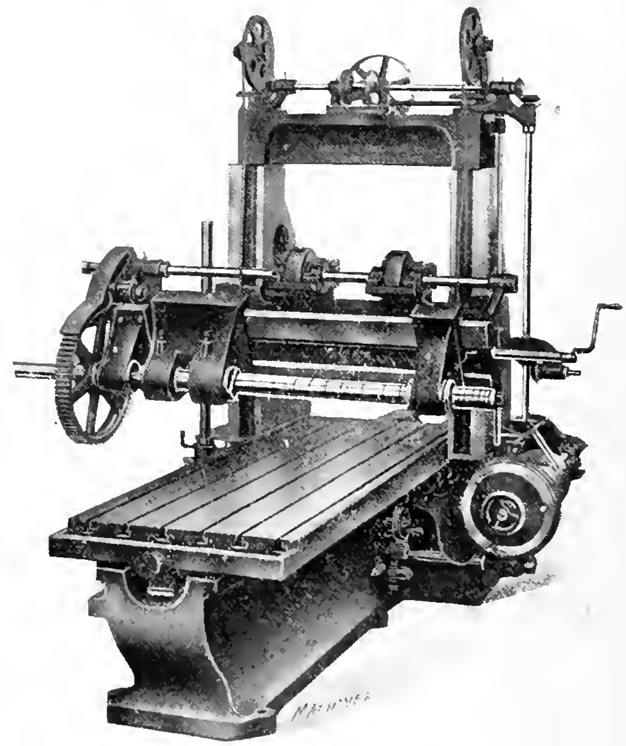


Fig. 1. Ingersoll Horizontal Milling Machine, with Supplementary Vertical Spindles on Back of Cross Rail.

this way, can be done with stock tools. It is also possible to machine surfaces at one cut that would be impossible to do even with gang tools, such as finishing horizontal surfaces and cutting tongues or grooves in the sides of vertical surfaces, at the same operation.

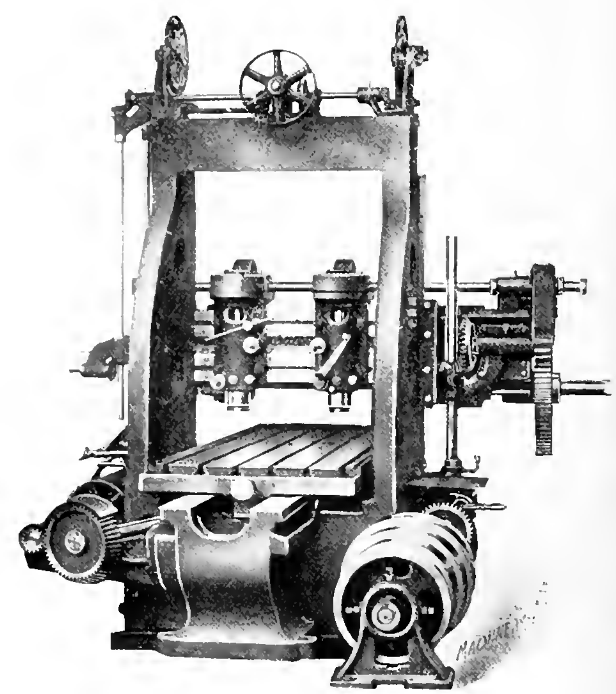

Fig. 2. Rear View showing Arrangement of Vertical Spindles

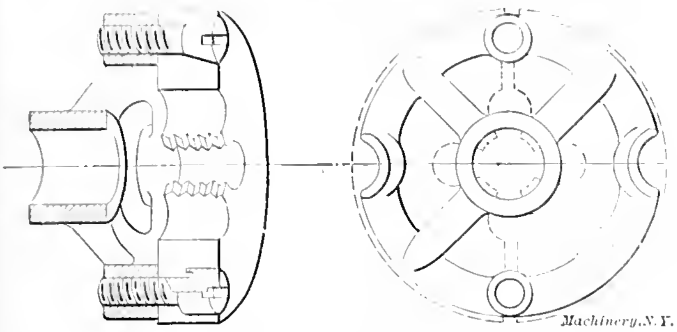
This method of attaching spindles at the back of a cross rail is not confined entirely to horizontal milling machines, like that shown in Figs. 1 and 2. The arrangement may be used with any other machine which has a cross rail, the builders having furnished vertical machines of this type with four heads on a single rail, two at the front and two at the back. This makes it possible to take cuts closer together than would be the case if all the heads were on a single rail.

GREEN RIVER SCREW PLATE FOR BRAZED BRASS TUBING.

The accompanying line cut shows a Green River die with an improved guide, designed for threading brazed brass tubing. The die used is the standard form furnished with the maker's ordinary sets for threading bolts and nuts. Particular attention is called to the long bearing provided by the style of



Green River Dies with Bushing Attachment for Threading Brazed Brass Tubing.

guide used, thus enabling the operator to always be sure of cutting straight and perfect threads. The dies are so formed as to leave a large space for getting rid of chips, and give also an excellent opportunity for oiling the work.

The device is furnished in all sizes, from 3-16 to 1 inch in diameter, the usual pitch being 27 threads to the inch for all American sizes, and 26 threads to the inch for all English sizes. These screw plates are made by the Wiley & Russell Mfg. Co., Greenfield, Mass.

FRONT CROSS FEED FOR GOULD & EBERHARDT SHAPERS.

The device, whose absence is indicated by the position of the operator in Fig. 1, and which is shown in use in Fig. 3, is not an entirely new idea, as it has been previously described in communications to trade papers. It is new, however, for the first time regularly applied to a manufactured line of shapers, so it is worth while bringing it again to the attention of our readers. This front acting table feed is being applied to the line of shapers built by Gould & Eberhardt, of Newark, N. J.

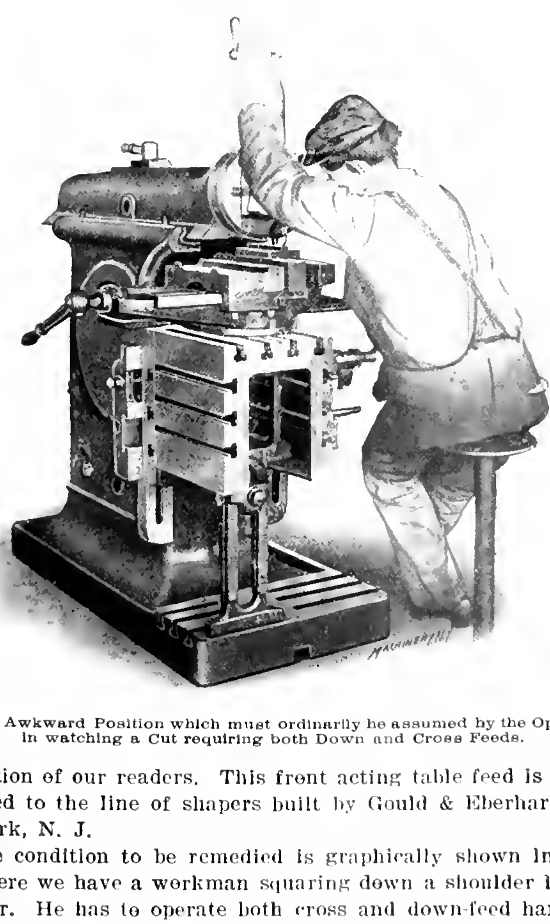


Fig. 1. Awkward Position which must ordinarily be assumed by the Operator in watching a Cut requiring both Down and Cross Feeds.

The condition to be remedied is graphically shown in Fig. 1. Here we have a workman squaring down a shoulder in the shaper. He has to operate both cross and down-feed handles, and, at the same time, has to keep an eye on the lines he is working to, scribed on the front face of the casting. With the handles placed as they are, this necessitates a bodily contortion which is far from agreeable or profitable. To remedy this, an additional connection for the cross feed is made. This is a shaft at right angles to the table and screw, having a crank handle at the front of the work table. With this, as

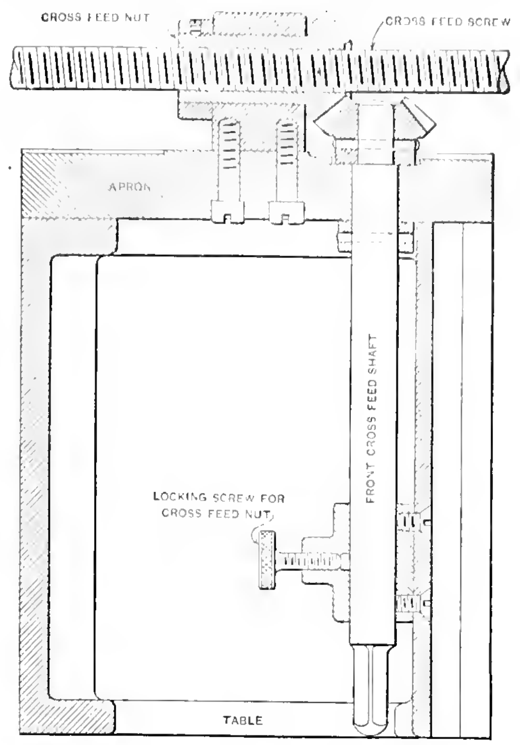

Fig. 2. Arrangement of Device used to work Cross Feed from Front of Table, as shown in Fig. 3.

shown in Fig. 3, the operator can place himself squarely in front of the machine, with both cross and down-feed handles in easy reach, and in a position to see surely what he is doing.

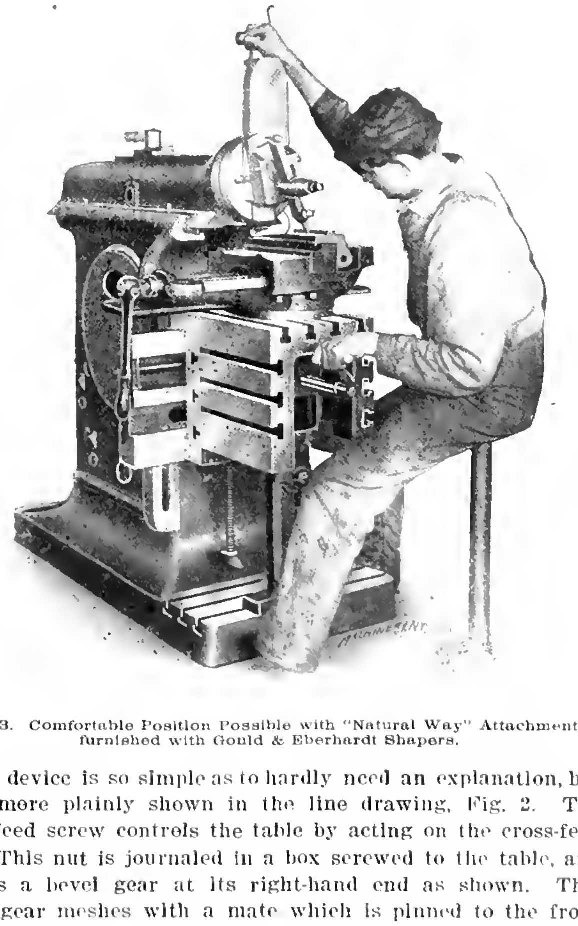

Fig. 3. Comfortable Position Possible with "Natural Way" Attachment, furnished with Gould & Eberhardt Shapers.

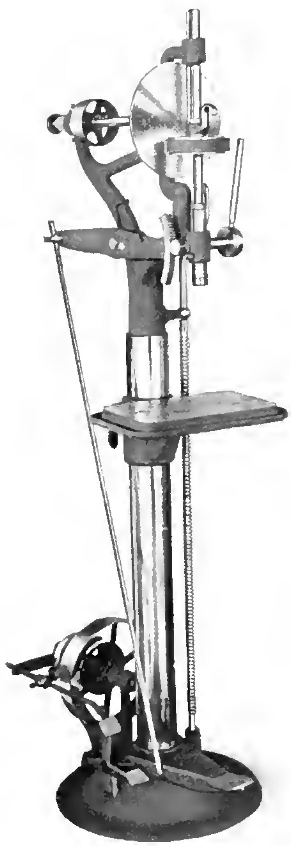
The device is so simple as to hardly need an explanation, but it is more plainly shown in the line drawing, Fig. 2. The cross-feed screw controls the table by acting on the cross-feed nut. This nut is journaled in a box screwed to the table, and carries a bevel gear at its right-hand end as shown. This bevel gear meshes with a mate which is pinned to the front cross-feed shaft, running out to the front of the table. This

shaft is squared, as may be seen, to fit the crank by which it is operated.

The lock screw shown has a cylindrical end, adapted to clamp the front cross-feed shaft and prevent it from turning. When the cross-feed shaft is so engaged, the cross-feed nut is stationary, and the table may be fed back and forth by the cross-feed screw in the usual manner. When, however, it is desired to use the crank on the shaft running out to the front of the table, the lock screw is turned back, so that the nut may revolve freely. The feed-screw then being stationary, the revolving of the crank, as shown in Fig. 3, feeds the table at the will of the operator.

BARNES FRICTION DRILL PRESS WITH COMBINED FOOT AND HAND FEED.

We show herewith an application of a combined foot and hand feed to the 10-inch friction drill made by W. F. & John Barnes Co., 231 Ruby Street, Rockford, Ill. The foot lever for operating this spindle is particularly useful for work requiring light drilling, which is yet so bulky as to need the use of both hands in holding and shifting it. As may be seen, the device is an addition to the regular hand feed, and does not supersede it. A lever having a segment of a gear formed on its outer end meshes with a pinion on the rack and pinion feeding shaft. The rear end of this lever is connected with the treadle by a long reach rod. Three different holes are provided in the treadle for attaching the reach rod, so that provision is thus made for applying varying degrees of power for drills of varying diameter.



Foot-operated Feed, applied to Barnes Friction Drill Press.

SMITH MICROMETER ADJUSTABLE REAMER.

The reamer shown in Figs. 1 and 2, made by the Wm. J. Smith Co., 424 State Street, New Haven, Conn., is called the Smith Micrometer Adjustable Reamer. It gets its name from the graduations provided on the body of the reamer, read by an adjustable sleeve in the same way that the readings for a micrometer caliper are obtained.

Aside from the blades, the tool consists of but three parts, shown disassembled in Fig. 2. These are the body and head of the reamer (formed in one piece), the adjusting sleeve, and the clamping screw. The blades are fitted in tapered slots cut in the head of the reamer. The adjusting sleeve is threaded to the shaft with a thread of fine pitch. It has a

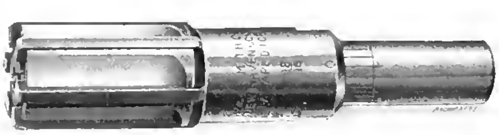


Fig. 1. The Smith Micrometer Adjustable Reamer.

cone-shaped inner surface, which engages the beveled ends of the blades, and holds them down to the bottom of the slot. The outer ends of the blades have under-cut bevel projections, which engage an internal cone-shaped surface under the head of the clamping screw. This clamping screw is threaded into the body, and serves to bring all the blades down to a firm and rigid bearing in the bottom of the slots.

In making adjustments, use is made of the graduations provided on the shank of the reamer. These are read from a zero mark on the sleeve, and give readings to one-quarter of a thousandth. To change the adjustment, the tightening screw is loosened, the adjusting sleeve is rotated to make the reamer larger or smaller by the desired number of thousandths, and the tightening screw is again set down firmly.

No threads are exposed in this reamer, all the adjusting parts being protected, leaving the exterior surface smooth and symmetrical with ample chip room for doing clean, fast work. The reamers are made throughout of high carbon steel, tempered to give the required hardness for resisting strain and wear. All the parts are interchangeable. The ream-

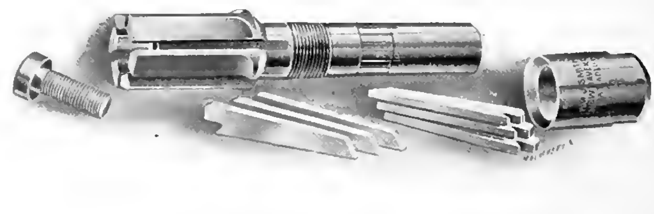

Fig. 2. Component Parts of the Reamer, showing the Simplicity of its Construction.

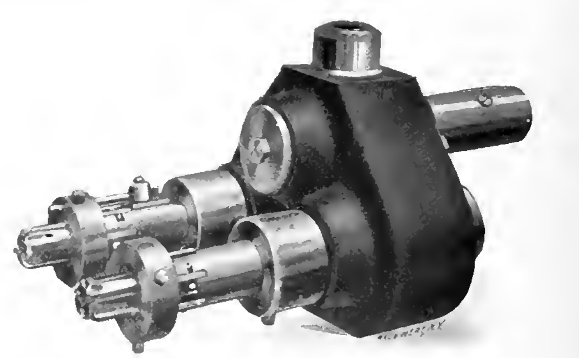
ers of this type are made and carried in stock in sizes from $\frac{1}{4}$ inch to 1 inch in diameter inclusive, varying by 32nds. Special sizes, of course, can be made to order. Micrometer adjustable reamers for tapered holes are also made on the same plan.

The blades used in these reamers are ground in the same way as described for the maker's "one lock" adjustable reamer in the October, 1907, issue of MACHINERY. As there explained, the blades are ground in a cylindrical grinder in a special arbor or fixture, which gives radial or eccentric relief to the work cutting edge of the blade. This form of relief will cut without chattering in all kinds of metal in which reaming can be done. Twelve jigs are required for covering the entire range of reamer sizes from $\frac{1}{4}$ to 1 inch diameter. These are furnished by the makers, or, if desired, blades may be sent to them for resharpening. This will be done at a nominal cost. A complete stock of interchangeable blades is carried by the builders, fitted and ground ready for use. The reamer bodies do not need to be returned for sharpening the blades or for fitting in new ones. They will be furnished of either carbon or high speed steel. Blades may be reground in the usual way if desired, but the special method devised for these reamers gives more satisfactory results.

MURCHEY DOUBLE COMBINATION TAPPING AND REAMING ATTACHMENT.

The device shown in the accompanying engraving was designed primarily for reaming and tapping two one-inch standard pipe threads at a time, in cast iron heater sections, such



An Attachment for Reaming and Tapping Two Holes at the Same Time without changing Tools or readjusting Work.

as are used in blower heating systems. It is built by the Murchey Machine and Tool Co., Fourth and Porter Streets, Detroit, Mich.

The two spindles of the attachment are connected by gearing with the driving spindle, which is revolved by the machine in which the tool is used. Each spindle carries a combined reaming and tapping head, by the use of which the holes in the headers can be finished without changing the tools. The tap is of the collapsible variety. When the tool is

first run through the holes, the chasers are withdrawn, allowing the reaming blades to do their work. The second time it is forced through, the chasers are in their working position, and the threads are tapped in the holes. When the proper depth has been reached, as determined by the threaded stop rods, the taps automatically collapse, and the tool may be withdrawn without requiring the spindles to be reversed. This saves a great deal of time, as compared with the reversing spindle machines employing solid taps formerly used for this work.

Though intended for the particular work mentioned, this attachment will be furnished by the builder to do work of any size, within a reasonable range. Taps of the kind used in this device, are furnished by the manufacturers in sizes to cut standard pipe threads from 1-inch to 12-inch, and they are used in all kinds of tapping machine and Monitor lathe work.

HOLROYD DRILLING MACHINE AND GRINDING MACHINE.

The machine illustrated in Fig. 1 is more especially intended for drilling the flanges of pipes and fittings. On a strong base is mounted an upright carrying the drill head-stock. At right angles is another base embodying the table slides. On the table is mounted a revolving square table. The head-stock carries a hard steel spindle 2 inches diameter which has an automatic feed of 12 inches by means of drop-out worm and wheel which is released by an adjustable knock-off. The spindle is bored No. 3 Morse taper and is driven through spur and bevel gears by a four-speed cone for 3¼-inch belt, the diameter of the speeds being 10, 11, 12, and 13 inches, giving speeds of 241, 287, 342, and 407 revolutions per minute. Quick hand traverse is by rack sleeve and pinion actuated by hand-wheel. The self-acting feed is 1/100 inch per revolution of spindle. The spindle has a vertical adjustment on the column of 36 inches, with a similar cross traverse, both operated by screws and conveniently placed hand-wheels. The table slides are gibbed to the bed, the longitudinal traverse of the table being 12 inches. The revolving table is 3 feet

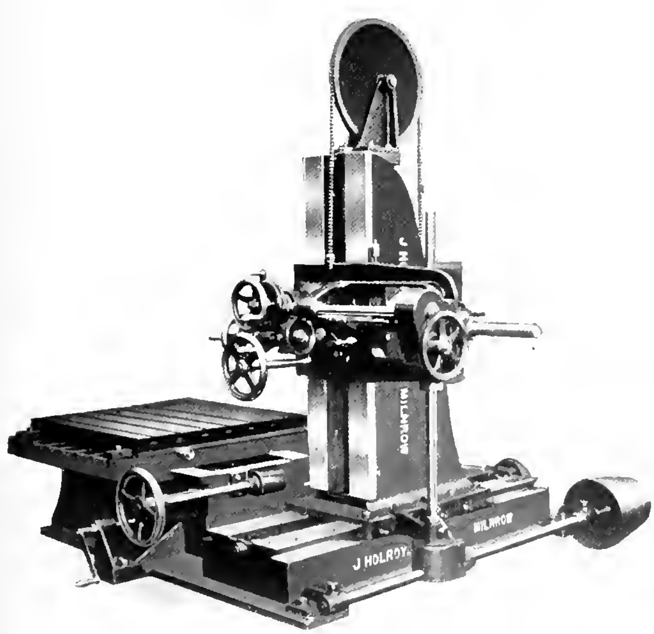


Fig. 1. Holroyd Drilling Machine.

square. The counter-shaft carries 12-inch by 4¼-inch pulleys, and runs at 470 R.P.M. The floor space required is 10 feet by 8 feet, and the total weight of the machine is 3 tons, and, as in the case of the bushing grinding machine illustrated in Fig. 2, the tool is built by John Holroyd & Co., Ltd., Milnrow, Manchester, England.

The second machine mentioned is specially designed for grinding the inside of bushings and cutters from 2 to 6 inches diameter, and up to 12 inches long. It has a strong body with facings provided to receive the spindle and table slides. The emery wheel spindle of hard steel runs in gun-metal bearings carried in the cast iron sleeve. The spindle is driven from a 12-inch diameter pulley for a 1½-inch belt onto a two-speed cone connected to a drum pulley 7½ inches diameter, which in turn drives the spindle pulley. The spindle slide is balanced and provided with self-acting vertical feed of 12 inches, adjustable stops being provided to reverse the feed at any desired point of the traverse. The feed is obtained from the main cone driving shaft through a series of gears onto rack and pinion. Hand cross adjustment of the spindle

Fig. 2. Holroyd Bushing Grinding Machine.

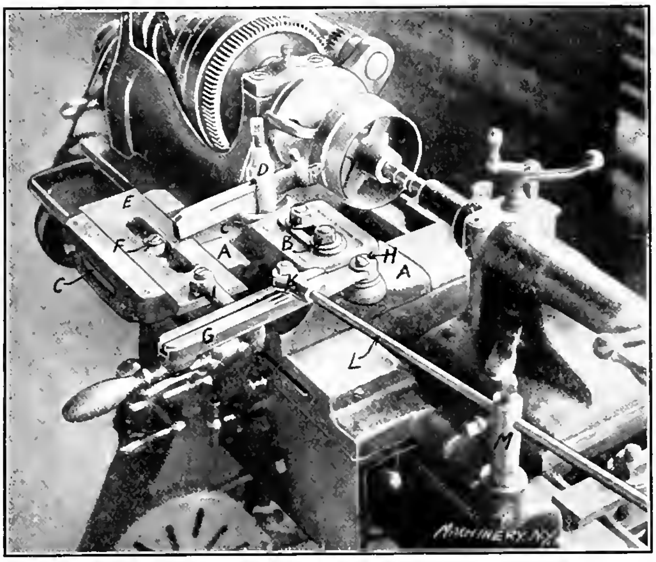
is provided, a micrometer disk being arranged to read to 1/1,000 inch. The work table is 18 inches diameter and has four tee-slots. The table drive is through spur and bevel gearing from a three-speed cone for 2¼-inch belt, the largest speed being 12 inches diameter. The table drive may be brought into or out of action independently of the rest of the machine, by lever and clutch, an advantage when gaging the work being ground. A hinged guard is fitted to prevent the lubricant splashing. The emery wheel speeds range from 6,900 to 10,800 R.P.M., and those of the table are 66, 100, and 150 R.P.M. The feeds per revolution of work are 0.166, 0.25, and 0.375 inch. The counter-shaft pulleys are 12 x 3¼ inches, and the speed 400 R.P.M. The floor space occupied by the machine is 5 feet 6 inches by 3 feet 8 inches, and its weight 2,900 pounds. J. V.

MOSSBERG PULLEY CROWNING ATTACHMENT FOR LATHES.

In the half-tone is shown a pulley crowning attachment, made by the Mossberg Wrench Co., of Central Falls, R. I. The notable features of this attachment are that it is adapted to turning suitable crowns for narrow or wide-faced pulleys, without requiring a change of formers, and that it is also adapted for being attached to a wide range of sizes and designs of lathes, without requiring reconstruction. A number of other advantages will appear in the course of the description.

It consists essentially of a main casting *A*, clamped by bolts *B B*, to the regular tool-post slot of the cross-slide. This main casting carries ways for slide *C*, on which the tool-post *D* is mounted, and also ways at right angles to, and above *C*, for confining former *E*. This former has a curved slot, operating on a roll *F*, whose pivot is fast to the tool-post slide *C*. It will thus be seen that a longitudinal movement given to former *E*, will, through the action of the curved slot on roll *F*, give an in and out movement to the tool-post, thus determining the contour of the surfaces being turned. This longitudinal movement is given by the link work shown. A bar *G*, pivoted at *H* to the main casting *A*, is connected with *E* by the link *J*. It carries a handle at its outer end, and its upper surface has a T-slot on which pivot *K* can be adjusted to any desired position. This pivot constrains the end of rod *L*, whose other end is fastened, at any length desired, to an adjustable bracket *M*.

As the carriage is moved back and forth, it will be seen that rod *L* will swing slotted bar *G*, which, through link *J*, will move the former *E*, thus affecting the turning tool and the contour of the work. If *K* is adjusted to position immediately over the connection point of link *J* in the slotted bar, then the former will stand stationary with relation to the bed of the lathe, while the carriage and the tool-post move back and forth by the feed or by hand. Under these conditions, the contour of the slot in the former will be exactly traced on the face of the pulley. If pivot *K* is clamped in the position shown, the swinging movement of *G* will be much greater for a given movement of the carriage, so that a shorter and more pronounced curve will be turned, suitable for narrow faced pulleys. If the



Attachment for Crowning Pulleys, which gives Curves Suitable for Pulleys of Different Faces with the Same Former.

pivot, on the other hand, is located at the extreme outer end of the slot in *G*, the movement of the former will be very much slower, and the conditions will be suitable for turning pulleys of wide faces which do not require a pronounced crown. This makes unnecessary the provision of a former for each shape of crown desired.

Another advantage of this device is the fact that special arbors with shoulders for locating the work are not required. In operation, when it is desired to start on a new pulley, the carriage is adjusted until the tool point is central with the face of the pulley; the set-screw in pivot *M* is then released, and slotted bar *G* is adjusted by the handle at its outer end until roll *P* is in the center of the slot in *E*, as determined by the center line traced upon it. The set-screw in *M* is then tightened down again, and the tool brought over to commence the operation of turning.

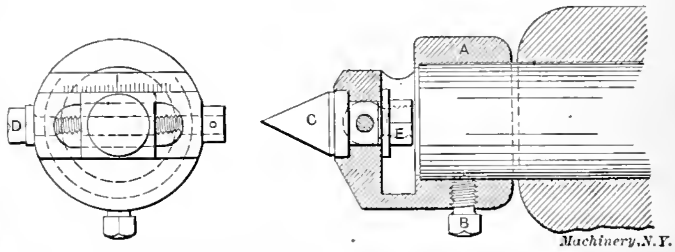
These features, and the self-contained construction of the attachment, should make it convenient for the work it is designed for.

CINCINNATI CENTER FOR TURNING TAPERS.

The device shown herewith has been designed by Max C. Zange, 2827 Sidney Avenue, Cincinnati, Ohio, for doing away with some of the troubles incident to turning tapers in the lathe by the method of setting over the tail-stock. One of the chief difficulties in turning tapers in this way, as is well known, is the fact that the center adjustment of the tail-stock is disturbed, and it requires considerable time and trouble to bring it back, after the taper job is completed, to a position where the lathe will again turn work to the required degree of cylindrical truth. With this device the tail-stock is not set over, the setting over being done on the center itself, provision being made in the attachment for this.

The body *A* of the device, machined out of round stock, is clamped to the tail-stock spindle by set-screw *B*, the regular tail center being removed for the purpose. The tail-stock spindle seats against a shoulder in *A*, to take the thrust of the work between the centers. The front of the body of the device is milled out to form ways in which the center *C* can be laterally adjusted. The lateral movement of this center is effected by the stationary adjusting screw *D*, and the amount of off-set is read by graduations on the body, as shown in the end view. After the required adjustment has been obtained, the center is clamped in position by nut *E*, which is reached by the wrench through the opening in the body left for the purpose.

The center is made of tool steel, hardened, and is made to an angle of 50 degrees instead of the usual 60 degrees of the



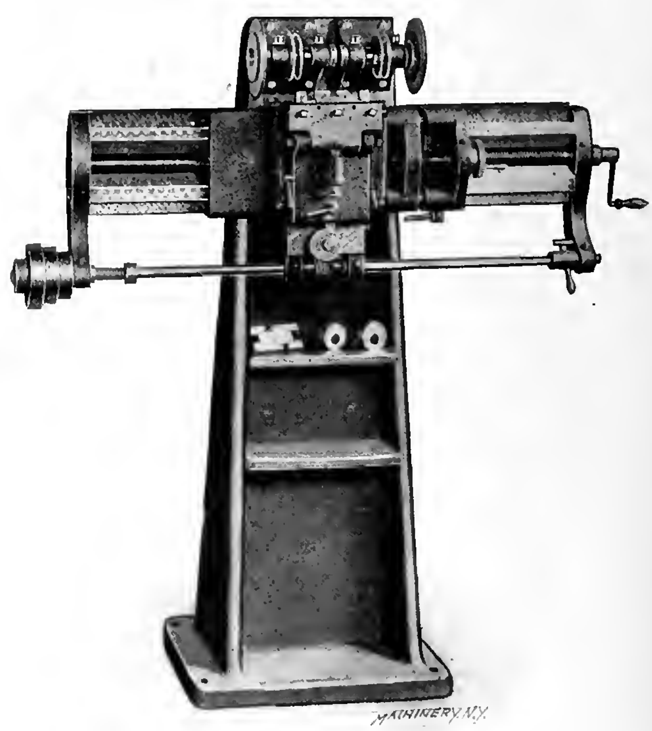
A Device for Setting Over the Tail-center for Taper Turning, without disturbing the Adjustment of the Tail-stock.

common lathe center. The pointed end is also slightly curved, both of these alterations being made to compensate for the angular position of the center in the work. The adjusting screw *D* has 25 threads per inch, and this pitch, in connection with the squared head of the screw, may be used in obtaining adjustments of hundredths of an inch.

Two sizes of this device are made, one of them suitable for bench and precision lathes, and the other adapted for larger machines. In the smaller one, the nut *E* is provided with a permanently fixed handle, so that it is not necessary to insert a wrench in the opening when the center is to be tightened in position. The small size is suitable for tail-stock spindles up to $1\frac{3}{8}$-inch outside diameter; the larger size will cover the range of from $1\frac{3}{8}$ to 1 15-16 inch outside diameter of tail-stock spindle.

GAGE LAPPING MACHINE, BUILT BY THE WALTHAM MACHINE WORKS.

We show herewith a machine for lapping gages, built by the Waltham Machine Works, Newton St., Waltham, Mass. It is intended for doing the work described in the article on machine lapping by Mr. Shailor in our November, 1907, issue.



A Machine for Grinding Snap Gages, and Finishing them by Lapping.

It will be remembered that the use of the milling machine was there spoken of for this work. This specialized tool accomplishes the same results in a somewhat more convenient way. The upright column of the machine supports two heads,

one of them carrying a spindle for a grinding wheel, and the other for a steel disk charged with emery or diamond dust, for the finishing operation of lapping. Since these arbors are run separately, appropriate speeds can be given to them. The gage to be ground is held in a vise, carried by a slide adjustable on the cross-rail, shown at the front of the column. The crank at the right, attached to the traversing screw, affords means for changing the work from the right-hand wheel to the left-hand, or vice versa. The small adjusting wheel is attached to a fine pitch screw, which is used for feeding the gage up to the wheel for the grinding or lapping operations.

In operation, the gage is brought up to the revolving disk with just enough pressure to give a suitable cutting action. The vise in which the work is mounted slides in vertical ways, and a vertical reciprocating motion is given to it by means of the heart-shaped cam shown, driven by worm gearing from a shaft running lengthwise of the cross-rail, below it. This cam does not give a uniform movement throughout the stroke. It accelerates its motion at the ends of the stroke to avoid the "bell-mouth" effect which is ordinarily seen in lapped gages. The holder or vise in which the gages are mounted can be swung outward at an angle of 45 degrees for gaging the work. A clutch is provided for stopping the cam driving shaft, without requiring the counter-shaft to be stopped.

This machine is built only to order by its makers. The one shown is quite elaborate and was so made to meet the requirements of the purchaser. Simpler machines of the same sort for lapping gages could be designed, and the makers will furnish them adapted to suit individual needs.

TOLEDO TOGGLE ACTION DRAWING PRESS OF UNUSUAL SIZE.

The Toledo Machine & Tool Co., of Toledo, Ohio, has recently shipped to one of its customers, what is believed to be the largest toggle action drawing press ever built. The ma-

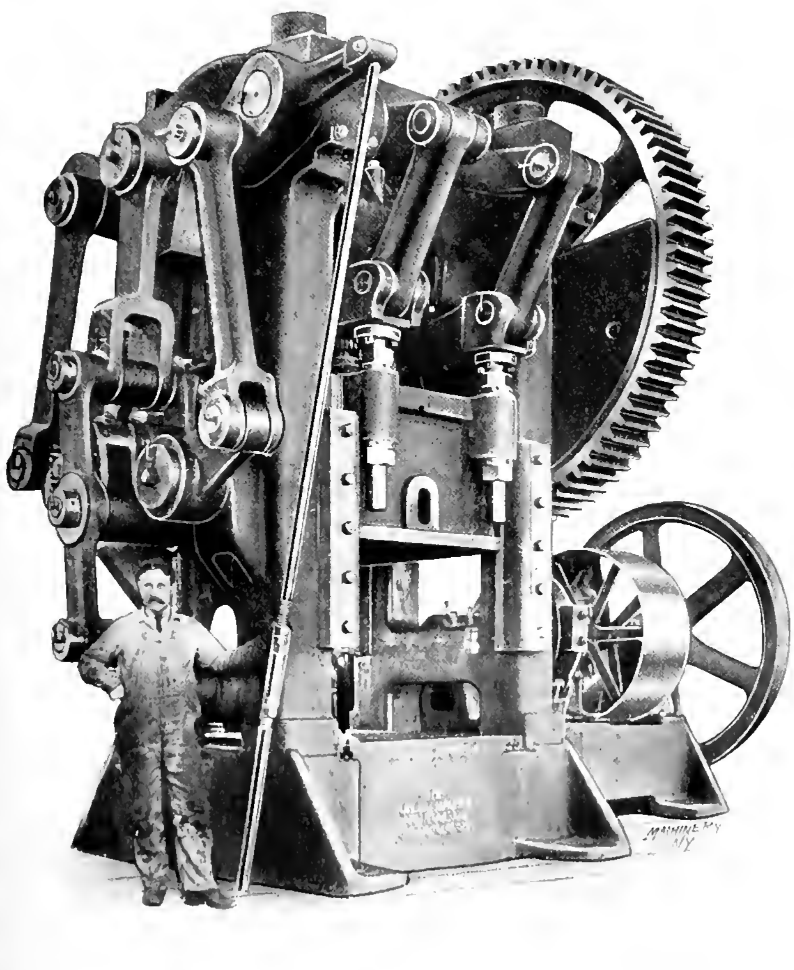


Fig. 1. Heavy Drawing Press with Blank Holder operated by a Toggle Mechanism.

chine is certainly of tremendous size, as will be seen by comparing it with the man who stands in the foreground of Fig. 1. It has interest aside from its unusual size, from the improved construction of the toggle mechanism (described also in the December, 1905, issue of MACHINERY), which gives a long "dwell," and is unusually efficient so far as power consumption is concerned. The press is intended for deep stampings in steel or other materials, particularly for brake drums for automobiles, sinks, bathtubs, and similar work.

The toggle mechanism, which is plainly shown in the half-tone, Fig. 1, and the line drawings, Figs. 2 and 3, is of such

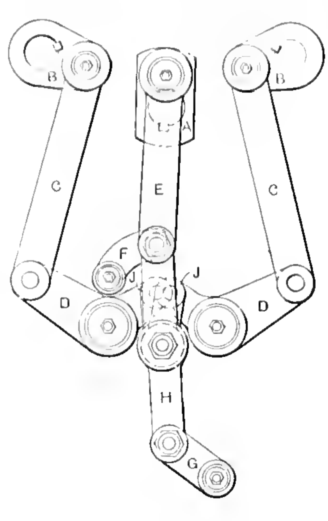

Fig. 2. The Outside Toggle Mechanism in the Position to raise the Blank Holder.

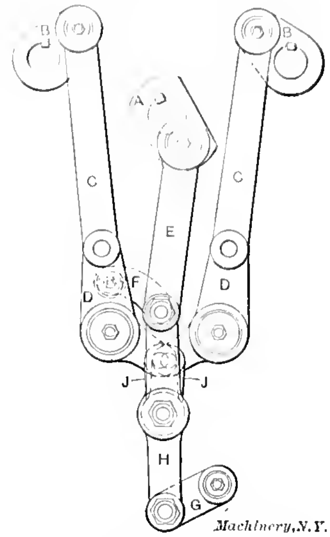

Fig. 3. The Toggle Mechanism while the Blank Holder is Lowered.

design that all sliding surfaces are eliminated, being replaced at all points with pivoted joints, most of which have but a very small angular movement. A (see Figs. 2 and 3) is a crank keyed to the main crank-shaft of the press. Connecting-rod E, attached to this, is pivoted in yoke H, which is suspended on rocker arms F and G, pivoted to the side frames of the machine, on opposite sides of H. Bell crank levers D are operated from the center pivot of H, through short links J. Links C connect the upper arms of bell cranks D with cranks B, which are keyed to rocker arm shafts. The rocker arms between the frames are directly connected with links to the blank holder slide, as shown in Fig. 1.

A comparison of Figs. 2 and 3 will show the action of the mechanism. In Fig. 2, crank A is at its highest position. In Fig. 3 the blank holder is down. It will be seen that in this position bell cranks D and links C are straightened out, so that a powerful toggle action with an appropriate dwell is obtained, lasting through a considerable portion of the revolution of the crank-shaft.

Cranks B, in turn, operate the rocker arms, which, with the links connecting them with the blank holder slide, form a second toggle joint mechanism. It will be seen that these two sets or toggle joints, acting in series as they do, give a powerful pressure to the blank holder, estimated by the builders at 2,000 tons. This gives a very long dwell as well. This extends to over 90 degrees of the crank action, without perceptible movement of the blank holder.

All the parts of the toggle mechanism are made of steel castings, and each bearing is bushed with bronze. The bearings of the outer movement are oiled through the ends of each of the pivots, by means of self-oiling or compression cups. The smoothness and ease of action obtained by this thorough lubrication and by the avoiding of sliding surfaces, allows the machine to be driven with an 8-inch belt, though it was supposed that a 10-inch double belt would be necessary. The press is operated by a powerful friction clutch, and is therefore under complete control of the operator at all points of the stroke of both plunger and the blank holder.

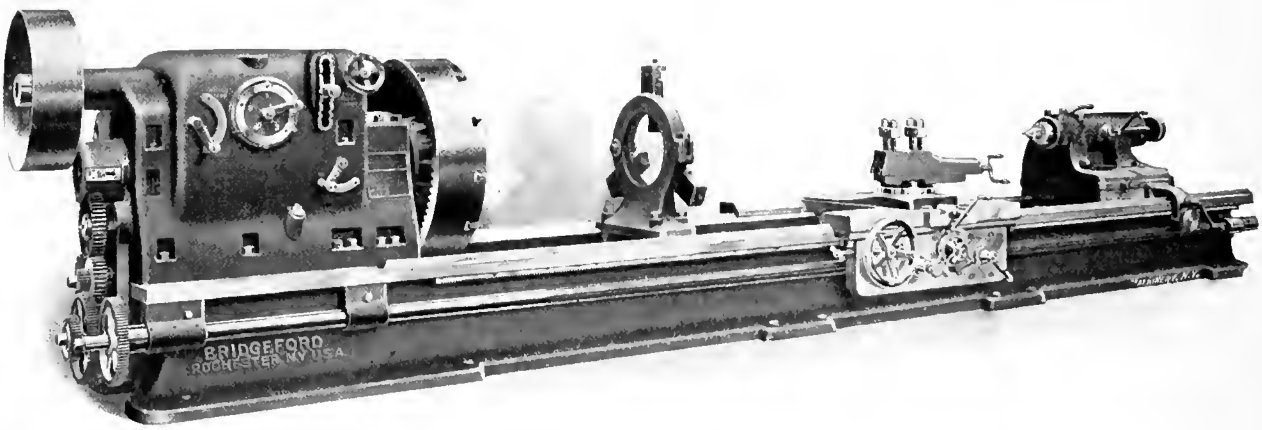
The distance between the uprights is 57 inches, this being also the width of the bed. The distance from the bed to the

blank holder, with the stroke down and the adjustment up, is 24 inches. The distance from the bed to the plunger with the stroke down and the adjustment up is 28 inches. The stroke of the plunger is 26 inches. The belt pulleys are 58 inches in diameter, designed for a 10-inch belt, and are intended to run at 250 revolutions per minute. This, with a gear ratio of 50 to 1, gives 5 strokes per minute for the press. The shaft is 13 inches in diameter at the crank bearing.

The total height of the machine above the floor line is 21 feet. It weighs, complete, 175,000 pounds.

BRIDGEFORD GEARED HEAD LATHE.

The Bridgeford Machine Tool Works, Rochester, N. Y., has recently designed a line of geared head lathes covering the sizes between 26 and 48 inches swing. The engraving shows the 42-inch lathe. The 48-inch swing is, so far as our memory serves us, the largest single speed pulley geared head lathe we have even seen illustrated or described. The lathe has been designed to meet the severest requirements, and is claimed to be limited in capacity only by the efficiency of the best of the modern high speed tool steels.



A Geared Head Lathe of Unusual Size, built by the Bridgeford Machine Tool Works.

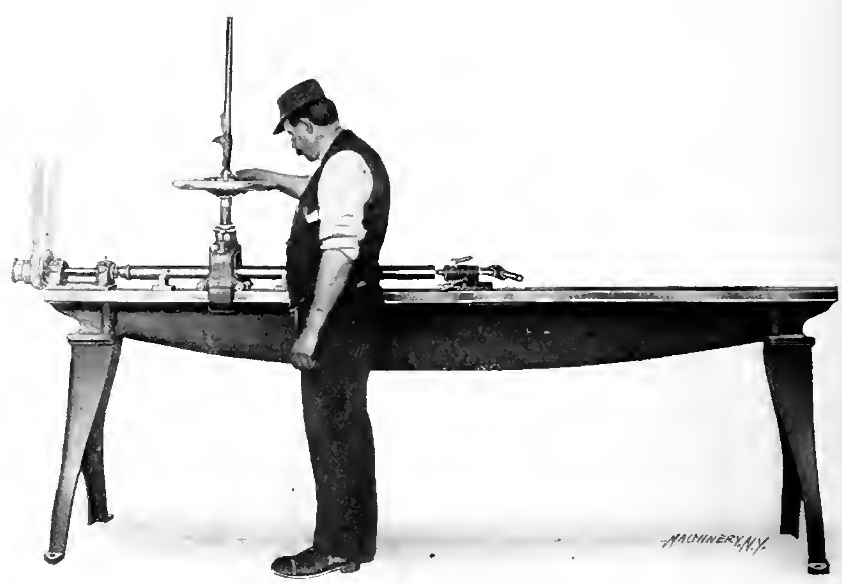
The power is applied to a constant speed pulley from which the 15 cutting speeds are obtained by change gearing. These speeds are arranged in geometrical progression, and the changes are accomplished by shifting the conveniently located levers, shown in the half-tone in front of the head-stock. All the driving gears, with the exception of the face-plate gear, are of steel cut from the solid. All those within the head run in oil, and provision is made for furnishing a constant supply of oil to all the bearings. The proportions of gearing used give from 2.26 to 110.8 revolutions of the driving pulley to 1 revolution of the face-plate. On a diameter of 42 inches the pulling power is about 25,000 pounds, or about four times that of the ordinary cone driving lathe. The spindle is of crucible steel, ground to size, running in heavy bronze bearings scraped to fit. The face-plate is pressed onto the spindle and keyed to it.

The bed is of ample width and depth, and is strongly reinforced with heavy cross ties of box pattern. It is also provided with a longitudinal rib with ratchet teeth cast in its upper face, which engage a pawl at the back of the tail-stock. This provides a positive stop for the tail-stock, which is a great advantage when the lathe is engaged on heavy work. The tail-stock is so shaped as to clear the compound rest when turning angular work. The carriage compound rest and apron are of heavy construction, and in keeping with the balance of the lathe. The direction of the feeds is changed at the apron, and the lateral and cross feeds are driven by independent frictions.

The following dimensions will give some idea of the rigidity of the design. The main spindle bearing is 8¾ inches in diameter and 14 inches long, with a 1 7/16-inch hole through it for removing the center. The centers are of tool steel, 3 3/16 inches in diameter. The 42-inch face-plate is 11 inches wide. The driving pulley is 30 inches in diameter, for an 8-inch belt. The lead-screw is 2 11/16 inches in diameter, two threads to the inch, and the rack is 2 inches wide, 5 diametral pitch. With a 16-foot bed, the distance between centers is 6 feet 7 inches. It can be built with a bed of any length desired. A 42-inch lathe with a 16-foot bed weighs 27,000 pounds; 6,500 pounds should be added for each additional foot of length. The regular attachments are: Compound rest, side-turning rest, 16-inch center rest, thread indicator, change gears, self-oiling counter-shaft, and the necessary wrenches and cranks.

ROCKFORD DRILLING MACHINE COMPANY'S STRAIGHTENING MACHINE.

The machine shown in the accompanying engraving is a combination of lathe and straightening press, for straightening centered work. Straightening presses have been built to use in the lathe, and straightening presses have been built provided with centers on which to spin the work to determine the "high spots," but this is the first device that has come to our attention that is really a combination of the straightening press and lathe. It would seem to be a very efficient ma-



A Combination of Lathe and Screw Press for Straightening Centered Shafts.

chine for use in places where there is considerable of this work to do. It is built by the Rockford Drilling Machine Co., Rockford, Ill.

The machine consists essentially of a heavy, rigid bed, carrying a power driven head-stock and an adjustable foot-stock, and supporting a straightening press with suitable blocks for the straightening operation. The head-stock spindle has a

three-step cone, on which the belt may be shifted to drive the work at a rate of revolution suitable for accurately determining its truth. A center is supported by this spindle in the front end in the usual way. Instead, however, of driving the work from a face-plate by a dog, a friction device is provided which revolves the work as soon as it has been clamped between centers. This consists of a collar fitting over the head-stock center, and provided with a leather face which is pressed against the work by four coiled springs. The support blocks used are provided in sets of two for each diameter of shaft. They are bored to accurately fit the diameter they are made to, but with centers 1/16 inch or thereabout below the center of the spindle. The tail-stock center is operated by a lever, and may be held in position by a clamp screw in the ordinary way. It will be seen that this method of supporting and driving the work is very convenient, since when the centers are released, the work drops into position in the supporting blocks, ready to be straightened. After the straightening is done and the tail-center is again brought up and clamped, it raises the work from the supporting blocks, the centers enter the center holes in the work, and the work is driven by the constantly running spindle, all of this being done in one movement of the tail-stock operating and clamping levers.

The carriage which supports the straightening screw runs on rollers, and can be shifted very quickly and easily on the bed to bring it to the point where the straightening needs to be done. This screw is of fine pitch, so that the hand-wheel provided is generally of sufficient diameter for providing enough pressure to straighten the work. For large work, however, the ratchet lever shown may be swung down into place, giving sufficient leverage to straighten any piece within the capacity of the machine. On this straightening screw is fixed a revolving dial, read from a stationary index point. The operator watches this in straightening a piece of work, and is able to use it for reference in applying pressure a second time to the same point, if the first application of the pressure was not sufficient. The bed is very rigid, and capable of sustaining as severe a straightening pressure as should be applied to any work within the capacity of the machine. It is long enough to give the machine a capacity of 8 feet between centers.

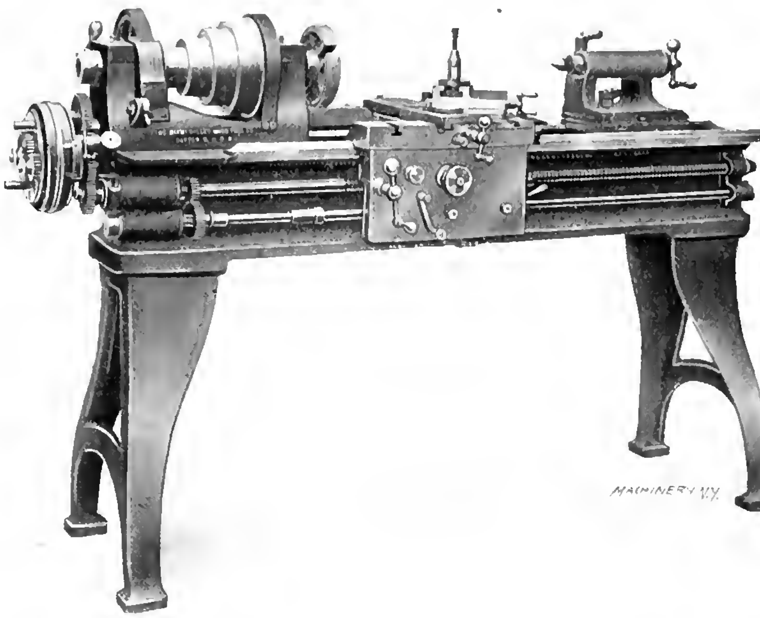
The builders have been using this machine to do all of their straightening with, none of it now being done in the lathe in their shops. They have found that it permits doing the work in a very much shorter time, owing to the convenience of operation which the design of the machine provides for. All of this straightening is best done by one man, who soon becomes skillful at the work, so that it is done in a small fraction of the time previously required.

IMPROVED MIAMI VALLEY 13 1-2 INCH ENGINE LATHE.

The machine shown in the accompanying engraving is an improved design of the lathe built by the Miami Valley Machine Tool Co., 843 W. Germantown St., Dayton, Ohio. Among the improvements made are: the addition of a quick change gear attachment; an automatic stop for the carriage feed; a chasing dial for cutting screw threads; and a taper-turning attachment.

The general design of the lathe is simple, rigid and serviceable. The spindles are of high grade crucible steel, ground accurately to size, running in bronze bearings. The head- and tail-stocks are of heavy design, and are held to the bed with a V-bearing at the rear, and a flat bearing on the front; the carriage has a V-bearing in the front, and a flat bearing in the rear. There being but one V-bearing in front, the carriage may be stiffened materially without decreasing the swing. The chasing dial is located just at the right of the carriage. It is connected to a worm-wheel meshing with the lead-screw, and the graduations on its face are used to determine the proper time for throwing in the lead-screw nut when cutting threads. The use of this dial makes it unnecessary to reverse the counter-shaft for thread-cutting. An interesting point in the construction of the compound rest is the fact that the screw is journaled in the swivel base, while the nut is fast to the tool-post slide. It is thus possible to lubricate the latter.

The quick change gear attachment shown is the well-known one designed by the National Machine Tool Co. It consists of a series of change gears, of various numbers of teeth, arranged in a circular casing and engaging with a central intermediate gear. Changes are made by rotating the casing and engaging the different gears in it with the lead-screw in different positions, and by placing the slip gear on the outside of the casing on the desired one of the various studs provided for it. The number of threads that can be cut varies from 4 to 56 per inch, including the 11½ per inch pitch for pipe threads.



Miami Valley Lathe, as arranged with Quick Change Gear Device.

This machine, which is built in the 13½-inch size, may be had in three lengths of bed—5, 6, or 8 feet. The lathe, with an 8-foot bed, weighs 1,450 pounds. The machine is regularly provided with the compound rest. A taper attachment, carriage turret, and quick change gear device are provided extra when desired.

MILLING MACHINE ATTACHMENT FOR CHAMFERING TRANSMISSION GEAR TEETH.

In the speed change mechanism used in the automobile, the changes are usually obtained by a sliding gear mechanism of some form. To facilitate the sliding of the gears into mesh when they are running at considerable speed, it is usual to chamfer the ends of the teeth, to guide them in entering into mesh with each other. Sliding gear mechanisms are coming into more frequent use in machine tools, so that a machine or attachment like that illustrated (for performing this operation of chamfering the ends of the teeth) is of wider interest than to the automobile industry alone. The device illustrated in Figs. 1 and 2 is built by the "Long Arm" System Co., Cleveland, Ohio. The attachment is fastened to the milling machine table, and its driving pulley is belted to a special counter-shaft. The mechanism is automatic in its action. All it is necessary for the operator to do is to place the work on the work-spindle, adjust the machine and the work properly, and start the counter-shaft. The mechanism revolves the work, feeds it up into the cutter, retracts it—and so on until the work is completed.

The cast iron frame of the device is in the form of a knee, which is bolted to the table. To this frame, on the front side, best seen in Fig. 2, is attached a bracket carrying the driving pulley shaft. A pinion on this bracket drives a gear, which

is connected with a face cam of the enclosed groove type. This cam gives movement to the vertical slide which carries the work spindle. It serves to feed the work upward into the cutter and return it again while it is revolving for the next tooth. This cam gear is connected by an intermediate with the gear driving the indexing worm, the cam and the indexing worm being geared to run together at the same number of revolutions per minute. The gear is its own index wheel. The index worm is adjusted in the T-slot provided for it in

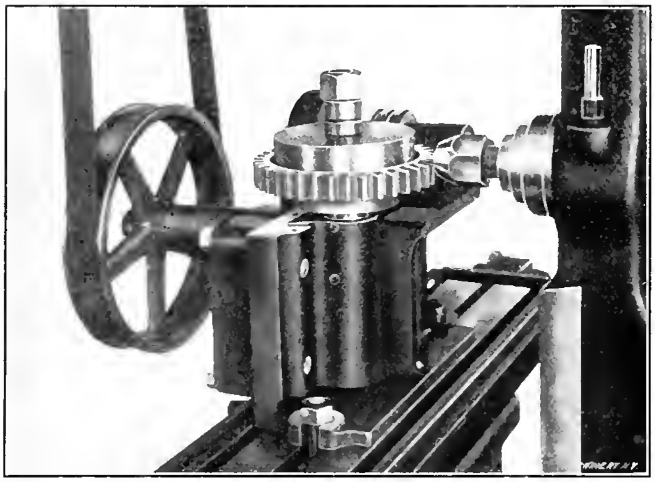


Fig. 1. The "Long Arm" Automatic Gear Tooth Chamfering Attachment at Work.

the body of the fixture until it meshes properly in the teeth of the gear to be cut, and it is clamped in this position, the intermediate gear from the cam shaft being adjusted to drive it without back lash.

When the machine is thus arranged, it may be driven continuously from the counter-shaft. The rotation of the driving pulley will then impart a constant rotary movement to the work through the index worm, the cam, meanwhile, raising and lowering it. With the cutter properly adjusted with relation to the work, it will be seen that this continuous action may be so planned that the cutter will trim off the corner of one side of a gear tooth as it drops into the tooth space, and trim off the corner of the other side as it comes out again, then drop into the next tooth space, beveling the corner as it does so, and continuing the work in the same way until the gear has been finished, and the work removed.

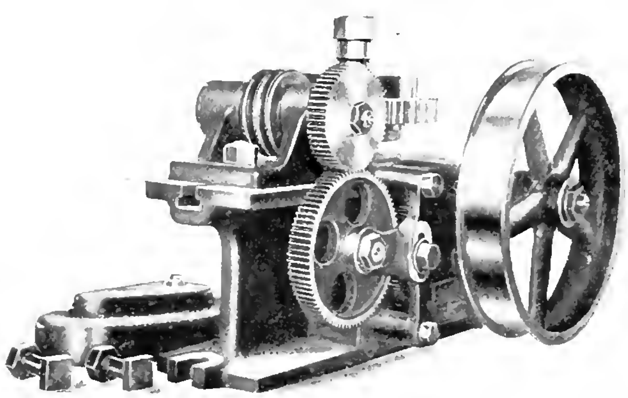

Fig. 2. Front View of the Attachment with the Gear Guard Removed, showing Mechanism.

In practice it is not necessary to stop the machine to put in the work or take it out again. The milling machine saddle is simply run back to withdraw the worm from the cutter, the nut on the end of the work spindle is loosened, and the work is removed. A new gear is then put in, the nut tightened, and the work again brought up to the cutter, when the attachment will continue in operation as before. The under side of the gear can be operated on by changing the position of the cam roll, to engage with the slot below the center of the cam instead of above it, at the same time altering the adjustment of the knee of the milling machine on the column to bring the work to the proper height.

In adjusting the device for gears of the same pitch but of different numbers of teeth, it is only necessary to adjust the indexing worm out or in to mesh properly with the new gear, and to set the machine so that the cutter is in the proper relation to the work. The same index worm will work properly with all gears of the same pitch within the capacity of the machine, a separate index worm being required for each pitch. The cutters used are double ended, of the formed end mill type, the body of the cutter being ½ inch in diameter. They may be held in the milling machine spindle by any collet adapted for holding ½-inch straight-shanked cutters. By using cutters of different shapes, different contours of chamfering may be given to the work.

The machine is well made. The worm is of hardened steel, as is also the work spindle and the cam with its cam roll. Means are provided for taking up any looseness endwise in the worm due to wear, and similar provision is made for taking up wear on the work slide. A gear guard is furnished to cover the intermediate and the worm-driving gears, thus protecting the operator from injury.

The capacity of the attachment is for work from 2 inches to 9½ inches pitch diameter, and from 4 to 10 diametral pitch. When run at the proper speed, about 12 teeth per minute can be chamfered or rounded. The attachment weighs about 80 pounds. A counter-shaft is provided having tight and loose pulleys and an idler pulley with an adjustable counterweight. The counter-shaft weighs about 90 pounds. The price of the machine includes the counter-shaft, clamping bolts, one indexing worm, one cam, two double end cutters, and bushings for locating and holding a gear of one size.

BETHLEHEM STEAM DROP HAMMER.

The Bethlehem Steel Co., South Bethlehem, Pa., has been for some time engaged in the drop forging business, making forgings from all grades of iron and steel to which the process is applicable. In fitting up the plant, it was at first equipped with board drop hammers of the best design and construction the firm was able to find at the time. These failed so seriously

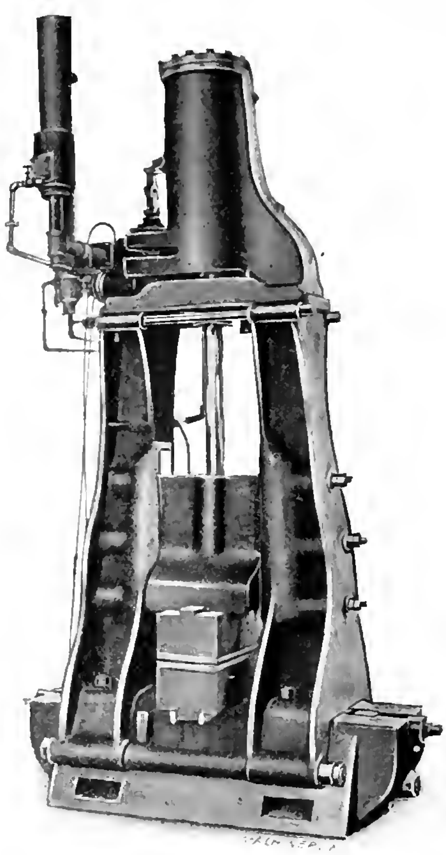

Fig. 1. The Bethlehem Steam Drop Hammer.

and often on ordinary work, involving expensive repairs and delays, that it was finally decided that all future additions to the equipment should be of the type in which the drop is raised by the pressure of steam beneath the piston.

It had been considered in the first place that the steam hammer was more efficient and economical than the board

hammer, but experience with it had shown that it developed serious weak points in service, when of the usual construction. The Bethlehem Steel Co. therefore decided to design a hammer in which the various defects were eliminated, so far as possible, by skillful design and careful construction. The result of this decision is the steam drop hammer we herewith illustrate and describe.

Experience has shown that the steam drop hammer, as ordinarily made, has too small a ratio between the weights of the drop and of the base to permit the most efficient work. This is remedied by increasing the weight of the drop. To prevent the base from cracking under the greater strain thus put upon it, it is made of a steel casting instead of cast iron, as was the previous practice. Another difficulty met with is the rapid wearing of the bearing surface of the housings on the base. This is due largely to the abrasive action of the scale, which makes it impossible to keep the dies properly matched. These difficulties have been overcome by providing ample bearing surfaces, and designing the parts so as to prevent the lodging of scale and the wear consequent thereon.

The severe side thrust arising from forging out of the center of the dies, brings about very serious difficulties, such as the breaking of the guides and uprights, and the consequent bending or breaking of the piston-rod. To overcome these difficulties, the uprights have been tied together to prevent spreading, and to distribute the strains so as to minimize any eccentric action on the part of the drop, thus extending materially the life of the piston-rod. In addition, the substitution of steel castings in place of iron for the uprights has obviated all the danger of the breaking of these parts.

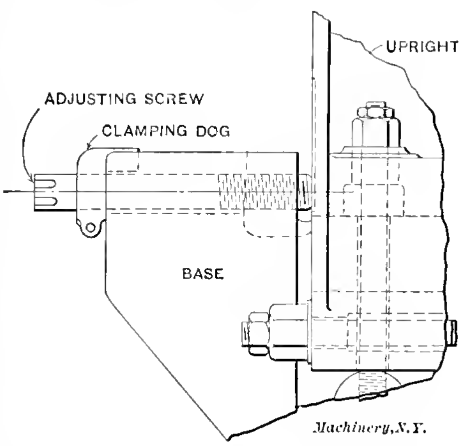

Fig. 2. Adjustment of the Uprights on the Base, for Centering the Dies.

In the ordinary steam drop, no provision is made for adjusting the dies in any other way than by the keys in the lower member. The screw and nut adjustment used in the board drop is short-lived, the screw either breaking or becoming fast in the nut. To replace these broken parts, it has been hitherto necessary to dismantle the hammer, an operation consuming from 1 to 3 days. On the Bethlehem steam hammer, as is shown in detail in Fig. 2, the screw and nut are made exceptionally heavy, and are so placed as to facilitate their renewal and the substitution of new ones in case of necessity—an operation requiring less than half an hour. The aligning of the dies, as may be seen, is effected by moving the whole frame-work of the hammer on the bed one way or the other, by operating the screws at the ends of the bed. These screws are locked by the dogs clamped to them, whose tails enter slots provided for them in the base.

The builders are prepared to furnish these hammers in any size from 500 to 10,000 pounds inclusive.

PEASE AUTOMATIC ELECTRIC BLUE-PRINT MACHINE.

The device illustrated in Figs. 1 and 2 is made by the C. F. Pease Blue-Print Machinery & Supply Co., 22 Fifth Avenue, Chicago, Ill. It consists essentially of a blue-print frame, mounted on pivots between uprights, and provided with mechanism for traversing at a uniform and adjustable speed across its face, an electric light of the Cooper-Hewitt type.

The printing frame is made of carefully selected hard wood, well finished and reinforced. The frame on which it is mounted is of iron, and is provided with a spring stop to hold the frame in the operating position shown in Fig. 1, or the position for removing or inserting the prints or tracings shown in Fig. 2. The lamp used, as is well known, consists of a hermetically-sealed glass tube containing a quantity of

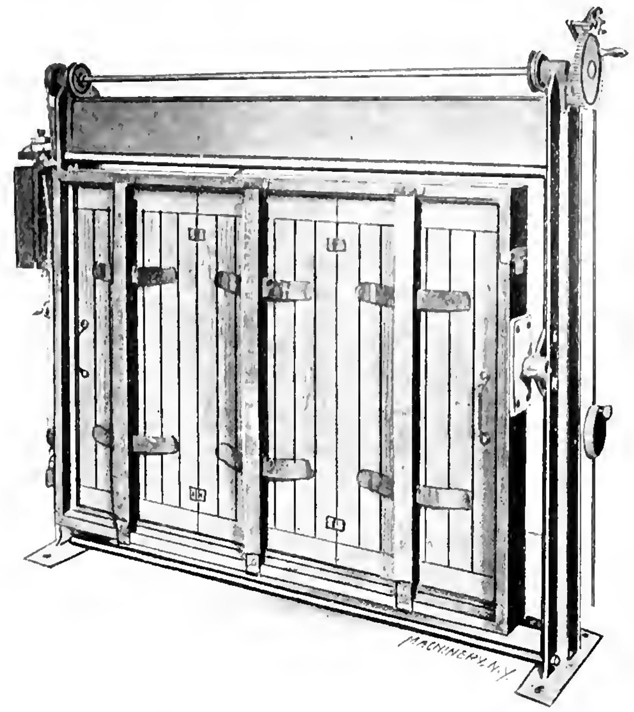

Fig. 1. Blue-printing Machine using Cooper-Hewitt Lamp, whose Descent is regulated by a Pendulum and Escapement.

mercury. As may be seen, the tube is placed in a slightly tilted position, with the mercury at the lower end. As soon as the current is established by throwing on the main switch, the tube is tilted by mechanical means provided for that purpose so that the mercury flows in an unbroken stream to the other end. When this has been done the tube becomes luminous throughout its length, and is then allowed to resume its normal position, as shown in Fig. 2.

The mechanism for traversing the tube across the face of the print comprises an escapement, regulated by a pendulum

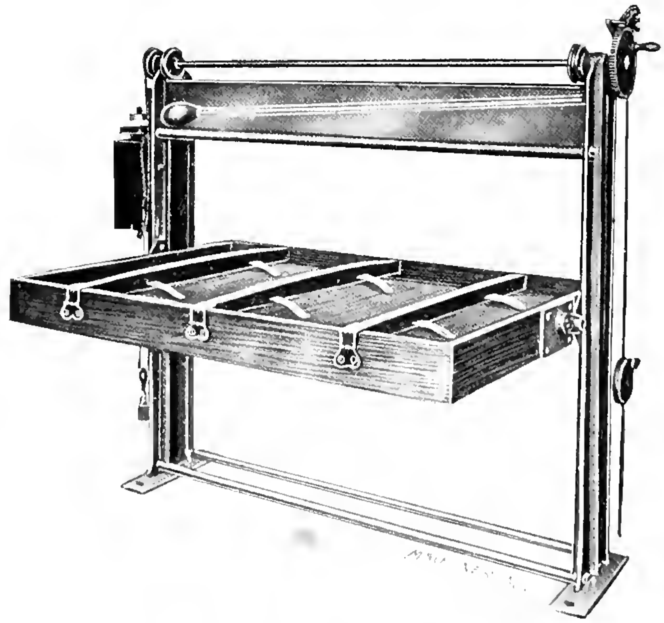

Fig. 2. The Printing Frame swung down to permit Insertion of Tracing and Paper.

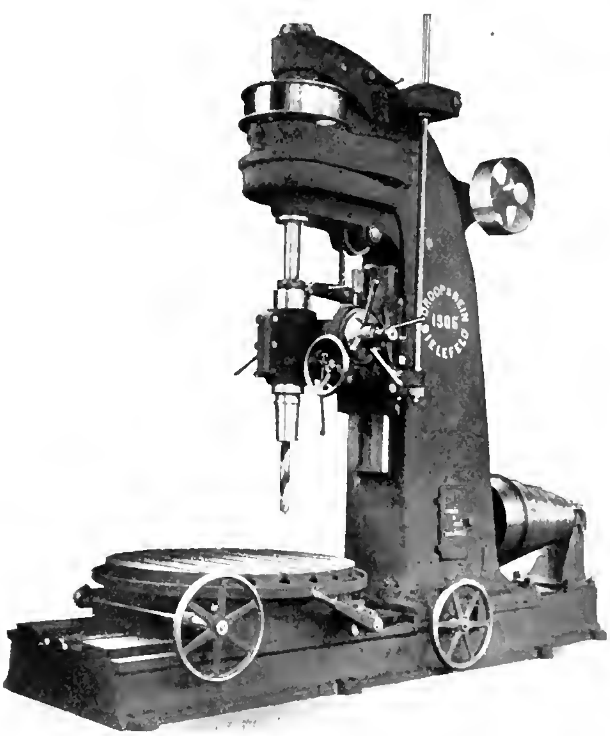
with an adjustable weight, which may be set to give the rapidity of printing required by the quality of the paper used, and the transparency of the tracing. The lamp is mounted in a well-ventilated reflecting box, not shown in the cut, guided between uprights on the main frame of the machine, and supported by cables attached to the speed controlling shaft at the top.

A number of advantages are claimed for this device. The machine is highly efficient as compared with those using arc lights. This is due to the use of the Cooper-Hewitt lamp, which gives about double the amount of light obtained from an arc lamp consuming the same amount of current. The amount of heat thrown off is also so small that the lamp may be placed close to the paper, so that the printing efficiency is much greater than with an arc lamp placed as far from the work as is necessary in a cylinder machine. The Cooper-Hewitt light is also very rich in chemical qualities, making it an ideal one for this use, since practically all the energy is transformed into actinic rays. It requires only 3½ amperes at 110 volts to print at the same speed as an arc lamp in a cylinder printer, consuming 15 amperes at the same voltage. A life of 2,000 hours is guaranteed for the tubes, and single tubes have been known to last twice this length of time. The cost of operating the machine is less than two cents per hour at the rate of five cents per kilowatt hour. The simplicity of construction and operation permits the machine to be handled by inexperienced help, an ordinary office boy being capable of running it to good advantage.

Three sizes of this machine are made for frames 20 x 24, 30 x 42, and 36 x 48 inches, respectively. They occupy floor space 12 inches in width, varying from 30 to 60 inches in length for different sizes. They are considerably less expensive than the cylinder type machines.

DROOP & REIN HIGH SPEED DRILL PRESS.

We show herewith an engraving of a businesslike-looking high speed drill press, made by Droop & Rein, Bielefeld, Germany. The frame of the machine is built in the form of a hollow housing, giving the tool the stiffness and strength necessary for drilling holes of large diameter with high speed drills. To allow easy adjustment of the large work for which the machine is intended, the work table may be adjusted lengthwise or rotated to bring the work into position for drilling.



A German Machine for Heavy Drilling with High Speed Steels.

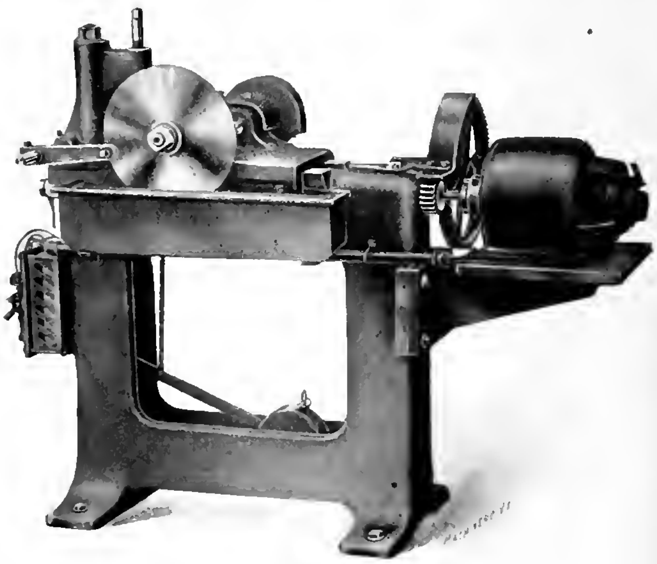
As may be seen, power is conveyed to the spindle by an endless belt, running from the driving cone pulley at the rear end of the machine near the floor, over idlers to the pulley on the spindle. This insures smooth running at the highest speeds. The back gearing is located on the spindle below the driving pulley. It is entirely encased so that it may be run in an oil bath. The maximum spindle speed is 670 revolutions per minute, and ten changes are provided for. All the driving gears are made of steel or phosphor bronze. The diameter of the spindle journal in the sleeve is 4 inches. It is hardened and ground, and is balanced, together with the sleeve, in the usual way. The feed mechanism is driven from one of the guide pulleys. It has eight changes and an automatic stop.

The table may be rotated on the saddle by which it is carried, and may be adjusted in and out on the bed as well. These adjustments may be driven by power, for rapid setting, but can be made by hand as well for minute adjustment. The table is about 4 feet 7 inches in diameter. The distance from the center of the spindle to the column is 2 feet 1⅛ inch. The whole machine weighs about 28,600 pounds.

As an example of its capacity in actual service (not for short trials) a large German manufacturer, who was the first user of this machine, has made the following record in everyday work, day after day, using high speed drills; 12 holes, 1⅞ inch each in diameter, were drilled in wrought iron flanges, 2 15/16 inches thick, in one hour—that is to say, at the rate of 5 minutes per hole, including the time necessary for setting up the work.

BURR MOTOR-DRIVEN COLD SAW FOR SMALL WORK.

The photograph shows a new motor-driven cold saw, built by John T. Burr & Sons, 34 South 6th St., Brooklyn, N. Y. It is adapted to the cutting off of stock, pipe, etc., up to 3½ inches in diameter. The saw-blade is 10 inches in diameter,



Burr Cold Saw arranged for Motor Drive.

and is fed by gravity, the pressure of the feed being adjustable by altering the position of the weight on the lever shown. The driving mechanism consists of a steel worm-gear, hobbed worm and steel pinions.

When arranged as shown, the machine is driven by a ½ horse-power constant speed motor, running at about 2,000 revolutions a minute. It is connected to the worm shaft by a rawhide pinion and a cut iron spur gear. All the gears are covered, and the starting box and switch are conveniently placed at the rear of the machine.

When desired, the makers will arrange the saw to be driven by an alternating motor.

GORTON CUTTING-OFF MACHINE.

Among the carefully designed and ingeniously constructed machines we are continually describing and illustrating in these columns, we once in a while have the opportunity to describe one which shows such striking originality of conception as to at once arrest the attention. This is the case with the cutting-off saw we here illustrate, built by the Geo. Gorton Machine Co. of Racine, Wis. The idea of turning the cutting-off saw "inside out" presents such obvious advantages that it is strange it has not been tried before. Very possibly it has been thought of; it would be strange if it has not been. But Mr. Gorton seems to have been among the first to think of it, and certainly the first to work the idea out in practical shape.

The difficulties met with in the design and operation of metal saws for heavy duty are well known. Fig. 2 shows the

conditions quite graphically. The saw is usually driven from a spur gear mounted on a saw arbor, which is of necessity very much smaller in diameter than the saw, to allow the latter to take a reasonable depth of cut. In the case shown, a not unreasonable one, the radius of the driving gear at the pitch line is only one-third of the radius on which the teeth

Fig. 1. The Gorton Cutting-off Machine, using Saw with Internal Teeth.

of the saw are cutting. This means that the driving power is lamentably weak, so that the consequent excessive vibration and chatter have established a limit in saw efficiency beyond which it has seemed impossible to pass. Various ingenious schemes have been tried for applying the power nearer the periphery of the blade, but in none of these, so far as we know, has it been possible to apply the power on a circle of greater diameter than that in which the saw blades revolve.

The mechanism by which this is made possible, is shown in Fig. 3. The saw, having inserted teeth of high speed steel, is mounted on a revolving ring and supported by a swinging frame, pivoted about the pinion shaft by which the ring and its attached saw are driven. The ring is journaled on its outside diameter in the swinging frame which carries it. The stock is passed through the center hole of the saw, and the saw is fed through the stock by swinging it about the center of the driving pinion, the frame for this purpose being provided with a 90-degree segment of a worm-gear, as shown, which engages the feed-worm below it. The ability to obtain a smooth and powerful drive by this means, and a smooth and powerful feed as well, will be readily appreciated.

Figs. 1, 4 and 5 show how the scheme of Fig. 3 has been applied in a commercial design. The frame of the machine, as may be seen, is of hollow, box-like construction, and exceedingly rigid. The main driving pulley (which is 14 inches in diameter by 10 inches face, and runs at 350 revolutions per minute) is connected by spur gearing with the driving pinion shaft, which is geared to the saw-carrying ring as described, and shown in Fig. 3. The swinging frame in which the ring and saw are mounted is shown raised in Fig. 4, and in working position in Fig. 1. The fact that this frame is hung on trunnions from above, avoids the possibility of having its bearings injured by grit and scale. This is an important detail in the construction of the machine, as is witnessed to by the badly cut ways frequently found on the usual types of sawing machines.

The driving pulley shaft is connected with the feed shaft at the rear of the machine, near the base, by a belt passing over a pair of six-step cones. These give six feeds in geometrical progression, which, on the 6-inch machine shown, will sever a 6-inch bar in from $1\frac{1}{4}$ to $5\frac{1}{2}$ minutes. As may be seen best in Fig. 5, this feed shaft is connected by worm-gearing in the enclosed casing shown, to a hollow shaft to which the feed worm is keyed. This shaft comes through to the front of the machine as may be seen in Figs. 1 and 4, where it may be operated by the large hand-wheel shown. The small hand-wheel controls a push-rod, which passes through the center of the hollow shaft and operates a clutch by which the worm-gear at the back of the machine is connected with the feed worm shaft. An automatic feed release is provided.

A geared lubricating pump is provided, with all the necessary piping, for conveying water or special lubricant to the cutting point. A generous reservoir is furnished by the base of the machine. An opening is provided at the rear (see Fig. 5) for the removal of the chips which settle into the chute shown, which is provided with a screen bottom, through which the lubricant drains off, while the chips slide down to the outside pan provided for them. This view also shows the adjustable gage, which may be used when desired, or swung

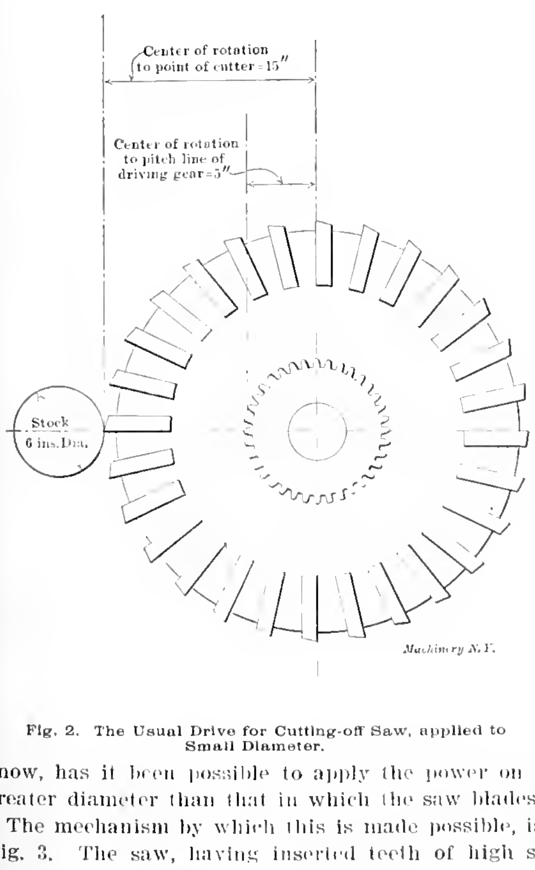


Fig. 2. The Usual Drive for Cutting-off Saw, applied to Small Diameter.

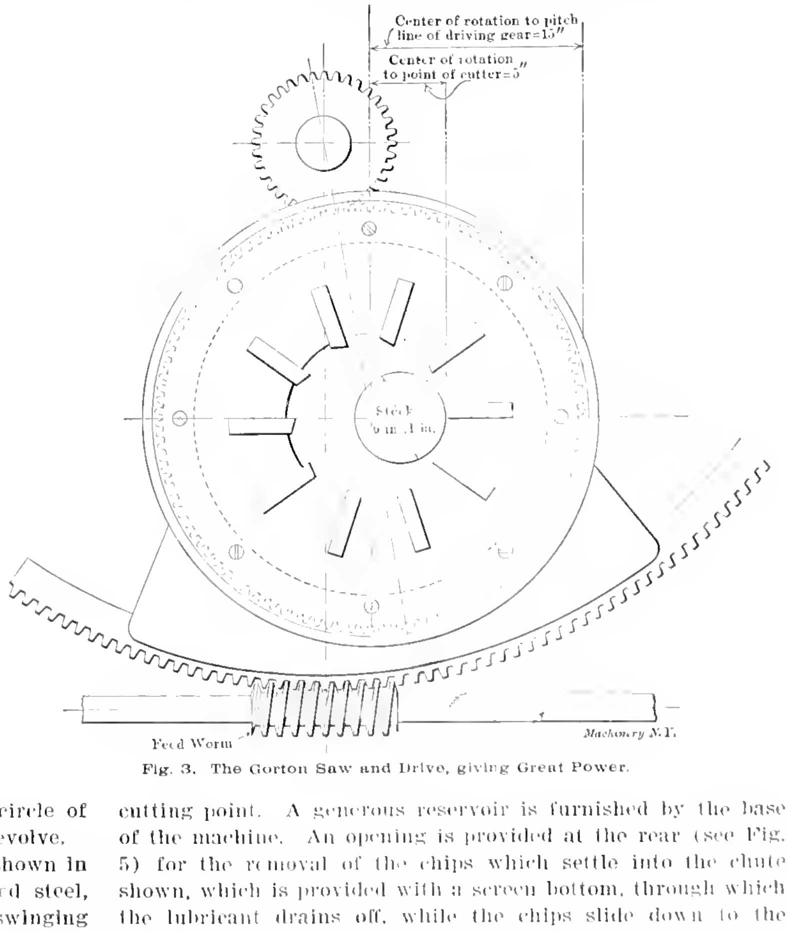

Fig. 3. The Gorton Saw and Drive, giving Great Power.

out of the way when not required. The rear stock support, as shown, enters the saw-driving ring close to the blade. Stock supports are furnished when desired, provided with rollers to enable heavy bar stock to be easily inserted and adjusted.

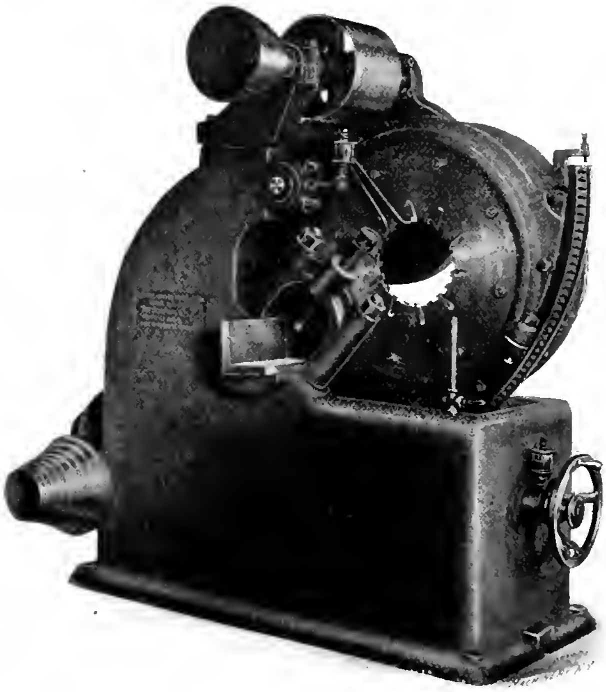

Fig. 4. The Machine with the Saw Frame Raised.

Special effort has been made to produce a machine capable of hard service through a long life, and one that it would be safe to trust to the care of unskilled operators. The gears are of generous proportions, and are all cut from the solid. The main driving pinion is a steel forging, formed integrally with the shaft. All the bearings either run in oil, are ring oiling, or are provided with sight-feed lubricators.

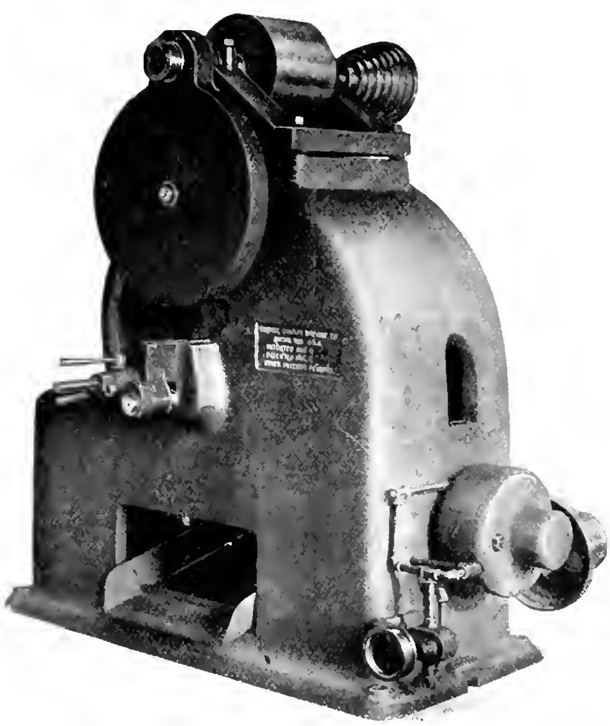

Fig. 5. Rear View of Machine, showing Feed Works, Chip Chute, Etc.

All these bearings are grit proof, and all the gears are fully enclosed. The feed worm is of generous size and runs continuously in oil.

Summarizing the advantages of this construction, we may say that the drive is from four to six times as powerful as on other machines of similar size; the feed is applied in a more effective manner, having as it does a 2 to 1 leverage; the saw blade works to better advantage, being supported around its entire periphery, so that it cannot buckle or "snake"; the machine is dust and grit proof throughout, and designed for operation by unskilled labor; and vibration and chattering is eliminated so that high saw speeds and heavy feeds are obtained.

We show an example of the work of the machine in Fig. 6. This shows a section cut from a 6-inch bar of open-hearth steel, with the saw feeding at the rate of 4 inches per minute, severing the 6-inch bar in a little less than 1½ minute. While doing this, it is said that the machine was entirely free from the slightest vibration. This was done on the machine we illustrate, which weighs about 7,000 pounds. The saw teeth cut at about 75 feet per minute, and were flooded with a compound of water, lard oil, soda, and soap. The power required for this maximum output is about 18 horse-power.

While this machine is a new one so far as being placed on the market is concerned, the idea is not a new one with Mr. Gorton, the designer; the main features of the machine have been a pet hobby with him for over twenty years. It has only been possible, however, to practically apply the principle in the last few years, since the advent of the high-speed steels, because the solid saw blades of the old type could be driven to their full capacity by the driving mechanism formerly in use.

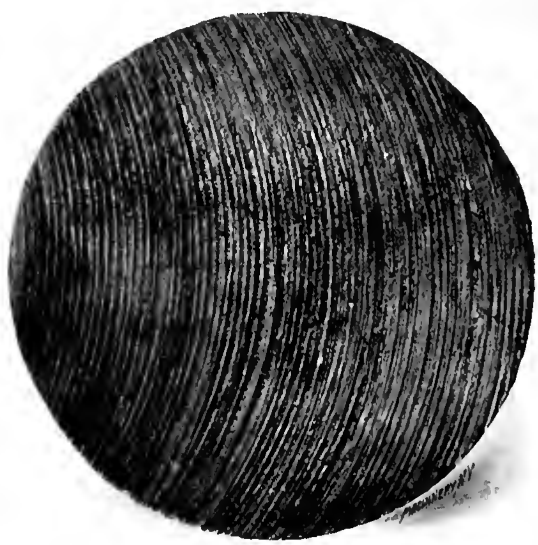

Fig. 6. This Section of 6-inch Open-hearth Steel was cut off in 1 1-2 minute, 75 feet per minute Cutting Speed.

The new steels plainly taxed the old design beyond its strength, and offered an opportunity for the practical application of the idea of an internal cutting-off saw.

In addition to the 6-inch size shown, three other sizes are in process of construction, these being for 4-inch, 9-inch, and 12½-inch stock, respectively. These machines weigh from 5,000 to 25,000 pounds each. They can be furnished either belt driven, or direct connected with an electric motor.

* * *

We have mentioned in the columns of MACHINERY, at various times, the proposed schemes for internal waterways in this country. Great as has been our railway development, we have, to a great extent, neglected the development of canals and inland waterways, which in Europe play so great a part in commerce and industry, supplementing the railways for such classes of freight as can be carried to advantage on the canals. The Inland Waterways Commission has now made a proposal to construct a vast system of canals, and to try to improve certain river channels, so that large craft may be able to use them, and an effort will be made to secure from the present Congress the necessary legislation for beginning the work. The most important of these proposals seems to be the construction of a deep waterway between the Great Lakes and the Gulf, but a number of other projects are also under consideration. It is likely that some of the railroads will oppose this work, but in view of the difficulty of the railroads in handling the traffic of the country in prosperous times, it does not seem reasonable that there should be any objections from these quarters.

INDUSTRIAL NOTES FROM EUROPE.

BRITISH TRADE TOPICS.

Though in some industries in this country a comparative depression is evident, the trade of the country as a whole would appear in a more healthy state than that of any other. However, in the engineering and machine building industries a great many discharges are taking place. It is not that so many less machines are employed than during last year, but in place of being worked night and day, they are working day shifts or moderate overtime only. From one large machine building firm in Nottingham about 800 men have been discharged during the last three months, but for a year or two previously such continuous pressure on the productive capacity had never before been experienced, the whole plant having been working night and day. Then again, the question of unemployment generally is much more closely looked into than formerly. The unemployed making their plight known in no uncertain fashion, so that a depression or slackness which would have been taken as a matter of course in former periods, now, at once, receives recognition, and pertinent inquiries are made as to the causes leading up to it, and the best remedy to be employed. Of course such a state of things gives plenty of opportunity for divergence of views regarding tariff "reform," free trade, etc. At the moment, in the case of the Amalgamated Society of Engineers—the leading trades union in its line—the number of members receiving out-of-work pay is 4,863, and in the Boiler Makers and Iron Shipbuilders' Society 5,916 are similarly placed, a proportion of the membership giving cause for apprehension. However, the outlook is not altogether depressing. It is the contrast of ordinary, or somewhat restricted, working with what was perhaps a somewhat unhealthy pressure which makes things appear worse than the facts warrant.

Speaking on January 25, after inspecting the Cardiff Docks and the Great Dowlais Ironworks, Mr. Lloyd-George (president of the Board of Trade) addressing the members of the Exchange, said "There are just a few indications that the ebb tide in trade is beginning," but his opinion, based on the investigations of the best intelligence department in the empire—the Board of Trade—was, that they were not going to have a bad ebb tide. They had seen times of great prosperity. British exports last year attained dimensions of which neither this country nor any other had ever before seen the like. They must not forget that the present depression started in America, it was being felt in Germany, "and," he added, "our turn will possibly come, but it is not going to be a bad one from what I hear."

Results of New Patent Act.

Again, the new patent act, though it only came into force on January 1, is already bearing fruit. According to Mr. Ivan Levenstein, a prominent Manchester chemical manufacturer who took an active part in the agitation leading to the new act, a number of foreign patentees have been, and are, negotiating with British manufacturers to carry on, in the United Kingdom, their British patents, whilst others have taken land for the purpose of erecting works in order to work their British monopoly. As an instance may be mentioned the Hœchst Farbwerke, working in conjunction with Cassella & Co. The combined capital is valued at $40,000,000. They have secured land near Chester for a large works to be employed in the manufacture of synthetic indigo. Another concern, the Elberfeld Farbenfabriken, together with the Badische Aniline and Soda Works and the Berlin Co., with a capital of $65,000,000, are about to erect works, probably near Manchester. A well-known American firm holding British patents for the manufacture of safety razors, hitherto made solely in the States, is reported to have secured land in Sheffield, and expect to employ about 500 men. According to Mr. Levenstein, "Scores of the foreign manufacturers holding British patents which they have previously worked solely abroad, are following their example, and there is not the slightest doubt that the new act will find additional employment for our people, the operative classes, highly trained engineers, and chemists, and give a new impetus to British enterprise. This will become more and more apparent as time goes on. Fortunately, the act, unlike preceding ones, is so definitely and clearly worded especially is this the case with Section 27, which deals with the revocation of patents worked outside the United Kingdom that there are no loopholes to afford escape from it. Surely Mr. Lloyd-George must feel proud of having passed such a far-reaching measure, an act that will confer greater benefits on our industrial welfare than any act passed during the last fifty years."

Labor Union Topics.

For some little time Mr. Lloyd-George has appeared all-pervading, in the facilitation of trading operations, and, more recently, in the influence he has exercised in the settlement of industrial disputes of unprecedented magnitude. Following on the railway men's dispute came that of the cotton spinners respecting revisions of piece-work price lists, which involved most complicated details and numerous side issues. A very reasonable solution was arrived at through Mr. Lloyd-George's direct intervention, and replying to the thanks accorded him he congratulated both parties very heartily on the splendid good sense and good feeling they had shown. He thought it was a real victory for British industry, and he felt that as long as British industry was conducted on both sides by men who were capable of settling disputes in that way, they had nothing to fear from rivals in any part of the world. Hardly was this particular dispute settled, when another broke out respecting the wages of female labor in another section of the trade—ring spinning. Though the number of workpeople primarily affected was small, a lock-out of the whole number employed which would, directly and indirectly, throw 250,000 people out of employment, was threatened. Finally, an eleventh-hour dramatic settlement was reached late in the afternoon of January 24, the day previous to the expiration of the lock-out notices.

Ship-building Notes.

Though last year closed unpropitiously as regards ship-building, the aggregate tonnage for the year was phenomenal. On the Clyde 509 ships were launched of a total tonnage of 620,000 tons as against 372 ships of 599,000 tons in 1906. Eleven years ago the highest total was 400,000 tons, and six years ago, 500,000 tons. Yarrows', the well-known torpedo vessel builders, are now practically removed from London to the Clyde. After one or two torpedo boats, now almost completed, are handed over, all business will cease at the old works. Some reduction in the rate of warship building was anticipated last year, but the new German program has necessitated a revision of the British scheme, so that busier times than the present are anticipated during the year in the warship building centers. Refrigerating machinery will, in the future, be much more extensively employed than in the past for cooling ammunition chambers in the navy, recent explosions in the French navy emphasizing its importance.

The manner in which the United States engineering corps is proceeding with the construction of the Panama Canal occasions commendatory notice over here. The fact that the United States government eventually lost patience with the propositions placed before it by commercial interests, and found it necessary to directly proceed with the work, appears rather a "nasty jar" for private enterprise, which is usually understood to be ahead of government managed concerns. The American consul at Sheffield reports a big decrease in the exports of special steel, for mining purposes, to the United States. For the last quarter in 1907, only $109,344 worth of this steel was exported to that market as against $736,970 the previous quarter, $810,895 six months before, and $783,075 a year previously.

Condition of Textile Machinery Trade.

The textile machinists still make a very good show in the matter of exports, the returns showing continued increases. For November the figures are $3,572,890 as against $3,057,105 for the same period in 1906. For the first eleven months of 1907 the figures were $36,723,665, against $30,396,505 in the corresponding months of the previous year. The increases have been mainly in spinning, as distinct from weaving machinery. It does not pass unnoticed that the export of machinery increases the competition to be faced by British

textile manufacturers, but the machinists, of course, cannot help that, and it is significant that the present year has been a record one for Lancashire spinners of American cotton, the profits being nearly double those of 1906. Taking the returns of one hundred mills, a share capital of $18,613,900 has earned no less than 35½ per cent net profit, an increase of 18 per cent. The total capital employed includes $11,887,330 loaned capital in mortgages, debentures, and short date loans, and taking it that 4 per cent has been paid on these loans, the total profit on the combined share and loan capital works out at about 23 per cent. These returns do not apply solely to new mills, but include some which have been in existence over thirty years. With increasing production and uncertainties in the supply of raw material and labor disputes, such unusually good returns are not anticipated during the coming year. While touching on these cotton trade matters—which have a more intimate connection with engineering and machine building prospects than is generally recognized—an important inquiry is being made by the British government as to the pros and cons of the practice of "steaming" or introduction of artificial humidity in weaving sheds, as regards its effects on the health of workpeople. The commission is very representative, and inclndes Sir Hamilton Freer-Smith, superintendent inspector of factories; Mr. J. D. Shackleton, M. P., and Mr. Joseph Cross, on behalf of the workpeople; Mr. Henry Higson and Mr. J. Roberts, for the employers, and Prof. Lorraine Smith, M.D., professor of pathology at Victoria University.

Machine Tools.

The use of disk grinding machines, mostly of British make, is spreading in this country, though the tendency seems in the direction of an increase in the range of quality, capacity, and adaptability. Many of the more expensive machines are fitted with accurate attachments, but the requirements of users who appreciate the advantages of this method of working, but have no need for continuous working of a machine or the acme of refinement, are now also receiving attention, and a number of reasonably well-made and durable machines are now obtainable at a very moderate cost. Tool grinding emery wheel machines are also developing on much the same lines. Arrangements for supplying the necessary water spray in a convenient manner, and also the provision of cheap and easily handled wheel truers, being well attended to. Richard Cremer, Aire Road, Leeds, is now supplying a handy range of clamps and divided machine vices, etc., of varying designs from those for holding constructional steel work whilst being drilled, etc., and those with one jaw of the clamp having a semi-globular grip enabling it to clamp work of varying tapers, to cheap, quick acting clamps for carpenters and cabinetmakers' work. Very satisfactory sales are reported.

In Germany, the Union of Iron and Steel Industries, in conference, mentions the possibility of the smaller industries syndicating in defense, in consequence of the action of large industrial syndicates. It was therefore necessary to bring about an agreement in time. Also, "perhaps the financial power and the intellectual training of Germany had been overestimated." In conclusion, the extent to which the British industrial classes, notwithstanding occasional accusations of improvidence, assure against sickness, and death, may be mentioned. In a recent government report, one society alone, the Manchester Unity of Odd Fellows, is shown to have an available capital of $66,851,345, and a number of others are proportionately well placed, and in the case of other societies which, through lack of actual data at the time of their inception, have been rather severely tested for some years, are now making very good progress in the right direction.

Importance of Machine Tool Business being More Recognized by European Engineering Journals.

A tendency recently more noticeable over here is the increasing attention given in the engineering journals to machine tool matters. It is evidently being grasped that improvements in design and manipulation are now made so rapidly that special effort is needed to chronicle them in such a form and with such promptitude as will make them of value to readers. JAMES VOSE.

Manchester, England, February 10, 1908.

MISCELLANEOUS FOREIGN NOTES.

EXHIBITION OF APPLICATIONS OF ELECTRICITY IN MARSEILLES.—An exhibition devoted to the application of electricity in the arts and industries will take place next summer in Marseilles, France, commencing on April 19, and closing on October 31. The exhibition is intended to be of international scope. Applications for sites should be sent to, and further information may be had from, the Commissariat-General, Boulevard Louis Salvator, 52, Marseilles, France.

AUTOMOBILE INDUSTRY IN GERMANY.—We have previously referred to the fact that the present reaction in the automobile industry has not affected German manufacturers as badly as those of the other three great industrial nations. One reason for this appears to be that a large proportion of the motor car builders in Germany are also engaged in some other line of manufacture, such as that of bicycles, sewing machines, typewriters, or even machine tools, and thus are able to concentrate their activities on their other industries when one declines.

AUSTRIAN TRADE CONDITIONS.—While it is stated that the condition of the iron and steel and allied industries in Austria is not on as favorable a basis as a year ago, there does not seem, from present reports, to be any serious cause for complaints. There are delays in deliveries, charged partly to scarcity of labor, but that is rather a sign of continued prosperity than the reverse. The true state of affairs may be that the financial flurry in the United States reacted throughout the world, causing a temporary depression, but not in any way unsettling business conditions.

DEPRESSION IN THE BRITISH SHIPBUILDING TRADE.—Continued depression in the shipbuilding trade in the northern portion of Great Britain is reported. Employers have been forced to issue the usual three months' notice that demands a reduction in wages of 5 per cent on piece work, and 2 shillings a week on time rates, this latter also being equivalent to a reduction of about 5 per cent, or perhaps a somewhat greater amount, of the wages paid. It is stated that the ship yards at present have plenty of work on hand, but that the orders for new work are not coming in to such an extent as to make the future prospects as bright as would be desirable.

THE JAPANESE EXHIBITION OF 1912.—The Exhibition Committee of what is termed the Grand Exhibition of Japan, which will be opened in Tokio, on April 1, 1912, has given out a statement in regard to the general rules governing the exposition. Foreign exhibits belonging to the five departments of education, science, machinery, electricity, and manufactured goods, will be allotted space in the exhibition buildings, specially erected for these departments. For exhibits other than those above mentioned, any nation may have a separate building, erected at its own expense, but no charge will be made for the space allotted for such buildings. Machines and articles imported from foreign countries for the sole purpose of exhibition will be admitted free of duty. It is also intended to afford special protection to all inventions, designs and models of foreign exhibits, and a bill to that effect will be introduced at the next session of the Japanese Diet. The site of the exhibition covers about 292 acres.

MACHINE TOOL TRADE IN GERMANY AND ENGLAND.—As time progresses it appears that the same reaction as has taken place in the steel industry in this country has also made itself apparent in Germany. There is a stringency of money, which is rather unusual, tending to prohibit the entering into new enterprises, and preventing the ordinary commerce from being carried on as usual. The conditions in the machine tool trade, itself, however, seem promising. In England, also, the latest information indicates steady conditions, and the outlook for new business does not seem unsatisfactory. Extensions of works are still carried on to a great extent, and the modernizing of shop equipment creates a great demand for machine tools. As the home market in this country is not placing as heavy demands on our manufacturers as usual, it is likely that they will be able to secure for themselves a share of this trade in Great Britain.

THE AUTOMOBILE INDUSTRY ABROAD.—Recent reports indicate that the automobile industry in Great Britain and Germany is placed on firm ground, while the manufacture of motor cars

in France is not in the same flourishing state as in the years past. The explanation of this condition, partly at least, is doubtless to be found in the fact that many French firms have devoted themselves exclusively to expensive pleasure vehicles, the demand for which is rapidly waning, while the German, and, particularly, the English makers have devoted themselves also to the development of cars for industrial purposes, and cheaper cars for everyday use in business, for which latter classes of motor cars the demand is increasing. The exports of British cars is steadily increasing. During the first eight months of this year these exports amounted to a value of $2,380,000 as compared with $1,200,000 for the same period the preceding year. At the same time imports of foreign cars to Great Britain have been decidedly smaller than last year. In France, while an increase of production is reported, several failures of automobile building firms are also on record. Thus, the Société Automoto in Saint Etienne, Loire, with a capital stock of 1,700,000 francs, has ceased payments, and a receiver has been appointed for the Pilain firm in Lyons, which has a capital of 1,500,000 francs. The figures stating the extent of Germany's motor trade for the six months ending June 30, 1907, indicate that Germany is still importing a greater number of cars than it exports, the imports being valued at about $2,900,000, while the exports were valued only at about $1,800,000, or less than two-thirds of the imports. It is a significant fact, however, that one-third of the exports were industrial vehicles, which rather confirms one of our previously made assertions that Germany is placed on a firmer basis in the automobile trade on account of having devoted more energy to industrial vehicle than to pleasure cars.

NATIONAL SOCIETY FOR THE PROMOTION OF INDUSTRIAL EDUCATION.

The National Society for the Promotion of Industrial Education held a three days' meeting at the Art Institute, Chicago, Ill., January 23-25. A public dinner was given at the Auditorium Hotel, January 23, of which Mr. Theodore W. Robinson, first vice-president of the Illinois Steel Co., was toastmaster. Papers on industrial education as an essential factor in our national prosperity, were presented by Dr. Chas. W. Elliott, president of Harvard University, and Mr. James W. Van Cleave, president of the National Association of Manufacturers, St. Louis, Mo. Dr. Pritchett spoke on the aims of the National Society for the Promotion of Industrial Education. At the public meetings of January 24 and 25 a number of notable papers were presented on various phases of industrial education, apprenticeship, etc. Among these were "The Apprenticeship System as the means of Promoting Industrial Efficiency," by Carroll D. Wright, Worcester, Mass. The list of speakers included men and women prominent in industrial education, among whom were Mr. W. R. Warner, Cleveland, Ohio, of the Warner & Swasey Co.; Mr. James O'Connell, Washington, D. C., president of the International Association of Machinists; Mr. J. F. Deems, general superintendent motive power, New York Central lines; Mr. Leslie W. Miller, Philadelphia, Pa., principal Pennsylvania School of Industrial Art; Miss Jane Addams, of Hull House, Chicago, and many others whose names are prominently connected with industrial betterment.

THE VALUE OF A TREATISE AS AN ADVERTISING MEDIUM.

About eight years ago a series of articles on mechanical draft by Walter B. Snow was published in MACHINERY, which attracted wide attention. These articles were afterward published in book form by the B. F. Sturtevant Co. with the title "Mechanical Draft," for which a nominal price of $1.50 was charged. The price, however, was a device to prevent needless distribution to a class that could make no good use of such a work. It was distributed free to concerns, engineers and others legitimately interested in the subject of mechanical draft.

Mr. Snow, the author of the work, published an article in the November issue of *Selling Magazine*, in which he referred to the extraordinary advertising value of such a work. The work on mechanical draft treated the subject in a comprehensive manner, giving rules, tables, and formulas of much value to the engineering profession. The fact that the book is essentially an argument for mechanical draft does not necessarily detract from its value as a contribution to engineering literature. Engineers who received a copy were only too glad to make it a part of their engineering library, where it became a source of information and an educational influence in favor of the use of the fan as a substitute for the high brick chimney.

The hint is one that is worth taking to heart by manufacturing concerns who spend large sums on their advertising literature. It is not enough that the best cuts, finest paper and elegant press-work be used in advertising literature. If the literature does not contain something of permanent value it will not be retained by the recipient, unless it is made part of a catalogue file. There are catalogues, however, of very ordinary appearance, but containing valuable tables and data pertaining to the subject matter in general which are treasured and frequently referred to. There is undoubtedly a wide field for the expansion of this idea. Many lines of work could be represented by catalogues which would be in effect, condensed treatises of great value on the subjects represented. Such advertising matter is not ephemeral but becomes more and more valuable with the years.

* * *

A remarkable test of endurance of automobiles was begun February 12 when six automobiles left Times Square, New York, for Paris, France. The route is across the United States to San Francisco, thence by water to Valdez, Alaska, thence by land to Cape Prince of Wales *via* Nome, thence across Behring Strait to Siberia, thence by land to Paris. The total distance is about 22,000 miles. The cars entering the race were Thomas (American), De Dion (French), Moto-Bloc (French), Sizaire-Naudin (French), Zust (Italian), Protos (German). The Sizaire-Naudin car broke down twice in traveling the first 100 miles and withdrew from the race.

* * *

PERSONAL.

W. P. F. Ayer, who has represented the Walworth Mfg. Co., Boston, Mass., for many years in the South, has been appointed assistant secretary of the company.

H. H. Vreeland, president of the New York Railroad Club, and a well-known street railway man, was the guest of honor at a dinner given by the club at the Hoffman House, February 7.

Arthur W. Graham, of the Builders' Iron Foundry, Providence, R. I., sailed January 25 for an extended trip to Mediterranean ports and other places of interest in Southern and Western Europe.

Robert McF. Dolde, consulting engineer making a specialty of hydro-electric power equipment and transmission, formerly of San Francisco, California, has removed his office from Colorado Springs to No. 528 Majestic Bldg., Denver, Colorado.

L. R. Pomeroy, a well-known railway shop equipment engineer, has resigned his position with the General Electric Co., to become assistant to the president of the Safety Car Heating and Lighting Co. He will have charge of the sales department.

Lester G. French, formerly editor of MACHINERY, and later manager of the Technical Press, Brattleboro, Vt., has been made editor of the Proceedings of the American Society of Mechanical Engineers, New York. Mr. French assumed his new duties March 1.

Charles A. Baemeister has been appointed western representative of the Monarch Emery & Corundum Wheel Co., Camden, N. J., with headquarters in Chicago. Mr. Baemeister has had extensive experience in the grinding wheel business, and is well prepared to fill his new position.

C. F. Harding has been appointed head of the school of electrical engineering, Purdue University. Prof. Harding is a graduate of the Worcester Polytechnic Institute. He has a broad practical training as an engineering teacher, and special training along the line of high tension railway work. He was electrical engineer for the first electric railway built in New England. He was engineer for the D. & W. Fuse Co.,

Providence, R. I., publication manager for the Fort Wayne Electric Co., Fort Wayne, Ind., and engineering expert for Stone & Webster, Boston, Mass. He was also associate professor of electrical engineering of Cornell University. Prof. Harding will assume his new duties about March 1.

* * *

OBITUARY.

Daniel Shafer, for the past three years salesman and engineer with the Allis-Chalmers Co., died of pneumonia January 24 at Nashville, Tenn., aged 47. His home was in Wheeling, W. Va. Mr. Shafer was well known and had a wide circle of friends. Prior to taking his present position he was associated with Hooven-Owens-Rentschler Co., Hamilton, Ohio.

Orrin S. Werntz, treasurer of the National-Acme Mfg. Co., Cleveland, Ohio, since its organization, died February 6, 1908, after an illness of about one month. He was born in Canal Fulton, Ohio, and was thirty-two years old. His first position was with the National Screw & Tap Co., which he retained until the organization of the National-Acme Mfg. Co. He is survived by his wife, mother and young son.

NEW BOOKS AND PAMPHLETS.

ANNUAL REPORT OF THE CHIEF OF THE BUREAU OF STEAM ENGINEERING TO THE SECRETARY OF THE NAVY FOR 1907. 56 pages, 6 x 9 inches. Published by the Navy Department, Washington, D. C.

A COMPARISON OF THE EFFECTS OF FREQUENCY ON THE LIGHT OF INCANDESCENT AND NERNST LAMPS. By Frederick W. Huels. 45 pages, 6 x 9 inches. Published by the University of Wisconsin as Bulletin 157. Price 25 cents.

TESTS OF PLAIN AND REINFORCED CONCRETE. Series of 1906. By Morton Owen Withey. 66 pages, 6 x 9 inches. Illustrated. Published by the University of Wisconsin, Madison, Wis., as Bulletin No. 175. Price 25 cents.

EXPERIMENTAL WORK CONDUCTED IN THE CHEMICAL LABORATORY OF THE UNITED STATES FUEL TESTING PLANT, St. Louis, Mo., January 1, 1905, to July 31, 1906. By N. W. Lord. 52 pages, 6 x 9 inches. Published by the U. S. Government, Washington, D. C., Department of Interior, U. S. Geological Survey.

This is Bulletin 323 and is devoted to an account of experimental work conducted on coals.

INVESTIGATION OF CENTRIFUGAL PUMPS. By Clinton Brown. 140 pages, 6 x 9 inches. Published by the University of Wisconsin as Bulletin 173. Price 50 cents.

This bulletin is devoted to a discussion of the theory of the centrifugal pump, and a record of tests of a 6-inch vertical centrifugal pump. It includes a description of the pump and impellers, general method of making observations, calibration of electrical instruments, effect of the number of vanes and variation of speed on discharge and efficiency, effect of curving the vanes of the impeller at entrance, power required to hold up the head of impending delivery.

HOW TO READ PLANS. By Charles G. Peker. 46 pages, 4¾ x 7¼ inches. Illustrated with 43 cuts and 8 folding plates. Published by the Industrial Publication Co., New York. Price 50 cents.

Many carpenters are handicapped by ignorance of ordinary working drawings, and this little work is intended to instruct such mechanics in the principles of working drawings so that any intelligent mechanic will be able to work from drawings intelligently. Incidentally the book will be found useful by carpenters who desire to make drawings or sketches of building details for themselves. The folding plates are of a six-room frame house and this set of plans alone is worth many times the cost of the book to the ambitous carpenter who would launch out in independent work.

A STUDY OF FOUR HUNDRED STEAMING TESTS MADE AT THE FUEL TESTING PLANT, St. Louis, Mo., in 1904-1905-1906. By L. G. Breckenridge. 200 pages, 6 x 9 inches. Illustrated. Published by the U. S. Government, Washington, D. C., Department of Interior, U. S. Geological Survey.

The fuel tests discussed in this publication were made under two Heine water-tube boilers by the U. S. Geological Survey Fuel Testing Plant at St. Louis, Mo. These boiler tests were begun during the Louisiana Purchase Exposition during 1903, and have been continued. The general information and results yielded by these boiler tests are of great value. The voluminous nature of the published reports makes the present study of much greater value to those who have not the time or ability to make an analysis of the previous publications.

TABLES OF THE PROPERTIES OF STEAM AND TEMPERATURE-ENTROPY TABLE. By Cecil H. Peabody. 131 pages, 6 x 9 inches. Published by John Wiley & Sons, New York. Price $1.00.

These valuable tables are too well-known by engineers to require an extended review. They were calculated about twenty years ago to accompany Prof. Peabody's work, "Thermodynamics of the Steam Engine." Since then they have been re-computed, and the results of important experimental investigations have been incorporated. The present edition is the seventh. The tables given are for steam, English units, degrees; steam, English units, pounds; steam, French and English units; ether; alcohol; chloroform; carbon-bisulphide; carbon-tetrachloride; aceton; ammonia; sulphur-dioxide; specific volumes of liquids; volumes of hot water; inches of mercury and pounds; connective factors, superheated steam, etc. The tables are presented in attractive typographical form and are indispensable to the testing engineer and others having to do with the calculations in thermodynamics.

STEAM TURBINES. By Carl C. Thomas. 334 pages, 6 x 9 inches. 145 illustrations and 20 large folding plates. Published by John Wiley & Sons, New York. Price $4.00.

This work has passed into the third edition. The development of steam turbines during the past few years has been very rapid, and the revised edition gives attention to the problems in design of the Curtis and Parsons types of turbines and to suggestions regarding turbine analysis. The book is written with a view of setting forth the principles essential for intelligent grasp of steam turbine work. It is to be recommended to designers, engineers and others having to do with the theory of steam turbine operation and construction. It discusses the general principles relating to the action of steam upon turbine buckets; thermodynamic principles involved in the flow of steam; calculation of velocity; the effect of frictional resistance on velocity; experimental work on the flow of steam through orifices, nozzles and turbine buckets; the impulse, and impulse and reaction turbines; the operation of various shapes of turbines. One chapter is devoted to marine steam turbines.

A STUDY OF ROOF TRUSSES. By N. Clifford Ricker. 28 pages, 6 x 9 inches. Illustrated. Published by the University of Illinois, Urbana, Ill.

This publication is Bulletin No. 16 of the series issued by the engineering experiment station of the university for free distribution, and is fully up to the high mark set by the previous bulletins. It records the results of several years' study and tests. About fifty trusses of a selected type and of different proportions and arrangement were designed in long-leaf pine and steel and changed until the assumed and actual weights of the trusses agreed. Other trusses were likewise designed in white pine and steel and a few entirely constructed of steel. To perform this work as conveniently and as rapidly and accurately as possible, it became necessary to devise simplified formulas and tables, with a systematic method of treatment, all of which are fully explained in the pamphlet. The results illustrated are mostly shown in graphic tables for ready appreciation. The most important features are a new formula for the weights of trusses; per cent of weight to be added for connections; most economical ratio of depth to span of truss; distance between trusses; number of purlins per panel; and dimensions of panels. It was found that white pine and steel trusses are about 10 per cent lighter than those of long-leaf pine and steel; also, that if carefully designed, steel trusses from 100 to 200-foot span have about the same weight as those of white pine and steel. It is believed that this bulletin will be valuable and suggestive to all persons interested in the design and construction of trussed roofs.

MEN WHO SELL THINGS. By Walter D. Moody. 295 pages, 6 x 9 inches. Published by A. C. McClurg & Co., Chicago, Ill. Price $1.00; by mail, $1.10.

Selling goods is an art that few master in the full sense of the term, but it is one which many may become proficient in, if we can accept the sentiments of the author. The masters of the art, if there be any, will not need to read this book to learn anything new, of course, but they will find it interesting, nevertheless, and perhaps helpful and uplifting in a moral sense. It was written by a veteran who worked his way from stock-boy to salesman, from salesman to buyer, from buyer to sales manager, and from sales manager to employer. It records the observations of over twenty years' experience in America and in Europe. The author denies that the trite expression "salesmen are born, not made" is unqualifiedly true. Failures or "near salesmen," as he calls them, are often such because of small faults or vices that could be and would be corrected if once they were recognized. The "near salesman" ordinarily does not recognize that he just misses being the "real thing," or if he does dimly see it he cannot see the cause for it. For such unfortunates this book, read in the right spirit, should be helpful, indeed. It is good for any one to read, being optimistic and moral in tone. It leaves no escape from the conclusion that strict integrity and uprightness of character are positively necessary to any salesman's success, in the long run. In fact the qualities requisite for success in a salesman are exactly those that are required in a merchant, banker, manufacturer or business man of any kind, salesmanship being not so very much different from any other business in the last analysis.

STANDARD HANDBOOK FOR ELECTRICAL ENGINEERS. Written and compiled by a staff of specialists. 1,283 pages, 4 x 6¾ inches (standard handbook size). Numerous illustrations, diagrams and tables. Published by McGraw Publishing Co., 239 West 39th St., New York. Price, bound in flexible red morocco, $4.00

No doubt one of the best forms of technical literature for everyday use is the engineer's handbook as it exists in numerous examples. These convenient compilations bring together into one comparatively small volume the equivalent of many books in their essentials, and when, as in this case, a copious index with cross references is provided, the comparative value of such aids to rapid work is beyond computation. This work is unique in that it is, in effect, twenty handbooks in one, there being twenty chapters or units on various subjects, each prepared by an expert in the subject treated. It contains about one million words, 1,300 illustrations, and the index has over 6,000 references. The mechanical and typographical features are exceptionally good. It is printed on India bible paper, 1,300-odd pages of which are only about 1¼ inch thick. The binding permits the book to lie flat open at any page without breaking down the back. Following are the headings of the sections: Units; Electric and Magnetic Circuits; Measurements and Measuring Apparatus; Properties of Materials; Magnets; Transformers; Electric Generators; Electric Motors; Batteries; Central Stations; Transmission and Distribution; Illumination; Electric Traction; Electrochemistry; Telephony; Telegraphy; Miscellaneous Applications; Wiring; Standardization Rules; Tables and Statistics. The handbook is one that can be heartily recommended to the electrical engineer and his brother the mechanical engineer, who, more and more every day, has to undertake work involving knowledge of things electrical.

CATALOGUES AND CIRCULARS.

BALDWIN LOCOMOTIVE WORKS, Philadelphia, Pa. Record No. 64, "Locomotives Built for the Central Railway of Brazil."

CULLMAN WHEEL CO., 1019 Dunning St., Chicago, Ill. Catalogue No. 6 of driving chain, sprockets, automobile differential gears, etc.

GREEN FUEL ECONOMIZER CO., Matteawan, N. Y. Bulletin No. 108 on mechanical draft illustrating, and describing the Green apparatus and applications.

BROWN & SHARPE MFG. CO., Providence, R. I. Booklet entitled: "Why the Constant Speed Drive Milling Machine," giving reasons why constant speed drive is preferable to the cone drive.

GISHOLT MACHINE CO., Madison, Wis. Loose leaf illustrating boring automobile cylinders on the Gisholt turret lathe, and a view in the Warren, Pa., shops.

WHITMAN & BARNES MFG. CO., Chicago, Ill. Catalogue No. 66 listing "Diamond" twist drills, reamers, screw wrenches, drop-forged wrenches, spring cotters, etc.

JENKINS BROS., 71 John St., New York. Supplement to 1907 catalogue superseding pages 70-71, and giving description and list prices of Jenkins Bros. extra heavy and medium pressure gate valves.

JOSEPH DIXON CRUCIBLE CO., Jersey City, N. J. Twelve-page booklet descriptive of graphite brushes for motors and generators. Useful information of those having electrical apparatus in care is given.

WHITMAN & BARNES MFG. CO., Chicago, Ill. Circular descriptive of the "Norka" high-speed twist drills, "Economy" high-speed flat drills, "Economy" chucks for flat drills and "Norka" chucks for Norka twist drills.

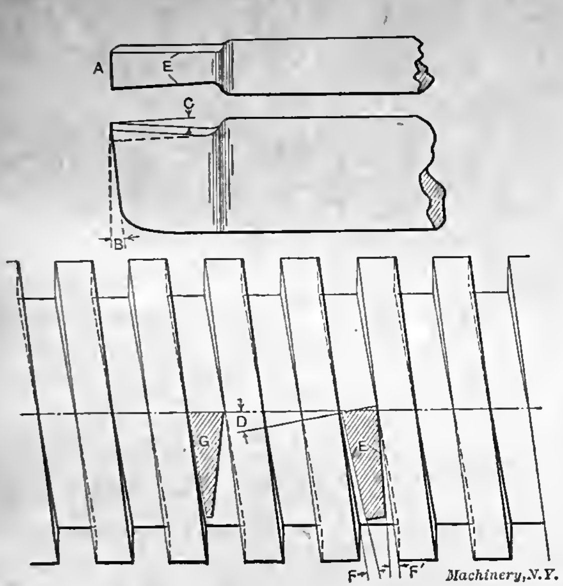
DE LAVAL STEAM TURBINE CO., Trenton, N. J. Bulletin 501, being a catalogue of turbine steam engines for driving dynamos, blowers and centrifugal pumps, and of electric motor pumps, multi-stage pumps, steel plate and cast-iron foundry blowers, etc.

BOSTON GEAR WORKS, Norfolk Downs (near Boston), Mass. Catalogue 131 of gears, chains, sprockets, bearings, automobile steering devices, etc. It will be found of general interest to mechanics, model-makers and others having use for gearing.

LUCAS MACHINE TOOL CO., Cleveland, Ohio. Flyer entitled "Matthew Mears and His Eight-day Clock," *but* advertising the Lucas power

SHOP OPERATION SHEET NO. 58.

E. H. Fish. MACHINERY, April, 1908.



To Grind a Thread Tool for Cutting a Square Thread.

1. Grind the nose *A* of the tool square across the end, and wide enough to be a tight fit between the teeth of the tap which the thread is to follow. If a tap is not used, make the width of the nose equal to one-half the pitch of the thread to be cut. If a close fit is required, the width of the nose may be made 0.002 or 0.003 inch less, and the thread finished to size by taking light cuts from the side of the thread.

2. Grind the front face of the tool until the angle *B*, of front rake, equals 5 to 8 degrees.

3. If the thread is to be cut in soft steel, grind the top of the tool until the angle *C*, of top front rake, equals from 5 to 10 degrees; if cast iron is to be cut, there should be very little top front rake, and when cutting brass the top front rake is often negative, as shown by the dotted line, varying from 0 to 5 degrees. The top of a thread tool should also be ground to an angle *D*, sufficient to make the top at right angles to the sides of the thread.

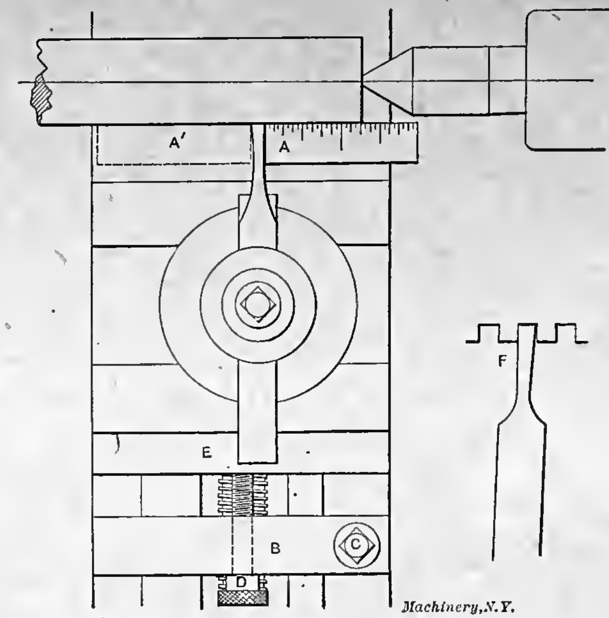
4. Grind the sides *E* so that they have a backward taper of from 1 to 3 degrees on each side, and a downward taper of from 3 to 5 degrees on each side. This downward taper is indicated by the angles *F* and *F′*. Note that the angle *F* is the angle between the side of the tool and the side of the thread at the bottom, while the angle *F′* is the angle between the side of the tool and the side of the thread at the top.

NOTE.—If the tool is ground as shown at *G*, it will rub on the left-hand side as the cutting of the thread progresses, and be gradually crowded to the right, impairing the accuracy of the thread.

Copyright, 1908, by THE INDUSTRIAL PRESS, 49-55 Lafayette St., New York, and sold only with subscriptions to MACHINERY. Binders holding 150 sheets postpaid for 25 cents. Back numbers furnished new or old subscribers.

SHOP OPERATION SHEET NO. 59.

E. H. Fish. MACHINERY, April, 1908.



To Cut a Short Right-hand Square Thread.

1. Center and turn the blank, making its diameter from 0.002 to 0.005 inch less than the diameter of the tap.

2. Gear the lathe so that it will cut a thread of the required pitch. See Shop Operation Sheets Nos. 13, 14, 15, in September, 1907, issue of MACHINERY.

3. Set the tool so that its cutting edge is the same height as the lathe centers, and set it square with the work by using a scale as shown at *A* and *A′*.

4. Place the tool against the work, and fasten the depth gage *B* to the carriage by a bolt *C*. Screw the screw *D* into the tool-slide *E* until its shoulder is against *B*.

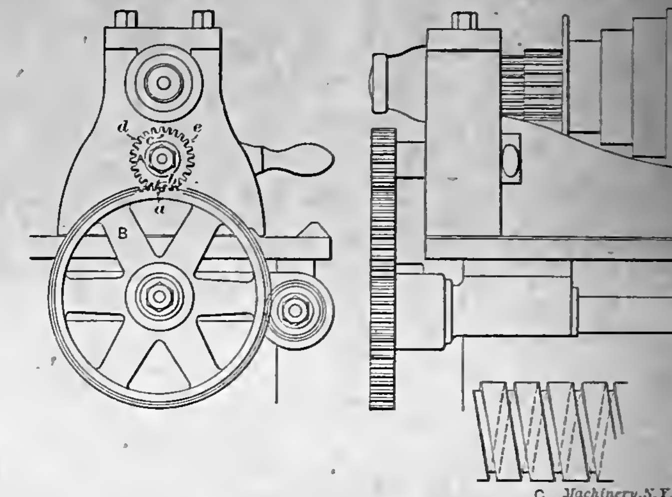
5. Loosen the screw *D* sufficiently to give the tool the proper depth of cut, move the tool to the right-hand end of the work, and start the lathe. Feed the tool inward until the shoulder on *D* is against *B*, and then engage the split nut with the lead-screw of the lathe, and take the first cut. When the tool has cut as far as desired, reverse the lathe and withdraw the tool at the same time. Again unscrew the screw *D* slightly, and when the tool has reached the right-hand end of the work, again reverse the lathe and feed the tool inward as before. Continue in this manner until the diameter at the root of the thread is from 0.002 to 0.005 inch less than the same dimension on the tap.

NOTE.—If the thread, when cut, is too tight a fit, it may be due to the tool having been ground too narrow, or to the pitch of the tap having changed in hardening. In such a case, the tool may be set as shown at *F*, and light cuts taken from the sides of the thread until the required fit is obtained.

Copyright, 1908, by THE INDUSTRIAL PRESS, 49-55 Lafayette St., New York, and sold only with subscriptions to MACHINERY. Binders holding 150 sheets postpaid for 25 cents. Back numbers furnished new or old subscribers.

SHOP OPERATION SHEET NO. 60.

E. H. Fish. MACHINERY, April, 1908



To Cut Double and Triple Threads.

1. To cut a double thread, gear the lathe so that it will cut a thread of the required lead, (the lead of a double thread equals twice the pitch) selecting a change gear *A* which has an even number of teeth. Mark a tooth *a* on the intermediate gear *B*, and a space *b* on the gear *A*. Half-way around gear *A* mark a space *c*.

2. Cut a thread on the blank, proceeding the same as if a single thread were being cut. After this first part of the thread is finished, the blank will appear as shown at *C*.

3. To finish the double thread, a second cut must be taken midway between the turns of the first cut. Turn the lathe until the tooth *a* is in mesh with the space *b*, and then disengage the gear *B* from *A*. Again turn the lathe until the tooth *a* will mesh with the space *c*, and then clamp the gear *B* in place. Cut the second part of the thread to the required depth. The tool should not be disturbed during this operation, and it is especially important that the tool be carefully ground so that it will not crowd sideways.

1. To cut a triple thread, gear the lathe so that it will cut a thread of the required lead, (the lead of a triple thread equals three times the pitch) selecting a change gear *A* with a number of teeth which is divisible by three. Mark the spaces *b*, *d*, and *e*, dividing the gear into thirds.

2. Cut the first thread to the required depth.

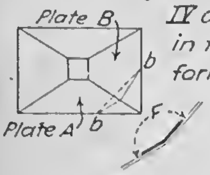
3. Disengage the gear *B* from *A*, and turn the spindle until tooth *a* meshes with space *e*, then cut the second thread.

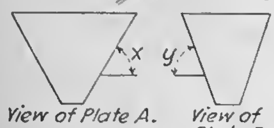
4. Again disengage the gear *B* from *A*, and bring the space *d* into mesh with tooth *a*, then cut the last thread.

NOTE.—This method of cutting multiple threads applies only when the stud on which the gear *A* is mounted and the lathe spindle have the same speeds. On some lathes the spindle makes two revolutions to one of the stud. In such a case the divisions on the gear *A* can be made on one-half of the gear.

I.—ANGLES OF HOPPER SIDE INTERSECTIONS.

Usually there may be passed through an ordinary hopper or chute, a plane which will cut out a section having four straight sides and four right angles, and to these cases only do the curves on sheets I, III and IV apply. Let plates A and B in the accompanying sketch form the angles x and y with the horizontal plane. If a plane b-b be passed through perpendicular to their line of intersection, and the angle of flare be called F, then cos F = − cos x cos y. The curves were calculated from this formula.



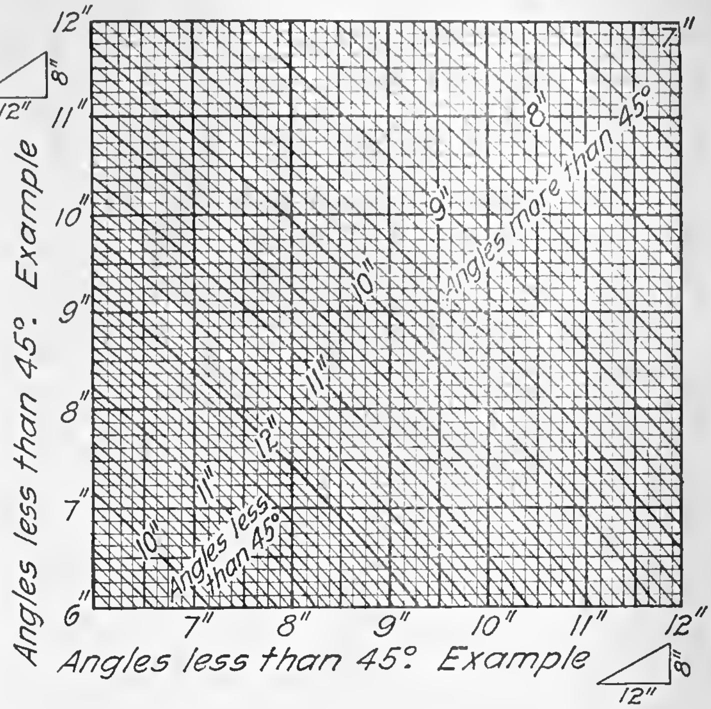


View of Plate A. View of Plate B.

The values of the angle of flare and the angles formed by the hopper sides are expressed in the slope of inches per foot.

The angle of flare is expressed thus  if the angle is more than 45 degrees.

The angle of flare is expressed thus  if the angle is less than 45 degrees.

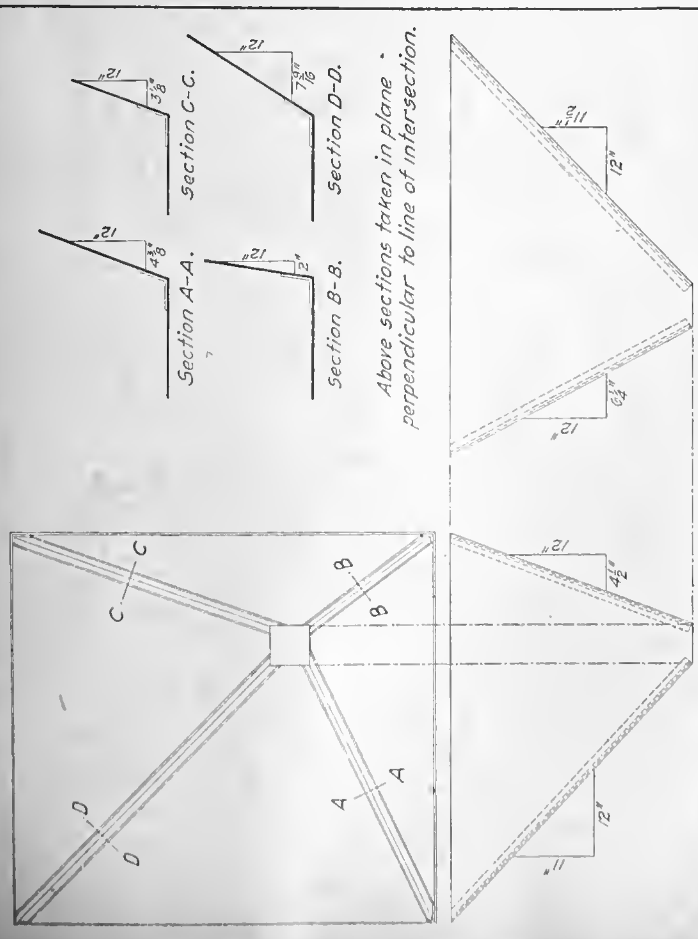


Three sets of curves are given for the three cases found in actual practise:

1. Two angles, x and y, both more than 45 degrees.
2. Two angles, x and y, both less than 45 degrees.
3. Two angles, x and y, one angle less, and one angle more than 45 degrees.

Contributed by Charles T. Lewis and Horace R. Thayer.

II.—ANGLES OF HOPPER SIDE INTERSECTIONS.



Above sections taken in plane perpendicular to line of intersection.

Directions for the use of the diagrams.

In the accompanying illustration of hopper, let the slopes of the four sides be known, as indicated by the slope in inches per foot. For the intersection angle of the side sloping 11 inches in 12 inches with the side sloping 12 inches in 6¼ inches, use diagram for one angle more than 45 degrees and one angle less than 45 degrees. (See upper diagram, sheets III and IV.) At the left of the diagram are values ranging from 6 inches to 12 inches for angles less than 45 degrees. Follow the horizontal line at 11 inches until it meets the vertical line projected up from 6¼ inches. The intersection of these two lines gives, on the curves across the diagrams, the nearest value for the intersection angle, which in this case is 4⅜ inches in 12 inches. (See section A-A of hopper on this sheet.) In a similar manner, use the diagram for two angles both more than 45 degrees (lower diagram sheets III and IV) for section B-B, and for section D-D use diagram for two angles less than 45 degrees, sheet I.

Contributed by Charles T. Lewis and Horace R. Thayer.

This data sheet is made up so as to be readily bound. It may be cut into four sections, 6x9 inches in size, and bound into note-book form for convenient reference, by means of staples inserted into holes punched at points indicated.

CUT ON THIS DOTTED LINE AND FOLD ON A—B

III. and IV.—ANGLES OF HOPPER SIDE INTERSECTIONS.

MACHINERY.

April, 1908.

ARMOR-PLATE FORGING AND MACHINING AT THE BETHLEHEM STEEL WORKS.

WHILE collecting material for the article published in the November, 1907, issue of MACHINERY, describing the armor-plate vault built by the Bethlehem Steel Co., the writer had the opportunity to see something of the forging and machining operations on armor-plate as carried on at this plant. These operations are so impressive that it has seemed worth while to speak of them briefly here. This description, especially so far as it relates to the forging, is necessarily non-technical, since this work is somewhat outside the range of the writer's practical experience.

So far as the spectacular features of the forging shop are concerned, the interest centers about the 16,000-ton hydraulic forging press, shown in Figs. 1 and 2. Beneath this press the ingots, as they are received from the casting pit, are worked to the proper dimensions for the finished plate into which they are to be formed and machined. With its attendant furnaces, hydraulic pumping engine, cranes and other handling apparatus, this machine forms a large share of the equipment of the department.

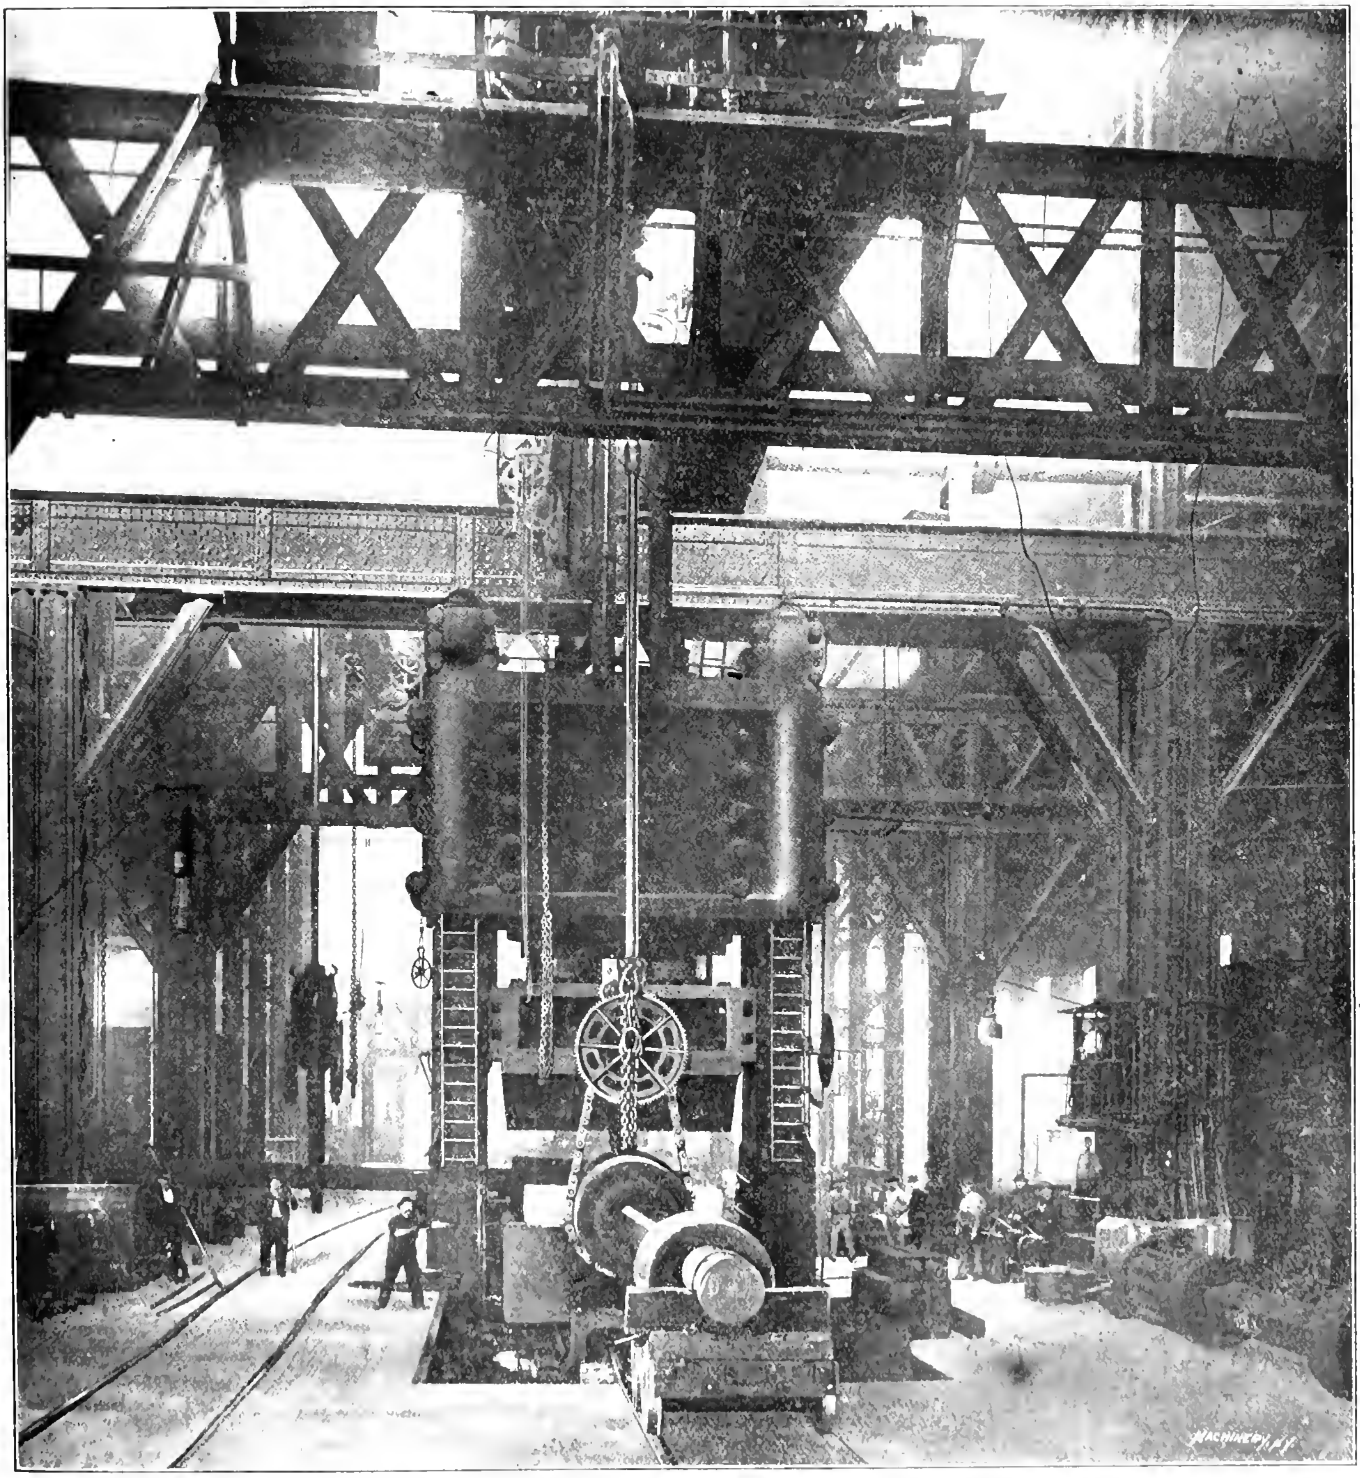

Fig. 1. An Ingot being worked to Shape beneath the 16,000-ton Press of the Bethlehem Steel Co.

The impressive thing in the forging is the handling of the great slabs of hot metal, entirely by mechanical means. It might, in fact, obviously be said of an armor-plate forging, as of a shredded wheat biscuit, that it arrives at its completed form "without the touch of human hands." As the observer

stands on the floor of the shop, gazing curiously at the huge machine and its numerous human attendants standing idly by it, a blast of heat strikes him in the face and he starts back, noting for the first time that the front of the furnace on his left is being slowly raised, revealing the glowing interior. Next, seemingly of its own volition, a car whose body forms the floor of the furnace, deliberately advances, bringing with it, on a pile of incandescent fire-brick, the ingot which has been soaking in the furnace, preparing for the forging operation.

As the ingot advances, we now have an opportunity to admire the dexterity of the crane operator. The geared reel seen depending from the crane trolley in Fig. 1, is provided for this operation with a pair of hooks, attached to opposite ends of a flat link chain arranged somewhat as shown in Fig. 3, one of the hooks being lower than the other. The ingot is so mounted on the fire-brick that its ends project. The crane operator catches one of the hooks centrally under the end of the mass of metal as shown, and then brings the reel over end of the beam which rests on the truck. The crane man, by the mechanism at his command, now has complete control of the mass of hot metal. He may raise it and lower it, turn it over (by revolving the reel), advance it toward the press or away from it (by operating the crane trolley, which is followed by the truck) or swing the whole from side to side about the centers of the truck as a pivot.

On the other side of the press this apparatus is duplicated, so that if the riser has been sheared off beneath the press, the ingot may be worked from end to end, being passed through by the front holder until it is half-way done, when the one in the rear grasps it and draws it through, returning it again, and passing and repassing it until the work is completed. After the riser has been removed, the plate is held by simple solid jaws at the end of the beams, in place of the sockets shown. These movements are all hydraulically controlled, the pressure for the crane movements being delivered to the bridge and the traveler by "scissors pipes"—jointed pipes which open and close to accommodate the movements

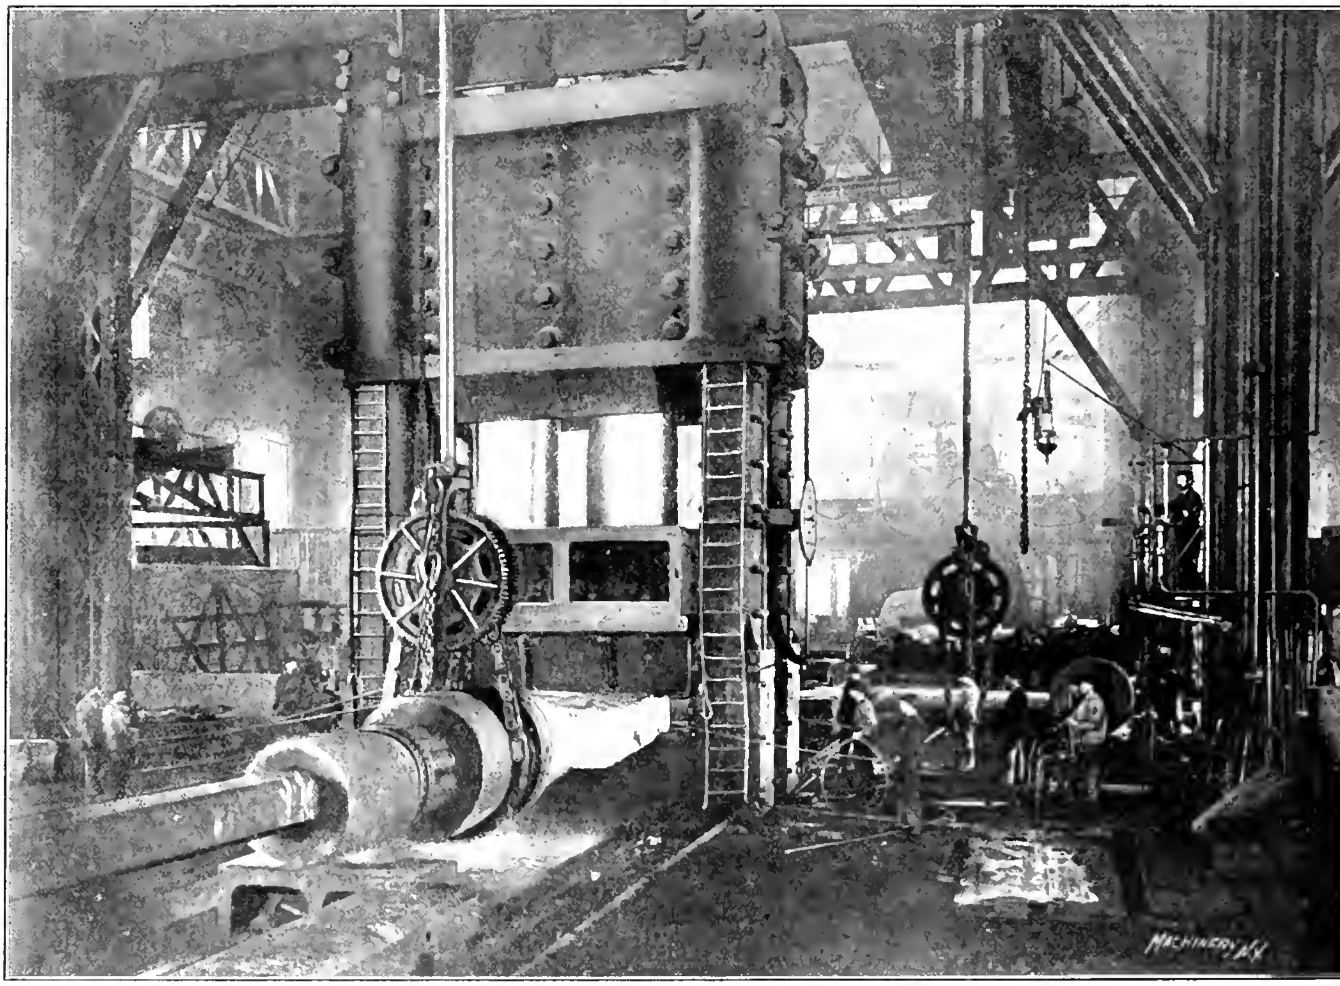

Fig. 2. The Forging Press with the Ram Lowered on the Work. Note the Discarded Steam Hammer in the Background.

until the other hook is engaged. He now raises it clear from the car (which retreats to the furnace, closing the door behind it), swings it about at right angles, and deposits it on one of the die-blocks in front of the press, with its squared stem or riser pointing toward us.

The crane operator has now to attach to the hot ingot what, in default of a better name, we may describe as the "handle" by which it is manipulated. This consists of a great beam whose rear end rests on the truck seen in the foreground of Fig. 1, and whose front end carries a socket with an aperture fitting the stem of the ingot. An endless chain is passed around the reel which hangs from the crane, and the socket is hung in this. Having been adjusted to the proper height by the crane operator, it is advanced toward the ingot and pushed into place over the riser. The crane operator now raises the reel, and with it the socket and ingot, and the bed on which it rested is moved back out of the way. The outer end of the "handle" is weighted (in Fig. 1 a heavy ring is used, as shown) so that the work may not over-balance the of the members to which they are connected. The die-blocks beneath the bed are also hydraulically operated, being brought into place or moved to one side and changed one to another as occasion may require. The men who operate the valves controlling these various movements as well as those of the press itself and of the furnace, are stationed at the right of Fig. 1.

As is well known, the operation of forging by pressure is quite different from forging under the hammer. Instead of pounding the ingot into the shape desired, the end of it is placed between the comparatively narrow dies and given what is apparently a gentle squeeze. The plungers are raised again, the ingot advances another step, and a second squeeze is given. This action is continued progressively until the entire area it is desired to flatten out has been passed over. This successive squeezing is then repeated until the metal has been worked into a plate of the required dimensions. The edges of the plate, when worked by this process, show the characteristic bulging edges resulting from pressure forg-

ing. This shows very plainly that the working of the metal extends clear through to its center, forcing it outward. As most of our readers are aware, it is the ability of the hydraulic press to thus thoroughly work the metal that has caused it to supersede the old-fashioned steam hammer treatment, which, on large work, does little more than deform the surface of the metal, the suddenness of the impact preventing

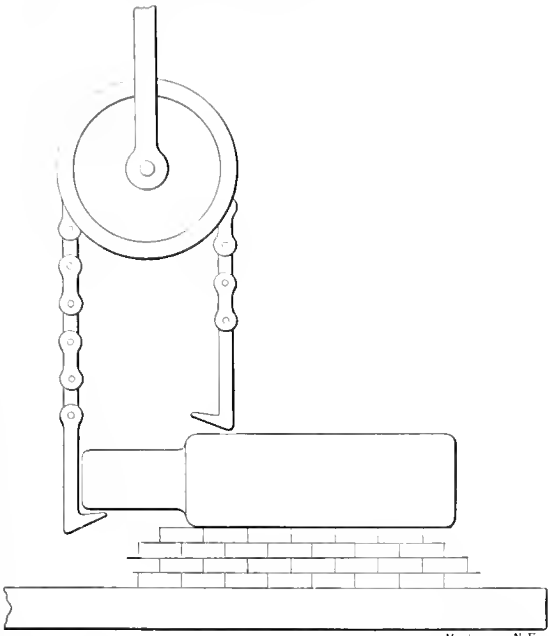

Fig. 3. Method of picking up Heated Ingot from the Furnace Car.

the transmission of the action throughout the whole body. The 125-ton steam hammer, of which a model was shown at the Columbian Exposition in 1893 and which was superseded by this press, may be seen dimly in the background of Fig. 2.

During the forging operation, the work performed on the mass serves to some extent to replenish the heat lost through radiation, so that it is nearly as hot at the conclusion of the working as at the beginning. A noticeable feature of the forging is the shelling off of huge scales of oxidized steel from the surface of the metal, as the operation proceeds.

After the forging, if the plate has to be curved to fit the lines of the ship it is to be applied to, or has to be bent to cylindrical shape for forming a gun turret, it is again heated and shaped under a forming press, similar in design to the forging press shown in Figs. 1 and 2, but of somewhat smaller capacity. In this machine, however, the two plungers are connected with the upper die block by ball and socket joints, and they may be operated independently, so that by using suitable upper and lower dies the plate may be pressed to any desired form.

The metal used for armor-plating, particularly that which is to be hardened by the Krupp process, being of a material which is very tough, even in its softest condition, requires tools and machines for finishing which have unusually strong construction. An idea of their massiveness may be obtained by referring to Fig. 4, which shows a double head milling machine, driven by direct-connected steam engines. This tool is at work finishing the edges of a pair of armor-plate forgings, one on either side. These heads are about 8½ feet in diameter, the cutting circle being 88 inches in diameter, with 12 cutters in each head. A pile of the massive cutters used is shown on the floor in the foreground, at the back and at the left of the small electric motor and controller shown on the floor. The stock used for them is 6 inches by 3½ inches in section. Each table is 8 feet wide by about 23 feet long and has a transverse feed of 21 feet. The double engines have cylinders each 10 inches diameter by 14 inches stroke. The heads revolve very slowly, apparently not giving a surface speed much over 20 feet per minute, or thereabouts. The chips taken are so heavy, however, that it is possible to advance a cut 2 inches deep on an armor-plate 12 inches thick, at the rate of 40 inches per hour.

After machining, the plates are given their heat treatment, being either Harveyized or hardened by the Krupp process. The former is a case-hardening operation pure and simple, though carried to a great depth, and involving weeks of time. The Krupp process is the Harvey process, plus a treatment of which the details are secret. This gives to the metal a peculiar tough fibrous structure which forms an almost unbreakable support for the hardened face of the plate. This hardened face may be chipped and cracked by the impact of the projectile, but the tough backing will hold the plate together without fracture.

In operation, the Krupp process is said to be a very delicate and uncertain one. Two pieces of identical shape may be treated together and laid aside to cool after the treatment is finished. So far as can then be determined, they are in the same condition and have had the same care in every respect. But one of them will have the metal of which it is composed hardened to a very high degree on the face, this merging into a tough fibrous structure with fibers running from front to back as though the plate were sawed across the grain from the end of a huge wooden beam. The other, capriciously and without warning, will crack in two when it

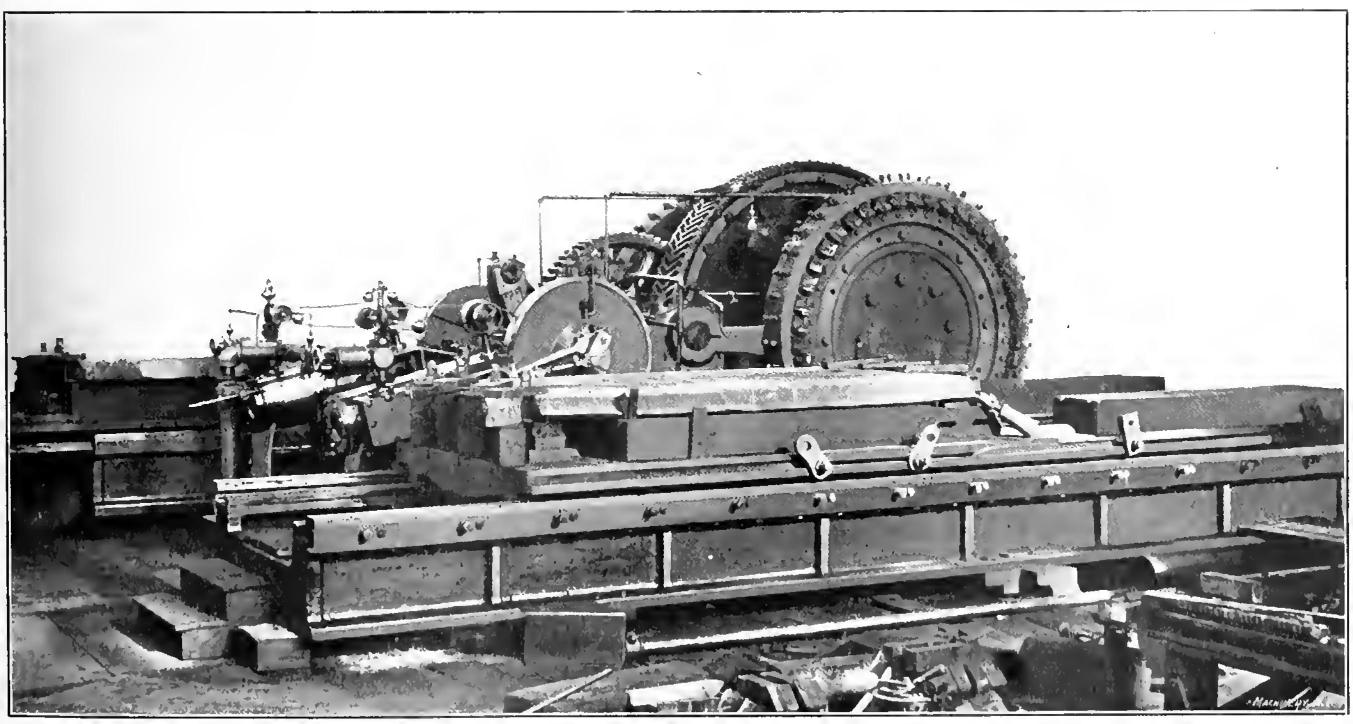

Fig. 4. Double, Steam-driven Rotary Planer, for Finishing the Edges of Armor-plate Sections.

has almost cooled to a point where it can be touched by hand, and the fracture will show a coarse crystalline structure absolutely useless for resisting the impact it may be called upon to stand. Something like 30 per cent of all the finished pieces of armor-plate treated by the Krupp process are spoiled in this way—apparently unavoidably. It is this large percentage of scrap, so the writer was told, which acounts for the high cost of making Krupp armor-plate.

After the heat treatment, the perfect plates again go to a forming press to be straightened, so that their finished surfaces are again squared and in line with each other. This is done by heating them gently, and bending them under the forming press previously described.

Though of huge size, the hydraulic forging press is of such simple construction that its tremendous power is not at first realizable. A walk to the upper end of the shop, however, where is located the 15,000-horse-power hydraulic pump which serves the press, gives the imagination data to work on in appreciating the tremendous amount of work expended in forming the hot ingot into a plate of the desired dimensions. This pump, which was built at the plant, was designed by the well-known engineer, E. D. Leavitt, of Cambridge, Mass. This engine and the press, as well, have been previously described in MACHINERY (see the issue of October, 1899).

* * *

DEFECTS IN THREADS FOR STEAM-TIGHT JOINTS.

In a recent issue of the *Valve World* attention is called to the fact that defects in the tapered thread of the joints of wrought iron and steel pipe are not of so great consequence in obtaining a tight joint as is ordinarily assumed. The Crane Co., of Chicago, has endeavored to show that the ideas held regarding the placing of too much importance on defects in the threads of pipe and fittings, are erroneous, and this company has made some conclusive tests on this subject. The results of these tests seem to give evidence that the many small defects for which pipe and fittings are often rejected, are entirely unimportant in regard to the efficiency of the threaded joints for making a tight connection. One of the common causes assigned for the rejection of pipe is that threads are a trifle broken. To prove of how little consequence this is, a piece of 8-inch pipe was threaded for a distance of 2¼ inches. This pipe was then put in a lathe and the thread was mutilated by turning three circular grooves, each 3/16 of an inch wide, on the surface of the pipe, thereby cutting away some of the threads entirely, and leaving only fragments of some of the other threads. The tops of the remaining threads were then turned off, so that they had a flat surface on the top 1/32 inch wide. At three places on the circumference of the tapered thread flat spots were then filed, one inch wide and two inches long. Twenty-five grooves were then filed in the thread of the pipe, and the same number in the coupling, all perpendicular to the direction of the thread, and two-thirds of the depth of the thread. When this deliberate mutilation was finished, the threads were cleaned, and were thoroughly coated with a cement for making a tight joint, in this case, "Crane" cement. The joint was then screwed up so that the lengthwise grooves did not come opposite each other. The outer ends of the pipe and the coupling were then plugged and the joint was tested to 425 pounds air pressure. The joint was found to be tight, and the same result followed a hydraulic pressure test of 1,000 pounds per square inch. This test also indicates of how little importance it really is in taper-threaded fits if the taper of the two components making the joint should not be exactly the same. In fact, in many cases, pipes are not threaded with the same taper on the outside as the taper of the tap used for threading the corresponding fitting on the inside, but nevertheless, a steam or water-tight joint is effected, by screwing the component parts tightly into one another, and using some suitable compound to make a tight joint.

A lathe shear is a poor anvil.
The squeak of the dry bearing goes round the world.
A crack in the floor is a poor straightedge.

THE PROBLEM OF THE SPIRAL CONVEYOR.

LAYING OUT THE FLIGHTS.

F. WEBSTER.

In making steel spiral conveyors of small sizes, the pattern for the flights is laid out and the disks are punched from sheet metal. Some makers use the following method for laying out the pattern:

Suppose the conveyor is to be 12 inches outside diameter, and is to have a pitch of 12 inches, as shown in Fig. 1, and that 2-, 2½-, and 3-inch pipes are to be used for the shafts of three sizes. The length of the helix on the outside of the shaft in each case is found by the triangle method: that is, the length equals that of the hypotenuse $a\,d$ of a triangle,

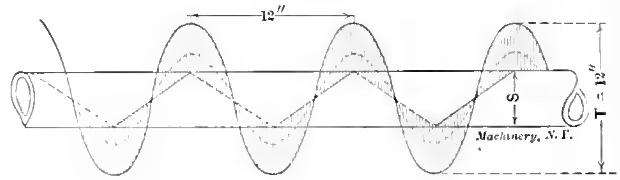

Fig. 1. Typical Spiral Conveyor, showing Pitch, Diameter, etc.

Fig. 2, having an altitude $a\,c$ equal to the pitch, and the base $c\,d$ equal to the circumference of the shaft. Thus, in the case of a 2-inch pipe which has an outside diameter of 2.375 inches, the length of the helix on the pipe equals $\sqrt{12^2 + (2.375 \times \pi)^2} = 14.13$ inches, and this divided by π (3.1416) gives 4½ inches as the diameter d, Fig. 3, for the circumference of the hole in the disk for the flight. For the 2½-inch shaft, the diameter for the hole in the disk is found to be 4 25/32 inches, and for the 3-inch shaft, it is 5 3/16 inches. The outside diameter D of the disk is found by adding the diameter d of the hole to the difference between the diameter T, Fig. 1, of the conveyor, and the outside diameter S of the pipe. For the 2-inch pipe, the outside diameter D of the disk equals 14⅛ inches; for the 2½-inch pipe, 13 29/32 inches; and for the 3-inch pipe, 13 11/16 inches. When the disks are punched, they are also cut along a radial line E, so that one end of the flight can be raised above the other. From a comparison of the values found for the outside diameter of the disk, it will be seen that the outside diameter becomes less as the size of the shaft increases, notwithstanding the fact that the diameter of the finished conveyor remains fixed at 12 inches. Hence, the inquiry arises, is this correct, and also is the method described above the correct one for laying out the pattern?

It is true that the outside diameter of the disks for the flights will be less for the large shaft than for the smaller ones, but this method of laying out the patterns will not

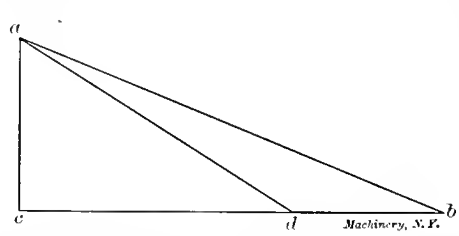

Fig. 2. The Triangle Method of finding the Length of the Spiral.

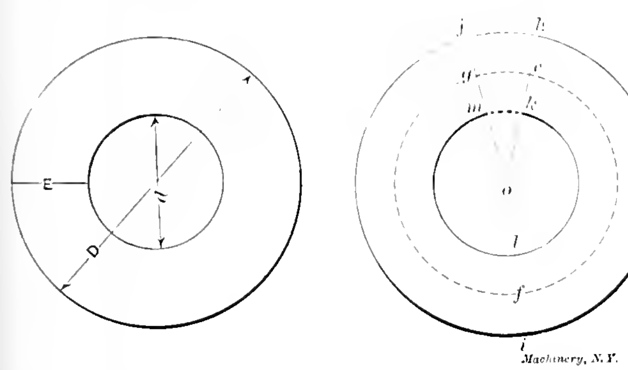
give the correct dimensions for either the inside or the outside diameters, as will be shown by the following discussion.

In the first place, it must be understood that the flight of a conveyor forms a warped surface, and this cannot be made directly from a flat surface without the material being bent and stretched, or *raised*, as it is called, in order to get the flight set square with the shaft and prevent buckling. The following method will give dimensions more nearly correct for the disk so that after the disk has been raised it will approximately fit both the helix on the pipe and the outside helix of the conveyor. The method consists in constructing a helix, shown by the dotted curve in Figs. 1 and 4, on the flight midway between the outside of the shaft and the edge of the conveyor. The length, $a\,b$, Fig. 2, of this helix is then determined by means of a right-angled triangle in the usual way. The length $a\,b$ of the hypotenuse of the triangle is not

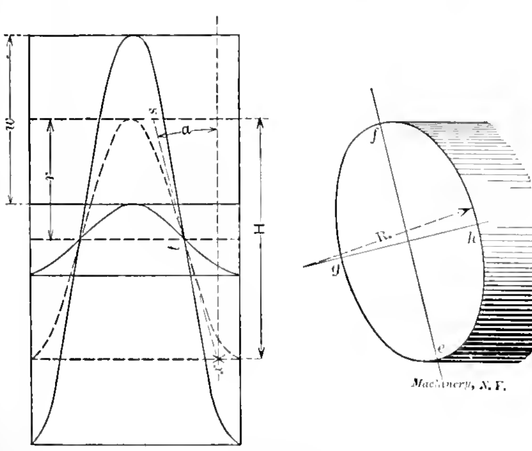
used, however, for the circumference of a circle, as was done in the first method explained, but an entirely different principle must be used for the remainder of the construction. This principle will be most easily understood by considering a more simple example than that of a conveyor flight, namely: the pattern for the surface of the frustum of a cone, shown in Fig. 5. The method requires the use of a slant height OC of the cone as a radius, drawing an arc A from the base, and an arc B from the top, and on these arcs laying off lengths equal to the circumference of the base and the top, respectively. The developed surface $KLMN$ is then the required pattern.

Applying the principle just explained to the construction of the flight of a conveyor, the layout may be made to approach the theoretical requirements as follows: Pass a plane through the tangent xs, Fig. 4, to the middle helix and perpendicular to the axis of the cylinder. The section formed will be an ellipse, as shown in Fig. 6, having its long axis ef equal to the tangent xs, Fig. 4, and its short axis gh equal to the diameter H of the cylinder. The radius of curva-



Figs. 3 and 7.

ture of the helix at the point t, Fig. 4, of tangency is practically the same as that of the flat side of the ellipse at the same point h, Fig. 6. To develop the curve on a plane surface requires the use of the radius of curvature of the helix for drawing the arc (in the case of the frustum of a cone given above, the slant height of the cone was used for the radius). The length of the radius of curvature R, Fig. 6, of a helix or ellipse equals $\dfrac{r}{\cos^2 a}$, where r equals the radius of the cylinder, and a is the angle of the helix as shown in Fig. 4.



Figs. 4 and 6.

This formula is derived by the use of analytical geometry, and will not be explained here. The length of the radius of curvature can also be found graphically.

When the radius of curvature of the middle helix is found by using the formula, draw with it a circle f, as shown dotted in Fig. 7. On this circle lay off the length of the middle helix, as taken from the hypotenuse ab of the triangle Fig. 2, and draw lines from the center of the circle through the extremities e and g of the arc efg representing the length of the helix. Lay off on each side of the central circle distances ek and eh equal to one-half the width w, Fig. 4, of the flight, and draw arcs l and i through them, thus completing the pattern $hklmjih$ for the flight. An inspection of the figure shows that neither the diameter of the hole, nor that of the outside of the disk is the same as the values derived by calculation, according to the method first used. It will also be seen that the punching, Fig. 7, does not form a closed ring as

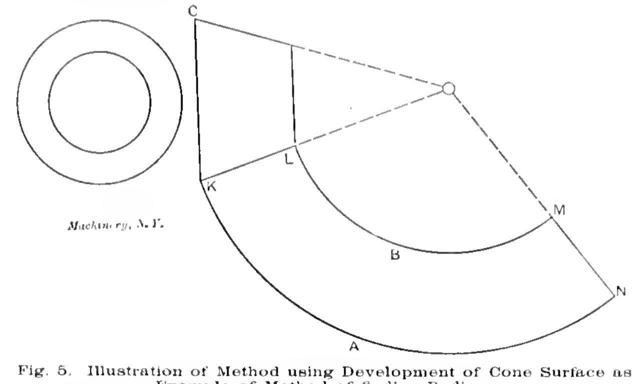


Fig. 5. Illustration of Method using Development of Cone Surface as Example of Method of finding Radius.

in Fig. 3, and hence, there will be more waste material in this case than where a closed ring is used for the pattern, but the work will be more accurate.

The reason for the outside diameter of the blank being smaller when a larger shaft is used, will be seen from a study of Figs. 4 and 6. If the diameter of the shaft be increased, the helix through the middle of the blade will be larger in diameter, and this will cause its tangent, xs, to have less slope. The plane through the tangent will then pass more nearly horizontal, and thus the ellipse cut from the cylinder will more nearly approximate a circle equal to the base of the cylinder. The radius of curvature of the helix then becomes shorter, or more nearly the length of the radius of the cylinder, and hence, the central circle in the layout will be less in diameter. This, in turn, decreases the outside diameter of the pattern.

* * *

CAN A BOY LEARN A TRADE IN A SCHOOL?

E. R. MARKHAM.*

The writer has read so many articles of late on this important subject that he concluded that a few ideas from him would not be amiss. The writer acknowledges that he is engaged in school work, and consequently would not be considered as competent to write from a practical man's point of view, but before he engaged in school work he had over 25 years practical machine shop experience, learned his trade, and worked as machinist and tool-maker for a number of years before taking charge of work himself, and while in charge of shops, the writer was instrumental in teaching the machinist's trade to more than one hundred young men. Having then been engaged in school work for seven years, he therefore feels himself in a position to speak with some understanding of the subject, and having also been connected with two manual training schools, in both of which evening classes for machinists and machine operators in machine shop work are carried on, he has become, in a measure at least, acquainted with the shortcomings of the present so-called apprenticeship system.

In the ordinary manual training school, as conducted at the present time, it is not possible to teach a boy a trade, neither is this attempted. What the school accomplishes, however, must be considered rather a surprise to a fair-minded man. For instance, a boy comes into the machine shop an hour and a half every other day, for a period of 80 weeks, five school days a week, this making a total of 300 hours, and from this should be deducted the time given to lectures and instructions along general lines. If the boy spent the whole 300 hours in the shop, the time for getting ready and cleaning his machine would have to be deducted, and, as he comes into a shop 200 times, this would aggregate a considerable amount to be deducted from the 300 hours. In a shop running 10 hours per day, six days a week, 300 hours would only make five weeks. Now, if the observer examines the range, quantity, and quality of the work done by the average

* Address: 66 Dana St., Cambridge, Mass.

pupil in the time mentioned, he must acknowledge that considerable progress has been made, and he will be convinced that a young man, under systematic training, will get along many times faster in a school than if placed in a shop under the conditions which now ordinarily prevail.

As previously stated, we do not attempt to teach trades to our pupils in the trade schools of to-day. However, we occasionally run across a boy who, although intelligent, shows no special fondness for academic work, or, in other words, book study; and such a boy may be given extra time in the shop and permitted to specialize in the shop. Such boys, when they enter into manufacturing work, and find employment in shops, generally give the best of satisfaction, and the schools many times receive word from manufacturers to send them all the young men of this type they can. It is apparent that many young men of this class cannot be furnished, and it is rarely the case that more than one or two at a time take this extra amount of shop work.

Instructors.

Any man, in order to be able to successfully teach any of the mechanical trades, must be a journeyman. He must have had a large all-around experience, and be able to explain to his pupils the various classes of work, as they present themselves. He must have a general knowledge of mechanics, and be able to give short lectures on the manufacture of iron and steel, shop methods, and explain desirability of certain metals for certain purposes. He must understand and also be able to impart to others, the most approved methods of doing work, and when having entered school work, must still try to keep in touch with the advancing achievements of machine shop work.

Outline Plan of an Efficient Trade School.

If trades are to be taught in schools, the mechanical departments must not be "the tail of the dog," as they sometimes are, and "bob-tails" at that. If a trade is to be taught, everything should be so arranged as to accomplish that end. The boy must be given sufficient time in the shop, so that it will be possible to give him the instruction necessary, and his studies must be selected so that he studies in particular those subjects which will help him in his shop work. Such subjects as are included under the head of mathematics, especially arithmetic, should be given special emphasis. The work in arithmetic should be made up of ordinary shop problems, and the use of various formulas entering into shop work. The problems in mechanics should be of a character that will help him in the shop, and apply to his every-day work. The drafting work should be of a kind that will render it easy for him to read working drawings, and he should be required to make drawings of the various details which he afterwards will be required to make in the shop. In this way, his drawing will not be a matter of copying, and the result aimed at will not be simply to get a neat drawing for the sake of getting a good, or passing, mark. The drawing becomes something more than a mere task to be performed. The pupil finds himself placing on paper something that he is to duplicate in wood or iron, and the matter of accuracy is more apparent to him, because if he makes a mistake in the figures, it may mean a great deal to him when he gets to working on the piece in the shop.

Objection to Trade Schools.

The main objection to the establishment of such courses, as have been outlined, in present schools is that it would entirely disarrange the established customs and programs of the school. This, however, would probably not be a bad thing. If a school is supposed to teach trades, everything ought to be shaped so as to give proper emphasis to the shop work. If the teaching of trades is attempted in the manual training high school, there will, of necessity, be a very sharp dividing line between the college course and the trade course. The training which will fit a boy to attend a college or some technical school must of necessity meet the requirements of such an institution, and very little time is left for shop work. Under the conditions existing in many schools, however, the amount of shop work given boys in the college and general courses is the same, and the boy who enters directly into practical work, when graduating, is no better equipped for his work than the boy who is to receive the education which will fit him for a more advanced engineering position. Therefore, if the time now spent in the study of subjects which will not be of direct benefit to the boy who intends to enter practical work directly from the school, were spent in acquiring specific trade education, the boy would be more directly benefited.

Commercial Basis of Trade Schools.

The argument is sometimes advanced that a school cannot be run on a commercial basis, and for this reason a trade cannot be taught along commercial lines. The writer does not know of any reason why a trade school could not be run on a basis at least *parallel* to that of a manufacturing establishment. The fact that such is not the case at present is no proof that it cannot be done. The difference might be that the boy familiar with arithmetic, as it should be taught to a boy learning a trade, would be given the proper speeds and feeds as a part of his trade, rather than to be told to "jack up the speed another cone," or "give her a little more feed," without being told what speed or feed is right for that particular job. In the shop, of course, a boy receives a large share of his instructions from the older men working with him, but whether it is wise or not depends altogether on the man instructing the boy, and on how much he knows, and how much he is willing to impart to the "kid."

If a real trade school is established, efficient journeymen should be employed about the shop. These men should be selected for their ability, character, etc., and being directly under the instructor, who should be a thoroughly practical man, would work according to his directions, so that the instruction which the pupils receive from observation of these men at work, will emphasize the instructions given directly by the instructor.

Then the question comes, what would one make in such a school? One could make some simple line of machinery, make all the jigs, fixtures and other tools necessary to use in the building of the machines, and also some articles of a "jobbing" character, in order that the pupil might get an extended experience. Some things made should be of a character that the shop was not equipped to handle, so that methods had to be improvised for carrying out such work, making the pupils resourceful.

It is no advantage for a young man to learn his trade in a shop where there is a machine specially made and equipped for each piece of work done. If he ever gets into a shop where the equipment is limited, and it is necessary to "invent" ways and means for doing certain work, he is apt to fail, as compared with one who has been taught his trade in a smaller and less pretentious shop. The shop should also have a regular cost keeping system. Each boy should be given charge for a given time, and should be expected to get out certain work in a given time, and try to devise means of getting it out quicker and better. The trade school should, in a word, try to teach the young man how to *think* as well as how to *work*.

Can a Boy Learn a Trade in a School?

In answer to the question suggested by the title of this article, the writer would answer: Yes, trades can be successfully taught in schools, provided conditions are made to suit the requirements, and the instructors are equipped by nature and experience with the qualities necessary, and love their work.

* * *

It is stated in the *Mechanical World* that Mr. Muller, a Bavarian inventor, has obtained a patent for a new insulating material which has a high specific resistance approaching that of gutta-percha and porcelain, and at the same time is almost incombustible in that it will even stand exposure for a short time to electric arc without burning. The composition of the insulating material, according to the patent specifications, consists of 100 parts of mineral pitch dissolved in 20 parts of volatile solvent, such for instance as benzine. From 25 to 75 parts of this solution are added to 100 parts of finely ground asbestos. This mixture is then submitted to high pressure, and dried at a low temperature in order that the solvent may be expelled.

FILLING AND PAINTING MACHINE TOOLS.

H. J. HUDDLESTON.*

Almost every plant has its own system for doing machine painting. There are, perhaps, not a half-dozen firms in the city of Cincinnati which do this part of their work alike. I have been in the employ of the R. K. Le Blond Machine Tool Co. during the past eight years, and as this company received the medal for "finish" at the Paris Exposition, its system, which will be explained, is doubtless worthy of consideration.

First, let all the planing and drilling be done on the casting before it is turned over to the painters, for if, after the work has been filled, rubbed down and painted, it is again handled in connection with machining, it will doubtless be necessary to again refill the work, and this cannot be done and the work made to look as it did originally. The casting should first be thoroughly cleaned, and all lumps and rough edges chipped off. All corners and angles should be filed smooth with a bastard file, and then the casting should be gone over thoroughly with a wire brush, which will loosen all sand and dirt. Next take an emery stone and stone it all over. After this has been done, wash the casting with gasoline or naphtha, using a piece of waste. This will take any oil out of the iron which may have accumulated from drilling and handling. After the casting has been washed in this way, it should be dusted, using an ordinary duster.

Now, in every foundry they make good and bad castings; quite often a casting has a blow-hole in it, and it is almost always in a conspicuous place. The S. Obermayer Co., of Cincinnati, Ohio, manufactures what it calls "National iron filler." This ingredient can be used for filling in blow-holes which may be found in castings. It should be mixed with just enough water to give it the consistency of putty. It can then be placed in the blow-hole, and in one-half hour it will be as hard as iron. After all the rough places have been made smooth, and any bad spots filled as described, the work is given a coat of heavy iron filler. Now, there are many kinds of iron filler on the market, but the one which I have found to give the best satisfaction, is the filler manufactured

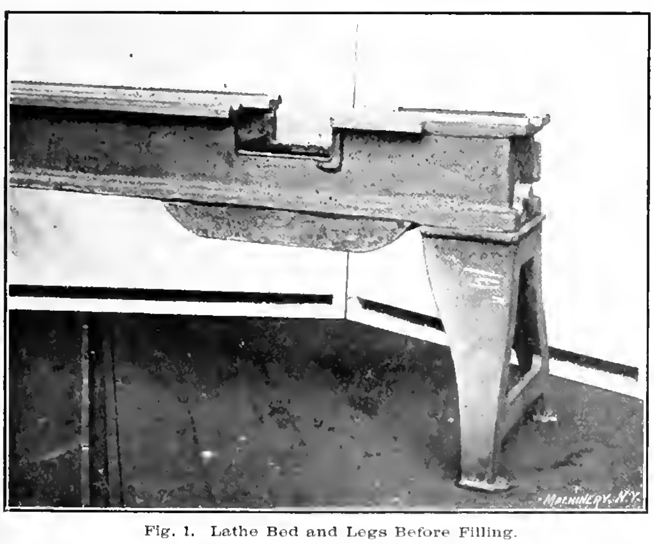

Fig. 1. Lathe Bed and Legs Before Filling.

by the Sherwin-Williams Co. This filler comes in a paste form, and is thinned with turpentine only. After the work has been given a priming coat, it should have about one hour in which to dry. After the filler is dried, the work is plastered. The plastering is done altogether with knives. The knives are of two kinds; one is known as a carrying knife, and the other as a plastering knife. The plastering knives range from 1 to 4 inches in width, while the carrying knives are from 5 to 7 inches in width. The iron filler which is to be applied, is held in a pan, say 12 inches square by 6 inches deep. The filler is thinned with turpentine until it is about like soft putty, then holding the carrying knife in the left hand, and the plastering knife in the right, the filler is applied to the work by cutting some it from the carrying knife with the plastering knife. Hold the plastering knife so as not to pull all the filler off, as it is possible to leave too much filler on the work or to take too much off. It is not well to attempt to handle too much filler on the knives at one time. After going over every part of the work, brush it thoroughly, in this way loosening all the particles of loose or dry filler. The work should now be given three coats of brush-filler, each coat being given about one-half hour in which to dry. The work should now be allowed to set for about five hours; then it can be rubbed.

In putting on the brush-filler, a bristle brush, about 3 inches wide, is the best to use. Care should be taken not to bear too hard on the brush, as brush marks are very hard to sand out. When the work is thoroughly dry and ready to sand, go all over it with No. $1\frac{1}{2}$ emery cloth; then dust it off, and

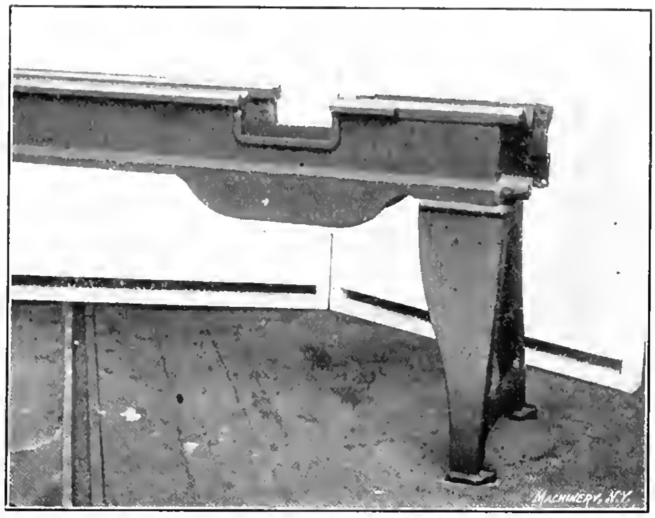

Fig. 2. Lathe Bed and Legs After Filling

go over it again with No. $\frac{1}{2}$ emery cloth, which will remove all scratches. Again dust the work, and it will be ready for painting.

There is, on the market, what is called an "intermediate surfacer," manufactured by the Sherwin-Williams Co. A coat of this paint will give an elegant body for whatever finish you care to give to the work. A paint suitable for finishing can also be bought from this same company, in any shade desired. If the foregoing directions are followed when painting machine tools, I am sure that the results will be satisfactory.

NOVEL PIPE NIPPLE MACHINE.

The Crane Co., Chicago, Ill., has developed an automatic pipe nipple machine embodying a new principle in pipe threading, we believe. The new principle lies in the action of the cutting dies. These consist of four revolving die heads, set 90 degrees apart around the pipe, which carry chasers on their peripheries and which revolve with the plane of the chaser heads parallel to the axis of the pipe being cut. As the pipe rotates, the rotation of the die heads is kept in step with the lead of the thread being cut, the action being essentially the reverse of the common hobbing process employed in making worm-wheels. The chasers thread the ends of two nipples at the same time. The cutting-off and chamfering tools come into operation after the thread is cut, there being two threaded portions of the pipe between the threading dies and the cutting-off tools. It is obvious that the dies working in this way do not cut a truly tapered thread. The threaded part instead of being a true taper of $\frac{3}{4}$-inch per foot included angle, is an approximation only, the outlines of the threaded parts being arcs of a circle having the radius of the cutter heads. This deviation from the true shape, however, is so little that it causes no trouble in practice. The productive capacity of this machine is high; when working on $\frac{3}{4}$-inch nipples it cuts 10 a minute, the cutters being made of high-speed steel and working at a speed of 70 feet per minute.

* * *

The output of the Baldwin Locomotive Works for the past year was 2,750 locomotives, being an average of $7\frac{1}{2}$ locomotives daily, representing approximately $15,000,000 worth of business.

STANDARD NOTATION FOR ENGINEERING FORMULAS.

At a meeting of the Civil and Mechanical Engineers' Society, in Great Britain, January 2, 1908, the question of standard notation for engineering formulas was discussed by several men well equipped for speaking authoritatively ou this subject. One of the most interesting additions to the discussion was offered by Mr. E. Fiander Etchells, who presented the suggestions for a uniform system of notations abstracted in the following. Mr. Etchells called attention to the fact that the real problem was deeper than that simply of notation; the real problem was one of nomenclature. One of the reasous for the condition that, at the present time, there are so many ways of writing the same formula, is principally due to the diversity of names for the same thing. As an example, some writers use S to represent the section modulus of a beam, S being the initial letter of "section," while others, referring to the same quantity, would call it moment of resistance, and would represent it by M or R or even by MR. The first problem, therefore, would be to agree on the nomenclature for the most general engineering and scientific expressions. Having agreed upon this, the following principles might be accepted as a guide for the selection of symbols.

The Initial Letter.

The best symbol to be used, would, evidently, be the initial letter of the word which the symbol was supposed to represent, but this can not, of course, be rigidly adhered to, as in some cases it would lead to confusion, although being adopted for avoiding confusion. In particular, established custom should not be disturbed unnecessarily, for accepted custom, as a rule, represents a natural evolution of unconscious or sub-conscious standardization. Attention was called to the fact that it was not without reason that π represented the ratio of the circumference or periphery of a circle to its diameter, for π is the initial letter of the Greek word περιφερος (periphery), now common on three continents. It would therefore be entirely out of place to try to alter such forms or notations as are already standardized.

Abolition of all Double Symbols.

It would be very inadvisable in any standard system of notation to use any double symbols, for instance, such as BM, representing bending movement, or MR, moment of resistance. Notations of this kind give the impression that M is multiplied by B or by R. Where two letters appear to be necessary, the second letter should be used as a subscript; thus, one would write M_R and M_B, which would be excellent notations for the moment of resistance and the moment of bending.

Self-explanatory Subscript Letters.

Subscript letters should, also, wherever possible, be made self-explanatory. It, for instance, is not at all advisable to say:

A_1 = area of concrete in pillar,
A_2 = area of steel reinforcement,
A_3 = equivalent area.

On the other hand, these three quantities would be very well represented by the notations A_C, A_S and A_E, respectively. Then there would be no need of constantly referring to the explanations of the notations, and the mind would be left free and unhampered to concentrate itself on the real work under consideration. Other things being equal, the less the memory is taxed in grappling with engineering problems, the more it would be possible to arrive at a thorough comprehension of the problems under investigation.

Superscript Letters or Numbers.

Superscript letters or numbers, used at the right-hand top corner of a letter, should be exclusively reserved to represent powers of that letter; thus, whenever the expressions B^2, B^n, etc., are used, it should always indicate the square of B, B in the nth power, etc. Whenever secondary notations are required, and they are not intended to express powers of the principals before them, they should be used as subscript letters, and one should write B_2, B_n, etc.

The Use of Capital and Small Letters.

Capital and small letters may be used to represent related matters; thus, for instance, W may be used to represent the total load, while w would represent the load per inch or per foot of span; P may be the pressure in tons, while p would be the pressure in pounds; L may be the span in feet, l, the span in inches; D may be the external diameter, and d, the internal diameter.

The Use of Greek Letters.

Greek letters should be used very sparingly, and one very important reason for this, which, on consideration, cannot be easily refuted, is because that important factor of civilization, the typewriter, has no such symbols on the ordinary key-board. Greek letters, in general, can easily be dropped, with the exception of the following:

θ = inclination to any horizontal plane; or, in another connection, the angle of torsion; or temperature in the $\theta\phi$, or temperature entropy diagram.

ϕ = inclination to any vertical plane; or the entropy of Clausius definition—*i. e.*, the heat weight of Zeuner—*i. e.*, the thermo-dynamic function of Rankine.

π = 3.141592.

Σ = "The sum of all such terms as."

τ frequently used for absolute temperature, could easily be replaced by T_A—*i. e.*, temperature absolute; most of the other letters could be treated in the same way.

Use of Initial and Second Letter where Necessary to Avoid Confusion.

The initial and the second letter of a word may be used to avoid confusion, the same as is done in chemistry, or in some cases the initial and the last letter may be used. Thus, just as in chemistry, C represents one atom of carbon, and Ca one atom of calcium, so could d represent the depth of a beam, and d_n or d_e represent the deflection of the same beam. This would save any use of letters not to be found on the ordinary typewriter key-board, such as $\triangle$ or δ. The only alternative is the use of the easily confusible d_1, d_2, d_3, etc., which have already been referred to as undesirable when not absolutely necessary.

In cases of notations for such expressions as "absolute temperature," for instance, one would use T_A, and not A_T. In looking in the index of a book for the expression "absolute temperature" one would look under "temperature" and not under the vague heading "absolute," and in the same way, in engineering notations the principal letter should be the one which expresses the principal meaning. For the same reason S_F is preferable to F_S as an expression of factor of safety, safety being the principal term in the expression. The illustrations given have been used only as examples. Perhaps these examples were not the best ones, but the principles laid down would insure clearness and certainty. While it may not be possible to get a complete standardization of engineering terms, it would be comparatively easy and very desirable that a much greater degree of standardization than existed at the present moment, would be accomplished.

* * *

A MACHINERY data sheet index is now ready for distribution, and copies will be sent to all subscribers upon receipt of request. The index is cumulative and supersedes the one issued December, 1905, as it covers all the data sheets, both regular and extra, issued from September, 1898, to December, 1907, inclusive. The twenty-four extra data sheets issued October, 1907, are included under numbers 74 to 79, inclusive. The total number, including the extra sheets, is 82, or 328 leaves, 6 x 9 inches. These fill the binder supplied by the Industrial Press, and the group will be designated as Volume 1. The next index will date from January, 1908.

* * *

Although so hard, the diamond is very brittle, so that a sharp blow will often fracture it. But Sir William Crookes, who has devoted much time during many years to the scientific study of the diamond, has shown that if a good one is placed between the steel jaws of a hydraulic press, and the pressure is applied without jerk so as to avoid fracture due to brittleness, the jaws may be made to meet without the slightest injury to even the edges of the diamond, the hard steel closing round it and taking an impression of the much harder diamond just like so much wax.—*Times Engineering Supplement.*

GEAR-CUTTING MACHINERY.—4.

RALPH E. FLANDERS *

As the rack-cutting machines we have just described (see the preceding installment in the March issue of MACHINERY) are derived in form from the milling machine with rack cutting attachment, so a machine may be made resembling in its movements the arrangement shown in Fig. 65, in which the cutter spindle is mounted on a shaper ram, which is fed forward bodily to pass the cutter through the work. One machine in very common use built on this plan is the Pratt & Whitney rack-cutter. This firm is no longer building this machine, so we do not show a cut of it here, though it is of common occurrence and familiar to every one engaged in the business. Another machine of the same type, built by the R. K. Le Blond Machine Tool Co., is described elsewhere in this issue of MACHINERY.

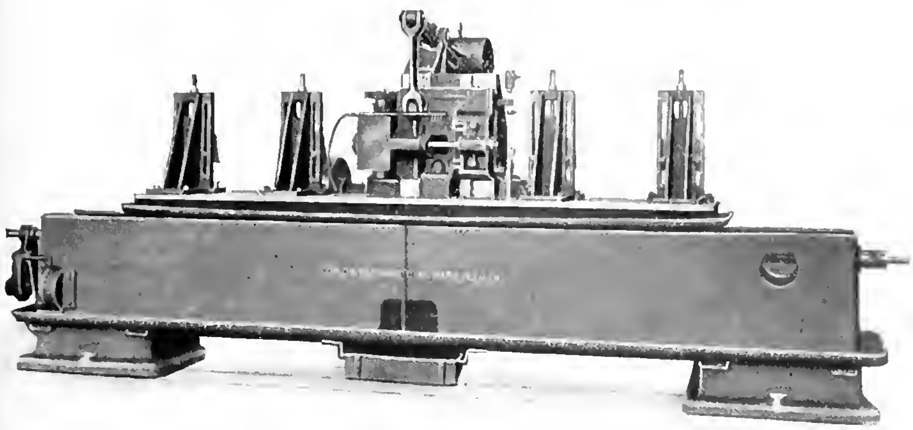

Fig. 69. The Gould & Eberhardt Automatic Rack-cutter.

A third form in which the rack-cutting machine is built, resembles in its construction the heavy type automatic gear-cutter, such as that built by Craven Bros., and shown in Fig. 37. The only difference is in the substitution of a longitudinal work-carrying slide and indexing mechanism, for the rotary work spindle and indexing wheel of the spur-gear machine. This likeness may easily be traced in the case of the Gould & Eberhardt rack-cutter, shown in Fig. 69. As in the spur gear machine, the spindle is mounted on a head sliding on vertical ways on the face of a column. This column may be adjusted in and out on the bed to suit the thickness of the work being operated on. The table, which takes the place of the spindle and face-plate of the spur-gear machine, slides on ways on the main body of the bed. It will be noted that these ways are of unusual length, supporting the table well, even when it is moved out to the extreme of its travel in either direction. The change gears regularly furnished permit the cutting of either diametral or circular pitches. The table can be geared to index in either direction. The work may be fastened either directly to the table by T-slots provided, or may be clamped in the angle vises shown. The cutter spindle is of chrome nickel steel, strongly gear-driven by worm and worm-wheel and splined shafts. The holding of the blank in a vertical position, and the vertical travel of the cutter slide, permit a rigid support for the work against the thrust of the cut, besides causing the lubricant and chips to drop freely out of the way. This type of machine is convenient for setting, inspecting and testing the work. An improved machine of this type is described in the "New Machinery and Tools" department of this issue of MACHINERY.

The machine built by J. E. Reinecker, of Chemnitz-Gablenz, Germany, shown in Fig. 70, like the preceding one, is entirely automatic in all its movements, though it is furnished, if desired, in semi-automatic form in which the spindle head after finishing the cut returns automatically to its starting position, where it stops; the dividing is then done by hand power by the dividing apparatus, after which the feed has to be started again. After the rack is cut through, a special arrangement returns the table to its starting position. This is of great advantage when stocking and finishing cuts are made, as the dividing follows the same direction and from the same starting point.

The driving difficulty previously mentioned as being met with in the rack-cutter, is overcome in this machine in a novel manner—see the line drawing, Fig. 71. As there shown, the cutter spindle is set on an angle with the work, and the forms of the cutters used are made to suit; that is to say, the formed tools used in shaping them are set at the same angle as that given to the axis of the cutter spindle. This arrangement obviously allows the use of a driving gear C considerably larger in diameter than the cutters. The drive is from a vertical shaft D, through a bevel pinion to bevel gear A, driving pinion B, meshing with gear C on spindle E. As here shown, there are two roughing cutters F, and two finishing cutters G. Of course the angularity of the spindle necessitates an increase in diameter for each succeeding cutter on the arbor.

This scheme is especially interesting to the writer because a similar suggestion occurred to him at one time in conversation with a designer who was planning the construction of a rack-cutting machine. In talking the matter over, however, the arrangement seemed inadvisable, owing to the necessity for special cutters and the added complexities of using them in gangs as here shown. Besides this, it would probably be impossible to cut cycloidal teeth of absolutely accurate form by this method, because it would be impossible to obtain clearance for the sides of the cutters at the pitch line where, when absolutely correct, the sides of the teeth are parallel for an infinitesimally small distance. For involute cutters, also, it is obvious that the angle made by the axis of the spindle with the face of the rack must not exceed the number of degrees in the pressure angle (or angle of the sides of the teeth) of the rack being cut. Mr. Reinecker appears to have found this method commercially successful, however, and an actual trial of it is the only true test in a case of this kind.

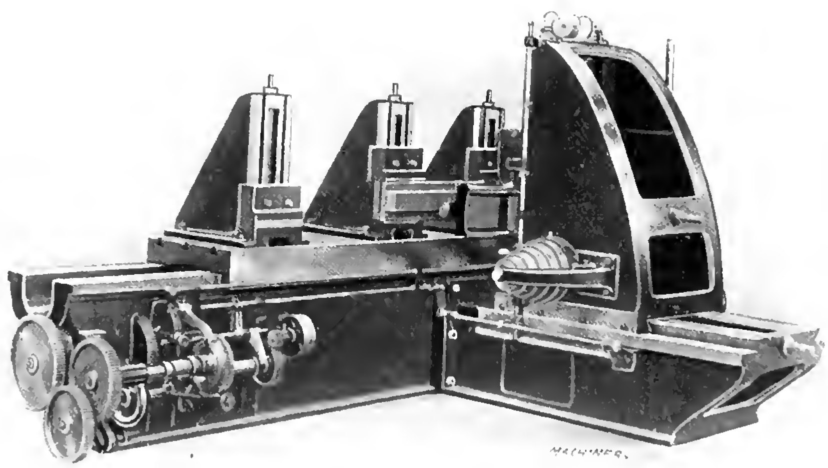

Fig. 70 The Reinecker Automatic Rack-cutter.

Miscellaneous Types of Rack Milling Machines.

The rack-cutter shown in Fig. 72, built by G. Wilkinson & Son, Keighley, England, is built after the planer pattern.

* Associate Editor of MACHINERY.

The cutter head is mounted on a slide on the cross rail on which it travels as it is fed through the work. The work is clamped to the platen of the machine, which is indexed longitudinally for the spacing of the teeth. The indexing is done by hand, though it is not released until the slide has been returned to cut a new tooth, this being done automatically, so that there is no possibility of the indexing being done by mistake at the wrong time. The slow forward feed and quick return of the cutter slide are automatic.

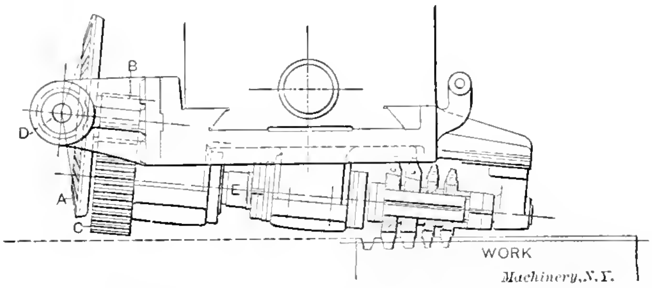

Fig. 71. Diagram showing Angular Position given the Spindle of the Reinecker Rack-cutter to obtain Large Driving Gear at C.

Another rack-cutter with the structural features of the planer is shown in Fig. 73. In the case of this machine it will be seen that its ancestors belonged to the "openside," instead of to the standard double-housing family of planers. The movements are about the same as in the previous case, though the machine has an entirely different appearance, and is built for much larger work. It will cut racks up to 1 diametral pitch, 10 inches width of face, 96 inches long, at one setting. For 1 diametral pitch racks, the machine will take one roughing and one finishing cutter. For finer pitches, cutters are used in gangs, as shown in the engraving, up to the full width of space on the cutter arbor. The table is provided with a quick return, operated by power. The machine is regularly made full automatic, but may be furnished in the half automatic style, if desired. It is built by the Walcott & Wood Machine Tool Co., Jackson, Mich.

The rack-cutter shown in Fig. 74 is built by Armstrong, Whitworth & Co., of Manchester, England. The arrangement of the movements is somewhat different from any of the others we have considered. The cutter spindle, as may be seen, is driven by a worm and worm-wheel. The feed is effected by the forward movement of the cutter slide on the ways provided for it on the rearward extension of the bed. The spindle itself is mounted on a bracket, which may be adjusted vertically to give the proper depth of cut. One interesting feature of this machine is the provision made for cutting very long racks by shifting the position of the work in the vise when the full range of indexing movement has been exhausted. The central vise indexes step by step, being under the control of the indexing mechanism. The short end vises are screwed to the bed and do not move, the clamp screws with which they are provided being loosened while the work is being indexed. These end vises are used, in shifting the work, to hold it, while the central vise is loosened and returned to the starting point for a fresh grip. The particular machine shown is a somewhat specialized form, built for cutting racks used in wire fence knitting machinery.

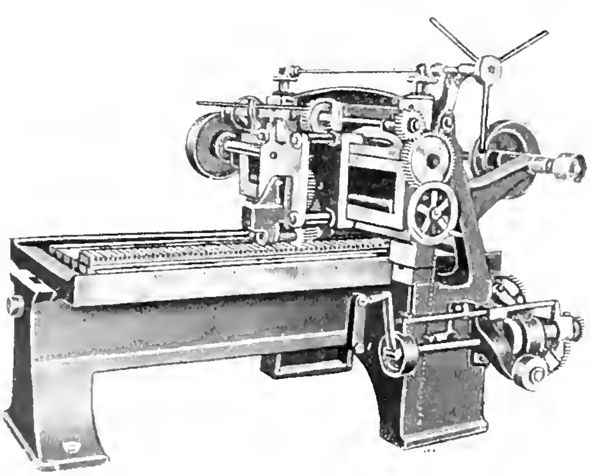

Fig 72. Planer Type Automatic Rack-cutter, built by G. Wilkinson & Son.

The Molding-Generating Method applied to Rack-cutting.

Besides the formed tool method, the only other one commercially applied to rack-cutting is the molding-generating method. The only example of this is in the Fellows system of gear shaping, which is applicable to the cutting of racks as well as to making spur and internal gears. The Fellows gear shaper as arranged for rack-cutting is shown in Fig. 75. This is a smaller size machine than the one shown in Fig. 63, cutting internal gearing, and the arrangement of its parts is somewhat different. In principle, however, it is identical, the same cutter being used and the cutter and work being connected together in the same way. The face-plate or other

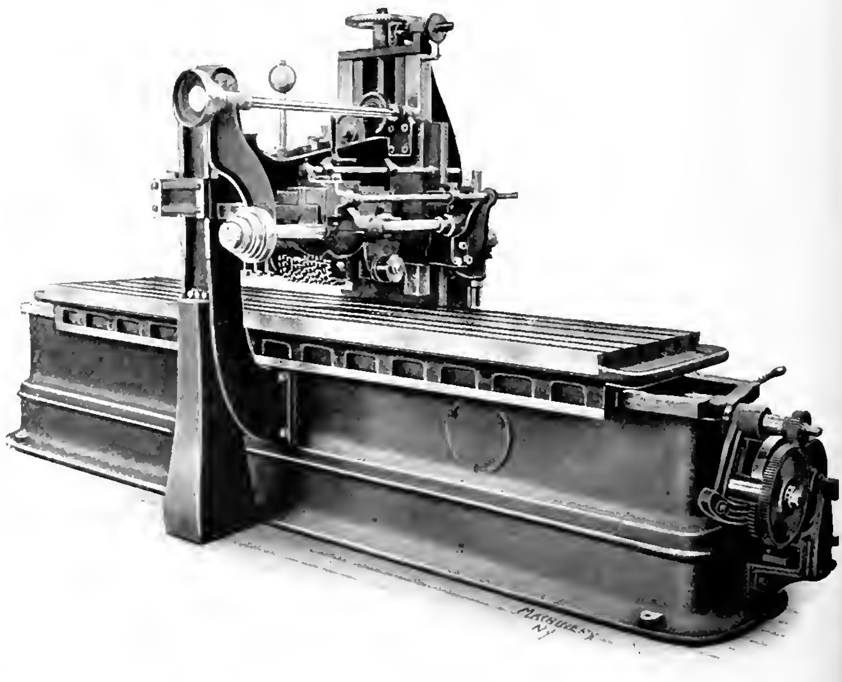

Fig. 73. Heavy Automatic Rack-cutting Machine of the Open-side Planer Type, built by Walcott & Wood.

work-holding device for spur gearing is removed from the spindle, and in its stead is placed a pinion, firmly fixed in the tapered hole of the spindle. A rack-cutting attachment is clamped to the machine, consisting of a guide provided with horizontal ways on which travels a work-holding carriage, having a rack in position to engage the teeth of the pinion clamped in the spindle. The vertical face of this slide forms a lengthened vise in which the work is held.

The method of operation is easily understood. If the spindle (and the pinion connected to it, which moves the work longitudinally) is geared in the proper ratio with the cutter, the machine may be started up with the cutter at the starting point, when the cutter will roll on the work, exactly as if it were a pinion, and the work were a rack with which it engaged. Under these circumstances the shaping action of the cutter will form rack teeth in the work, of suitable shape to mesh with all the gears in the series to which the cutter belongs. The operation is the same as shown in Fig. 8, except that it is reversed. Instead of having the rack the cutting tool and the gear the work, the gear is the cutting tool engaged in forming teeth in the rack. In addition to using an attachment to the regular machine, as in this case, the Fellows Gear Shaper Co., Springfield, Vt., have made special rack-cutters involving this principle, in which the work table slides on a long bed, as in Figs. 69 and 70.*

* Described in article entitled "Fellows Rack Shaper," in the December, 1901, issue of MACHINERY.

This completes the consideration of machines for cutting spur gears, internal gears and racks.

MACHINES FOR FORMING THE TEETH OF WORMS, AND OF SPIRAL AND HERRING-BONE GEARS.

Spiral gearing, twisted and herring-bone gearing, and worm gearing, are all radically different in their action. The first two forms, however, and the worm member of the third, are identical so far as the principles governing the forming of their teeth are concerned; so we will consider them together in this section of this series of articles. It might be mentioned in connection with the name "spiral" gearing, that gears of this kind are not spiral at all, but helical. A spiral is a figure contained in a plane. It has the same shape as the ordinary watch or clock spring, starting from a central point, about which it circles in widening curves. A helix has the shape of a string wound around a cylinder. The name "helical" has come into common use in describing springs of helical shape, and it ought to be used for gears as well. The writer would suggest that the reader practice using the term "helical gear." Criticism might also be directed toward the term "spiral staircase," but since carpentry is out of our field, we will not spend any time here in inaugurating that reform.

Almost as great a variety of methods of cutting teeth are possible for helical as for spur gears. Commercially, however, the two important principles are the formed tool and the molding-generating methods. The templet, odontographic and describing-generating methods of cutting gear teeth (in each of which the outline is worked out by the *point* of a tool, suitably constrained) are most useful for cutting gears of large size, in which tools acting on the formed tool or molding-generating principle would be subject to too heavy cuts. Since helical gearing is generally confined to small and medium sized work, these processes are unnecessary, being by nature rather slow in action, and dependent for their accuracy on the preservation of the shape of easily injured points of comparatively small cutting tools. As in the case of spur gears, the molding-generating method is of comparatively recent introduction, and is confined almost wholly to the production of teeth of involute form.

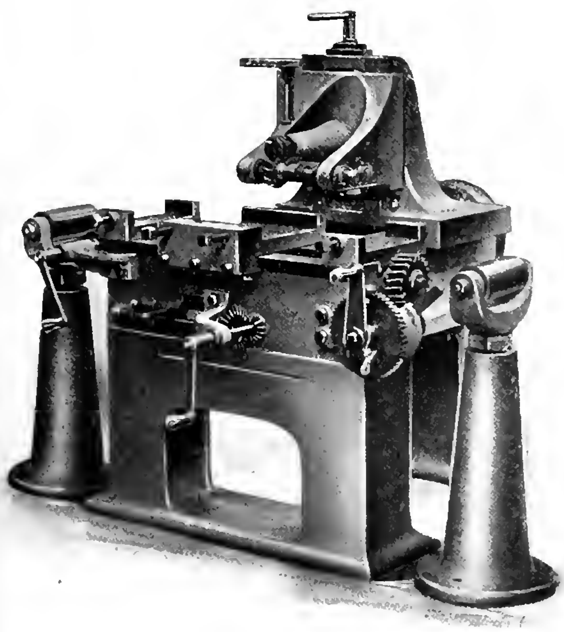

Fig. 74. Armstrong-Whitworth Automatic Rack-cutter.

Machines using Formed Tools in a Shaping or Planing Operation.

With the twisted teeth which we have in gears of the class we are discussing, it is evidently necessary, in employing shaping or planing operations, to give a rotary movement to the blank being operated on, at the same time as, and in the proper ratio with, the cutting stroke of the tool. This is necessary to compel the tool to follow the helix on which the teeth of the gear or the worm are to be formed. In Figs. 76 and 77 are shown two attachments for the shaper, working on different principles, giving the work the proper motion for cutting helical teeth. Both of these attachments were built by Gould & Eberhardt, of Newark, N. J.

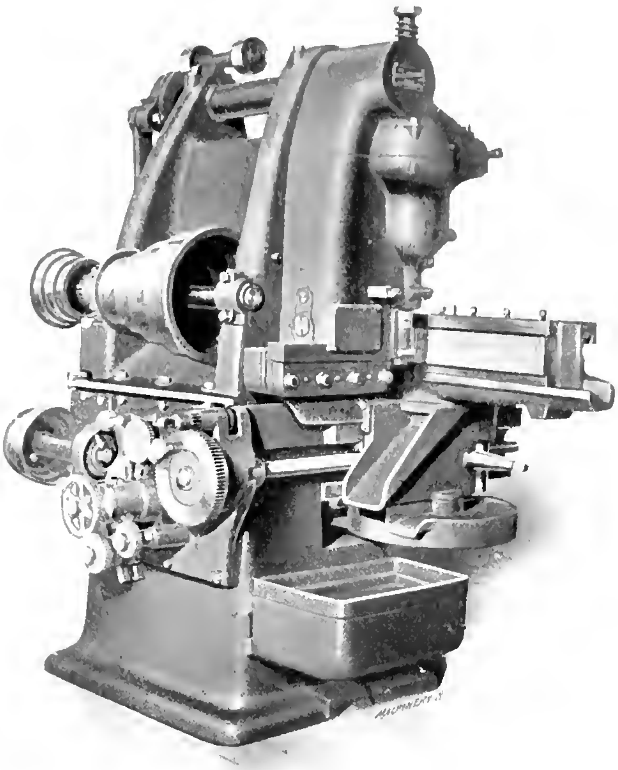

Fig. 75. The Fellows Gear Shaper, with Rack-cutting Attachment.

In the first of these, Fig. 76, the work is mounted between centers on a supplementary bed, fastened to the work table of the shaper. The face-plate by which the work is driven from the head-stock spindle is connected to that spindle by an indexing mechanism, consisting of a notched plate, with a locking bolt for holding the work in the different positions for the different numbers of teeth required. The head-stock spindle is connected, by spiral gearing and a set of change gears, with a pinion operated by a rack, which rack is fastened to the shaper ram. It will be seen that this connection with the shaper ram will give a rocking movement to the head-stock

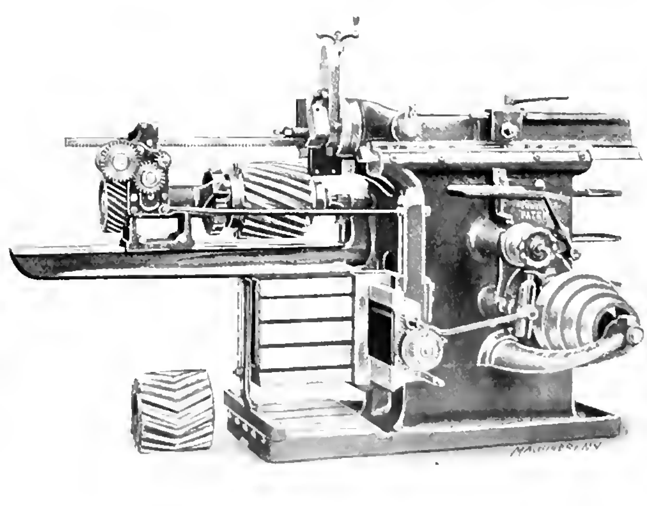

Fig. 76. Helical Planing Attachment for Gould & Eberhardt Shaper, in which the Lead of the Helix is obtained by Change Gears.

spindle and the work, in unison with the stroke of the tool. By selecting suitable change gears, this rocking movement may be made of any desired amplitude for a given length of stroke, so that any lead of helix or spiral desired may be obtained. Provision is made, in the means by which the rack is attached to the ram, for raising or lowering the work

table to the position required for different diameters of work. The tool is, of course, fed downward by hand, and the indexing is done manually also. On the floor at the base of the machine will be seen a pair of right- and left-handed helical gears, similar to the one being operated on; the two form a herring-bone gear.

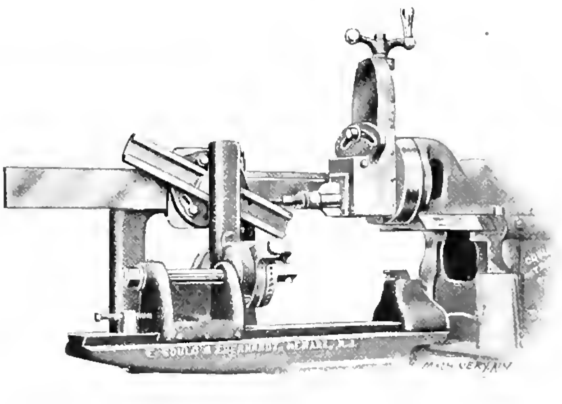

Fig. 77. Helical Attachment for Gould & Eberhardt Shaper, in which the Lead of the Helix is obtained by the Adjustment of a Swiveling Guide Bar.

The second attachment, shown in Fig. 77, employs a radically different principle for varying the amplitude of the rocking movement of the head-stock spindle for a given stroke of the ram, to obtain different leads of helix. The reader, of course, understands that the lead of the helix is the length of the cylinder required to allow a complete revolution of the helix. In this case, a spur gear keyed to the head-stock spindle meshes with a vertical rack, sliding in a guide which is cast integrally with the head-stock. This vertical rack is pivoted to a block which slides in a guide attached to a swiveling head, so that the guide may be adjusted to any angle. This swiveling head, in turn, is attached to a bar, which is fastened to the ram, and is guided on ways supported by a framework at the back of the head-stock. It will thus be seen that the forward and backward movement of the ram will impart an up and down movement to the rack, which will, in turn, give a rocking movement to the spindle of the head-stock, and the work which it drives. The amplitude of this rocking can be increased or diminished by setting the swiveling guide at a greater or less angle, so that the helices of various leads can be obtained. This makes the use of change gears unnecessary. The indexing device is similar in principle in the two arrangements.

It will seem strange at first thought, perhaps, to describe the cutting of worms in a lathe as an example of the use of formed tools in shaping or planing operations, but the operation is essentially the same as that shown in Fig. 76. Compare this with Fig. 78, imagining that the lead-screw shown

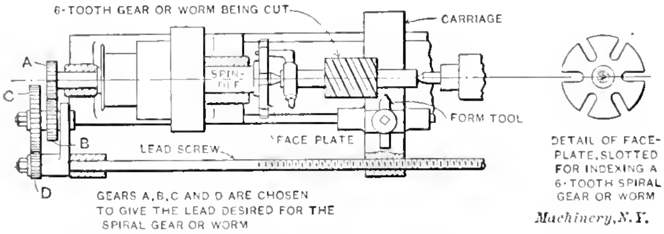

Fig. 78. The Lathe Method of Planing Helical Teeth in Gears or Worms.

in the latter is of such steep pitch that it can be rotated by pushing the carriage backward and forward. Under these circumstances, if provision is made for reciprocating the carriage (corresponding to the ram for the shaper), the lead-screw will be rotated in unison with it, and this movement will be transmitted through change gears A, B, C, and D to the head-stock spindle, giving a rocking movement to the work. The only difference in the two cases is that in the lathe a screw of very steep pitch would be used to change the reciprocating motion of the tool to the rocking motion required by the work, while in the case of the shaper the more natural rack and pinion movement is employed. In the case of the lathe, of course, the power is not applied to the carriage but to the spindle. For that reason it is best adapted for cutting spiral gears of comparatively small lead, or "worms" as we ordinarily call them. If it were attempted to cut 45-degree spirals, for instance, the lead-screw would have to be speeded up so fast, as compared with the movement of the spindle, that the driving belt would be unable to operate the machine. Special lathes have been built for cutting steep worm threads, in which the power has been applied to the lead-screw, the spindle being driven from it through the change gears. A lathe so arranged would have as much difficulty in cutting fine pitches as the ordinary lathe does in cutting coarse ones.

Different methods of indexing may be used for the lathe. It will be noticed that in Fig. 78 the face-plate used has the same number of slots as the required number of teeth. After one tooth space has been cut, the work can be removed, and replaced again between the centers with the tail of the dog in another slot. After this space has been completed, the next one is cut, and so on until the whole six are finished. Other methods are in use, such as slipping of change gears A and B past each other a certain number of teeth, as determined by calculation.

Special lathes are built for threading, some of which are automatic in their action. One of these is shown in Fig. 79. It is built by the Automatic Machine Co., Bridgeport, Conn.* The size shown is especially adapted to cutting worms. It is provided with mechanism for duplicating the action of a

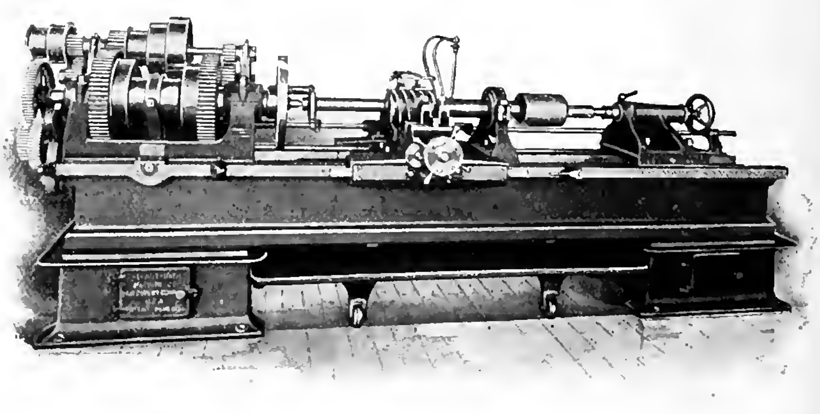

Fig. 79. Automatic Threading Lathe for Worms, made by The Automatic Machine Co.

manually operated lathe engaged in threading. After a piece of work has been placed between the centers and the machine has been started, the work revolves, and the carriage feeds forward until the proper length thread has been cut; then the tool is withdrawn, and the carriage returns to begin again on a new cut—and so on without attention from the operator. The tool is fed in a certain suitable amount, at the beginning of each cut, the amount of this feed being automatically diminished to give a fine finish for the final cuts. When the depth for which the tool has been set is reached, the operation of the mechanism is automatically arrested. In cutting multiple threaded worms in this machine, multiple tools may be used, thus avoiding the necessity for indexing the work. As many as eight cutting tools have been used at once on this machine, giving a total length of cutting edge of 8 inches.

Machines Using Formed Milling Cutters.

We have spoken hitherto of the formed tool or cutter method of shaping the teeth of gears, as being one in which the tool accurately reproduces its shape in the tooth space it forms. This is true in cutting straight tooth spur gears, and in planing the teeth of spiral gears by the process just described. It is not exactly true, however, of any possible process of milling spiral teeth. This is best seen in Fig. 80. In the three cases here shown, we have first, a planer tool; second, a disk milling cutter; and third, an end milling cutter—all formed

* See "New Tools of the Month" section of MACHINERY, February, 1908.

to the same identical outline, and cutting helical grooves of the same lead and depth in blanks of the same diameter. The section in each case is a plane one, taken normal to the helix at the pitch line. (Of course the true section to take would be that of the helicoid normal to the helicoid of the groove being cut. The plane in which we have taken the section, however, so nearly approximates this helicoid that the error is negligible.)

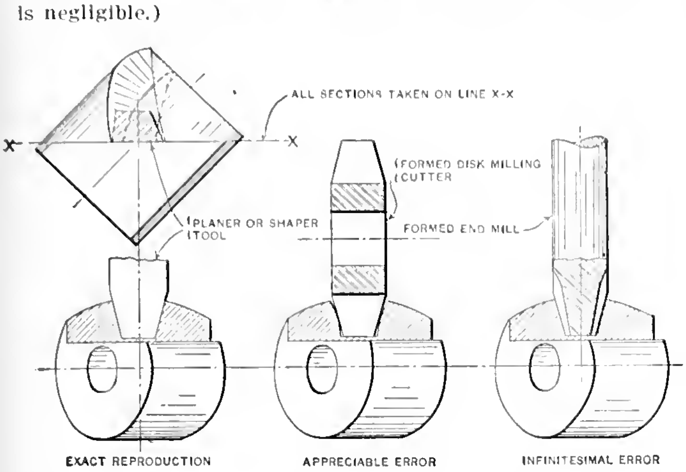

Fig. 80. Comparison of the Accuracy of Form Reproduction Obtainable by Formed Planing Tool, Formed Disk Cutter, and Formed End Mill

The planer tool necessarily cuts a groove of the same shape as its outline, the plane of its outline being the same as the plane of the section shown. The disk milling cutter, however, interferes with the sides of the groove it cuts. This interference takes place on one side as the teeth are entering, and on the other as the teeth are leaving. This results in a generating action, which takes place in addition to the simple forming action, so that the tooth cut is not an exact duplicate of the outline of the cutter. In the case of the formed end mill there is also an interference of the same kind as with the formed disk cutter, but it is so slight as to be absolutely undetectable, in all ordinary cases. We only know of its presence from theoretical considerations.

In spite of its imperfect reproduction of the desired form, the disk cutter is the type generally used for milling, since it may be so relieved as to retain its shape even after repeated

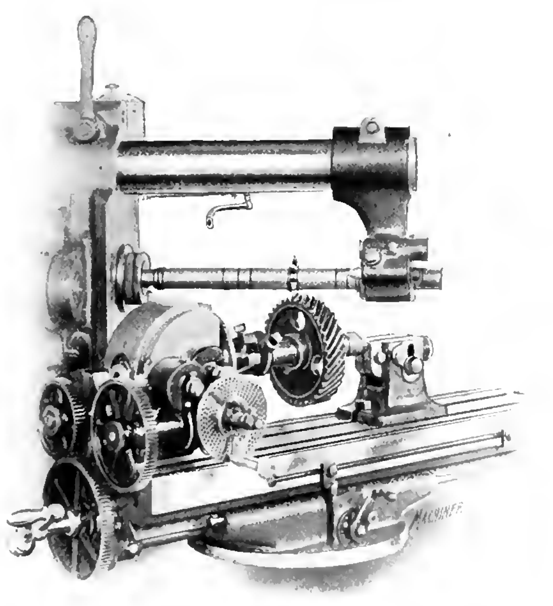

Fig. 81. Brown & Sharpe Milling Machine arranged in the Usual Manner for Cutting Spiral Gears

grinding. The end mill type of formed cutter cannot remove so much stock in a given time, and it is difficult to make it so that it can be ground without changing its form. The only way in which this grinding can be practically performed, is by the use of some form of templet grinding machine,* such as has recently been described in these columns. The formed end mill is used to a limited extent, nevertheless.

The simplest way of using the milling process for cutting helical gears or worms, makes use of the universal milling machine. With this machine, the work, and the feed-screw of the table on which it is mounted, are so connected by means of gearing that the forward feeding gives a rotary movement to the work, producing a helix of the required lead. The mechanism is identical in principle with that shown in Fig. 78 for the lathe, and in Fig. 76 for the shaper, the only difference being that in the milling process the longitudinal movement is a steady feeding motion, made once for each tooth space, instead of being a continuously reciprocating motion, as in the previous cases. The simple indexing devices shown in Figs. 76 and 78 are replaced by the more elaborate index plate and worm-wheel device of the spiral head.

This mechanism, as exemplified in the Brown & Sharpe universal milling machine with its spiral head, etc., is illustrated in Fig. 81. The work has to be swung at an angle with the cutter to agree with the helix angle at the pitch line, as indicated. This is done by swiveling the table of the universal

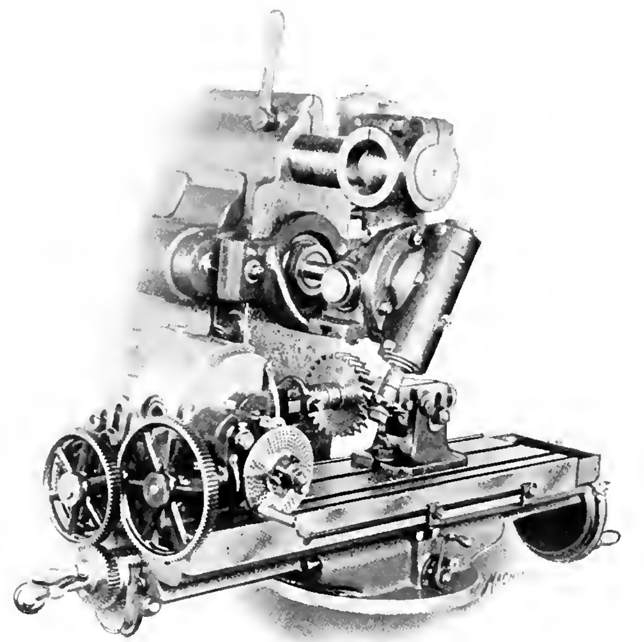

Fig. 82. Cutting Spiral Gears of Helix Angle too Great to Allow the Method of Fig. 81; employing the Brown & Sharpe Vertical Milling Attachment.

milling machine to bring the work to the proper angle with the cutter. In most makes of machines, it is inconvenient, if not impossible, to swivel the table to a greater angle than 45 degrees. For greater angles, special attachments are provided for swiveling the cutter, leaving the table in its normal position at right angles to the spindle of the machine. Two examples of this are shown in Figs. 82 and 83. The first case, Fig. 82, shows a Brown & Sharpe milling machine engaged in cutting a spiral gear, using for the purpose a vertical milling attachment, which has been set to the required helix angle. The change gearing used for connecting the spiral head with the feed-screw of the table can be plainly seen at the left. In Fig. 83 an attachment of another form is shown, built by the Cincinnati Milling Machine Co., Cincinnati, Ohio. In this case the cutter is adjustable about a vertical axis, being driven from the spindle by bevel and spiral gears. It may be set at any angle throughout the whole circle, and cuts on top of the blank, the table being set in the normal position, the same as in Fig. 82. The vertical attachment shifted to a horizontal position, or a rack-cutting attachment, may also be used in milling helical gears to bring the cutter spindle at right angles to the main spindle of the machine. By this means it is possible to mill gears having a greater helix angle than 45 degrees, without shifting the table more than 45 degrees, since the table is set at the complement of the helix angle, thus making it possible to cut even fine pitch worms.

These various attachments allow the milling machine to work throughout a wide range of angles for helical gears and

* See article "Notes on the Manufacture and Upkeep of Milling Cutters" in the engineering edition of the March, 1908, issue of MACHINERY.

worms, the only limitation being one similar to that imposed on worm cutting in the lathe, though the limitation is reversed. For worms or gears of too small lead as compared with their diameter, the rotary movement of the blank is so great that

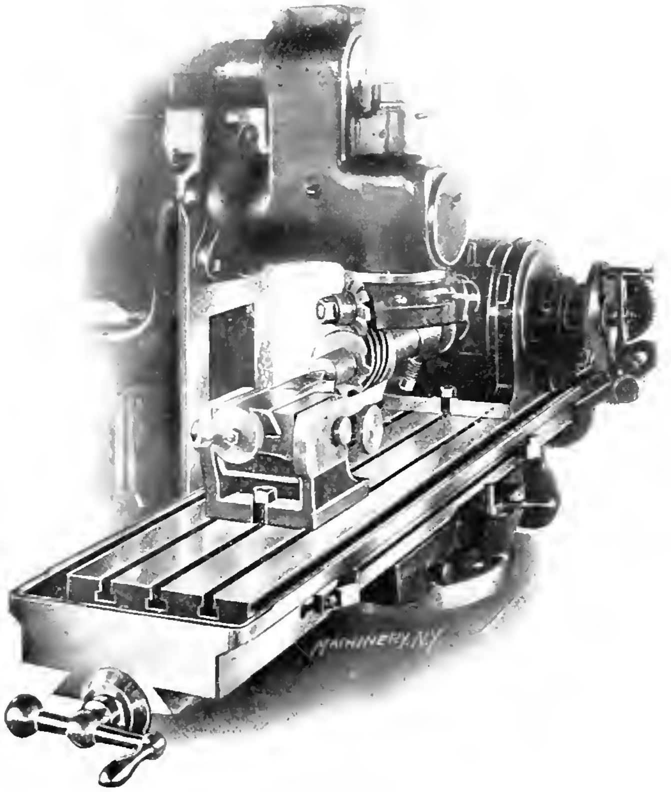

Fig. 83. Universal Milling Attachment of the Cincinnati Milling Machine Co in use Cutting Gears of Large Helix Angle.

the comparatively slow-moving feed-screw is unable to speed up the spiral head mechanism to get the required movement, and still furnish power enough for feeding the work against the cutter.

Specialized Forms of Milling Machines for Cutting Spirals by the Formed Cutter Method.

The principle of the universal milling machine for cutting spiral gears and worms has been applied to the design of various special machines for the same purpose. A number of these are shown in Figs. 84 to 88. The specialization of the machine includes making the spiral and indexing mechanisms integral parts of the tool, so that they have a much greater capacity for taking heavy cuts than is the case where they are merely attachments, as in the cases previously shown.

In the first case we show, the spiral cutting mechanism is still something in the nature of an attachment, the machine being designed for cutting other kinds of gears as well. This tool (see Fig. 84) is the universal gear-cutting machine made by Nya Aktiebolaget Atlas, Stockholm, Sweden, already illustrated in Figs. 34 and 61. The cutter spindle is mounted in a swiveling head, which may be set at the required angle for the helix to be cut, the angular adjustment thus being identical with that in Fig. 83. The cross rail with the cutter is fed down through the work, which is rotated by its gearing connections so as to produce the helix required. In this machine, the indexing is done by power, being regulated by change gears as in the orthodox automatic spur gear cutter. There must, then, be some sort of a differential gear mechanism combining the indexing movement and the rotation of the work for the helix, both of which must be allowed to operate on the work without interfering with each other. We are not informed as to the exact nature of this mechanism, though it is doubtless similar in principle to that described for the following machine.

It was stated that the spur gear cutting machine shown in Fig. 51 is a modification of a universal gear cutting machine made by J. E. Reinecker, of Chemnitz-Gablenz, Germany. In Fig. 85 is shown a side elevation, and in Fig. 86 a diagram of the index worm connections, of the universal machine referred to, as arranged for cutting helical gears by the formed milling process. The machine is arranged, like the Becker-Brainard machine (see Fig. 20), on the general lines of the milling machine, excepting that the work spindle is at the top of the column, and the cutter spindle on the knee.

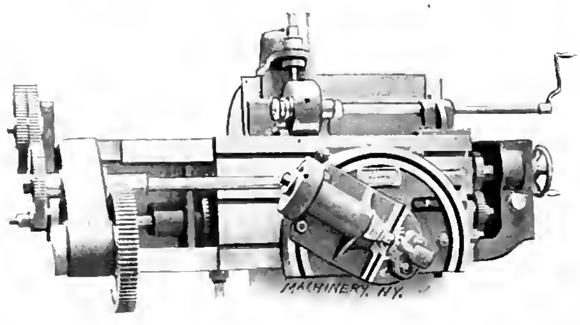

Fig 84. Helical Gear-cutting Attachment used with the Atlas Gear-cutting Machine shown in Fig. 34.

The cutter, at *B*, is driven by an internal gear *A* of large diameter (see also Fig. 51) and is mounted on a swivel table *C*, which can be set to the required helix angle. The form of cutter slide shown will give any angle up to 30 degrees. For greater angles, this is replaced with a slide which can be rotated to any angle throughout the whole circle.

The screw which feeds cutter slide *C* along the knee is driven from cone pulley *D*, through vertical shaft *E* and its gear connections. Cone pulley *D* is also connected with change gearing *F*, which is, in turn, connected with the index worm, so as to rotate index wheel *G*, and the work properly for any desired helix. The principle of this is the same as in the universal milling machine, change gears *F* acting the same as the change gears used to connect the spiral head with the table feed-screw in Fig. 81. Now the worm-wheel *G* is used for indexing, as well as for rotating the work for the helix,

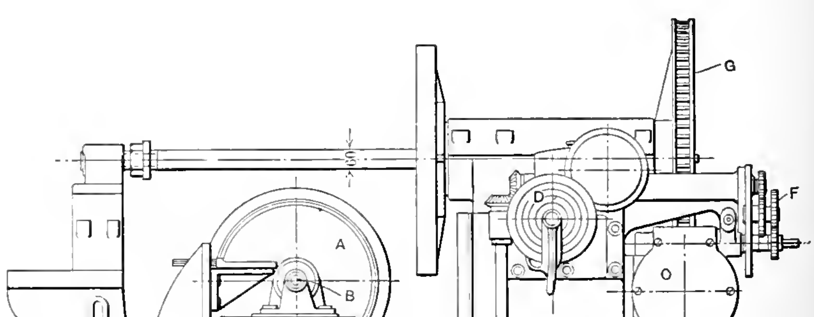

Fig. 85. Side View of the Reinecker Universal Gear-cutting Machine, showing the Geared Connections between the Index Worm-wheel and the Feed of the Cutter Slide.

in unison with the feeding of cutter slide *C*. The way in which these two motions are imparted to *G* without interfering with each other, may be understood by reference to Fig. 86; similar parts have similar reference letters in this engraving and the preceding one.

At *H*, on the opposite side of the machine from that shown in Fig. 85, are mounted the change gears by which the index-

ing is accomplished. These gears drive bevel gear J. Index worm K, meshing with index worm-wheel G, is mounted on a hollow sleeve, keyed fast to the bevel gear L. Shaft M carries a hub with projecting pivots on its right-hand end, on which are mounted bevel pinions N. Shaft M is driven by worm-wheel O, connected with the feed of the slide cutter through change gears F. Gears J, L and N form a differential mechanism of the well known "jack-in-the-box" type. The

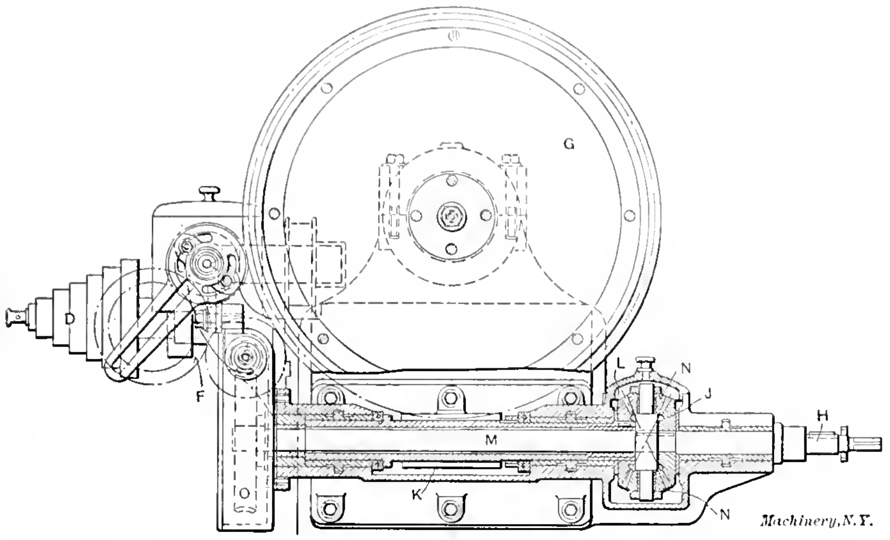

Fig. 86. Detail of the Machine in Fig. 85, showing the Differential Mechanism by which the Motions for Helical Cutting and for Indexing are combined to Rotate the Work.

action of this mechanism is such that if shaft M be at rest, change gears at H may be operated for the indexing, transmitting the motion from gear J to L through pinions N as idlers, thus revolving index worm K. On the other hand, with the indexing mechanism still and the cutter slide feeding, the movement thus imparted to shaft M may be transmitted (by the rolling of pinions N on stationary bevel gear J, and the consequent rotation of bevel gear L), to worm K, and thence to worm-wheel G and the work. It will thus be seen that the indexing, and the rotation for the helical cutting, can take place independently of each other. But more than this, the two motions can be operated together without interference. In fact, either of the motions imparted to shaft M or gears at H, may be stopped or reversed independently, and each will have its proper influence on the index wheel and the work.

With this understanding of the differential mechanism, the operation of the machine is easily comprehended. Change gears H are connected through a one-revolution friction trip with the main driving shaft. The cutter, set at the proper angle, is fed forward through the work, which is rotated by change gears F, shaft M, and worm K, at the proper rate to cut the proper helix. The cutter is then dropped down to clear the work (provision for this being made in the machine), and returned, ready to begin on a new tooth. The indexing mechanism is then tripped by hand, and the work is rotated into position for the new tooth, by change gears at H, gear J, and worm-wheel K. This is repeated until the gear is done.

A gear-hobbing machine made by Maschinenfabrik Lorenz of Ettlingen, Baden, Germany (to be described in the next installment of this series), cuts spiral gears in a fashion similar to the Reinecker machine just described. Owing to the fact that it is primarily designed for hobbing, however, it will be described with other machines of that type.

In the machines hitherto shown, power is applied to the feed-screw, from which the work is rotated through change gearing. This arrangement is best for helices of great lead. When it comes to milling helical gears with small leads, or worms, it is necessary to use the lathe principle and apply the power to rotating the work, the longitudinal feed being driven from the work spindle through change gearing. We show two examples of machines of this kind in Figs. 87 and 88.

The well-known thread milling machine made by Pratt & Whitney, Hartford, Conn., is illustrated in Fig. 87. Probably few mechanics have ever thought of this as being a gear-cutting machine, but it is here shown engaged in the perfectly legitimate work of cutting a worm, so that it should be classified with gear-cutting machinery of the kind described in this section of the article. The machine is so well known as to scarcely need description. The cutter spindle is mounted in a head which can be swiveled to any angle, and the slide which carries it is fed lengthwise along the bed, the proper lead being obtained by connecting the head-stock spindle and feed-screw by change gearing.

A second machine of this kind is shown in Fig. 88. It is built by J. E. Reinecker, of Chemnitz-Gablenz, Germany, and is intended especially for milling worms, although it is well adapted for small spiral gears also. The cutter, driven by worm gearing, is mounted in a heavy swiveling head, which is fed along the bed on ways at the rear of the machine. The adjustment for diameter is made by moving the work table, with its head- and foot-stocks, away from or toward the cutter. Cone pulleys and gearing are provided for varying the rate of feed of the cutter head, while the connection between the feed movement of the cutter and the rotation of the work is governed by change gears. On the worm-wheel which drives the

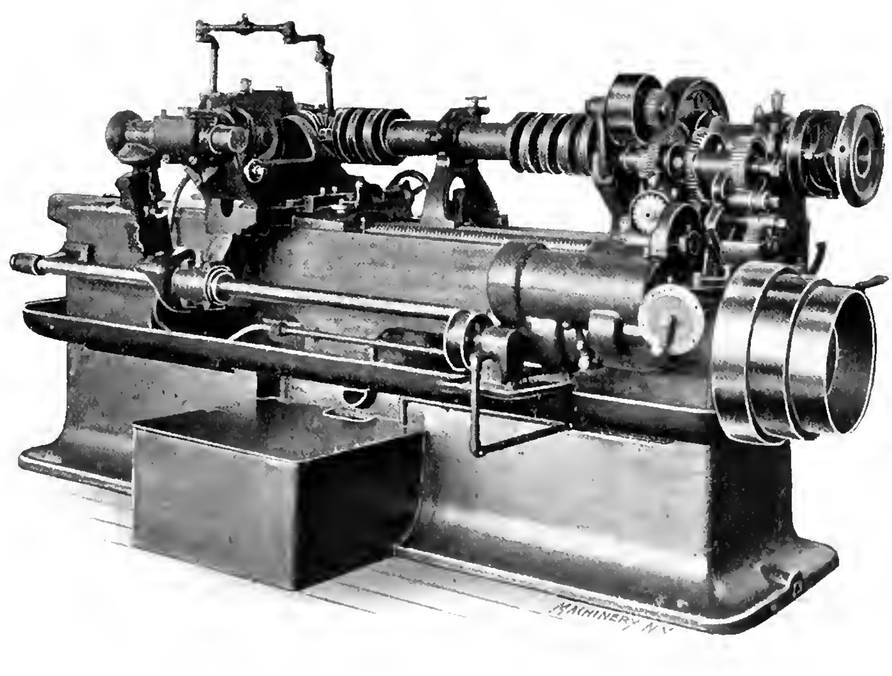

Fig. 87. The Pratt & Whitney Thread Milling Machine, engaged in Cutting a Worm

work spindle will be seen mounted a change gear mechanism which is used for indexing. The indexing is by hand, and the whole mechanism is carried around by the spiral movement, so that a differential mechanism is unnecessary.

Specialized Form Milling Machines for Herring-bone Gears.

A machine for helical gear cutting, but provided with some special features, is shown in Fig. 89. This machine is used by C. E. Wüst & Co., Seebach, Zurich, Switzerland, for cutting

herring-bone gears of a special form, in which it is unnecessary to cut the two halves separately, in separate sections, as is the usual case. As may be seen in Fig. 90, the cuts are staggered so that the teeth on one side run into the spaces on the other, in such a way as to permit cutting them with rotary cutters without having one side interfere with the other. The machine for doing this is built on a very simple plan, as may be seen. It consists of a vertical spindle carrying the work, which is apparently indexed by power. The

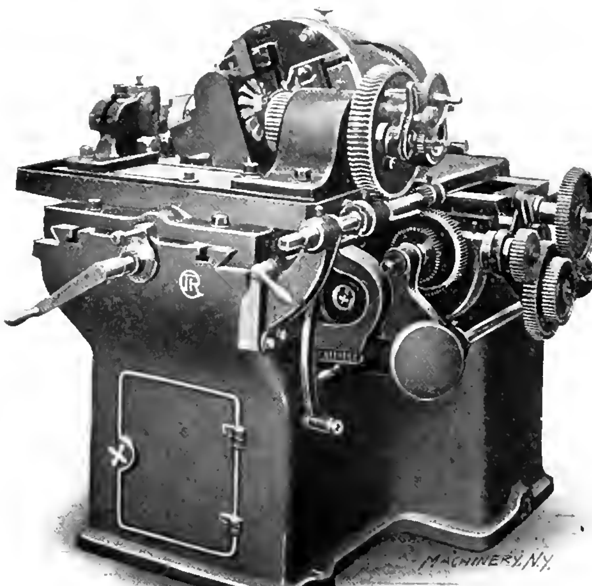

Fig. 88. The Reinecker Worm Milling Machine.

indexing wheel is connected by the usual change gearing with the two vertical slides on which the cutters are mounted on either side. These cutters work simultaneously, one feeding downward to cut the upper half, while the other is feeding upward to cut the lower half. It is not possible to say, from the information at hand, whether or not the machine is fully automatic. Probably it is not. The most interesting thing about the machine is its product; the large gear shown in the machine in Fig. 89, and the pinion shown in Fig. 90, are examples of two extremes in the range of work for which the process is applicable.

There is another specialized form of herring-bone gear which has been illustrated in MACHINERY,* that made by André Citroën & Co., 202 Rue de Faubourg St. Denis, Paris. The teeth of these gears, we are informed, are shaped by an

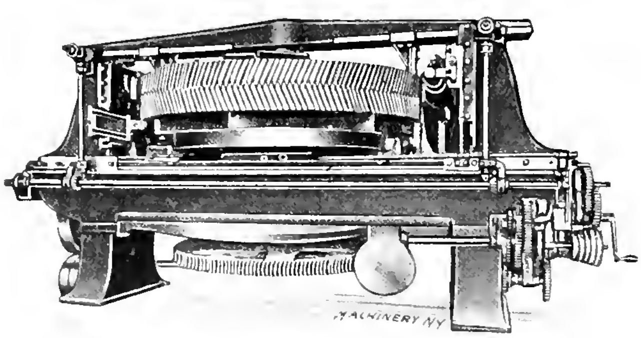

Fig. 89. Machine for Cutting Solid Herring-bone Gears by the Wust Process.

end cutter like that shown in Fig. 80, guided by suitable mechanism to produce the continuous "wavy" form of herring-bone teeth characteristic of these gears. This process also has the advantage of not requiring the blank to be made in two pieces. The same principle has been applied by the builders to the cutting of herring-bone bevel gears.

Other manufacturers make use of the formed end mill, to a limited extent, at least. The arrangement devised by Gould & Eberhardt for milling large helical gears in the lathe, recently illustrated in MACHINERY,* used this form of cutter, and the worms or spiral gears which drive the racks of the Sellers drive planers, made by at least one of our prominent planer builders, are cut by end mills in a specialized milling machine of simple design, made especially for this purpose.

* See article "Herring-bone Gearing with Cut Teeth," in the engineering edition of the April, 1903, issue of MACHINERY.

* See Figs. 3 and 4, in the article entitled "Emergency Methods in Gear Cutting," in the November, 1907, issue of MACHINERY.

PAINTING GALVANIZED IRON.

It is well known that ordinary paints will not adhere for any length of time to galvanized surfaces, unless the surface has been exposed to the weather for a long time—and not always then. Galvanized materials are usually dipped in a non-drying oil for the purpose of preventing atmospheric corrosion, and this neither combines with paint, nor permits a bond between the surface and the paint. Even when this oil has been removed, ordinary paints will not adhere to the zinc surface, and it is necessary to prepare the surface by changing it to an oxide of zinc. Exposure to the weather does this naturally, but slowly. The same thing may be accomplished in a short time by neutralizing the oil by an acid. The acid also forms a thin coating of zinc oxide, to which certain paints adhere very well. A very satisfactory wash for the purpose indicated consists of two ounces each of copper chloride, copper nitrate and sal-ammoniac, all dissolved in one gallon of soft water. After these are dissolved, add slowly two fluid ounces of crude hydrochloric (muriatic) acid, and stir carefully. Do not inhale the fumes. Of course, the solution must be made and kept in glass or earthenware jars or bottles, not only to avoid corrosion of the containing vessel, but to prevent precipitation of the copper salts.

Fig. 90. A 7-tooth Pinion, Formed by the Wust Process.

Cover the surfaace to be painted with this solution, using, preferably, a wide brush. The black appearance of the surface which immediately follows disappears within a few hours, and is replaced by the gray appearance characteristic of zinc oxide, the same as is seen after galvanized surfaces have been exposed to the weather for several months. Red lead, mixed with raw linseed oil and turpentine, half and half, will adhere very well to this surface. This may be followed by coats of any desired paint. A preliminary wash of vinegar, nine parts, and muriatic acid, one part, is recommended. It is to be followed by a priming coat of Prince's mineral brown, thinned with turpentine. Still another wash, consisting of nothing but vinegar or another dilute acetic acid, is recommended as giving satisfactory results in most cases. This, also, is to be followed by a priming coat of Prince's mineral brown, as above. O. M. B.

* * *

A gas engine of rather interesting design is described in a recent issue of the *Engineering Record*. In this design, the so-called "hit-and-miss" type of valve mechanism has been applied to the exhaust valve, the gear being spring-retained in its unlatched or inoperative position, so that unless specially actuated, the valve does not open to exhaust on the exhaust stroke. The spring, holding the latch or dog, is attached to a piston in a miniature cylinder, connected with one side of the main engine cylinder at such a point at the crank end that the engine piston uncovers the opening at the extreme outer stroke only, and admits the pressure of the exploded gases. The movement of the exhaust valve is so timed in relation to the admission of pressure to the miniature cylinder that the latch, which is forced out by the piston in the latter, is caught, and causes the exhaust valve to open for the regular exhaust of the cylinder; but, if the explosive mixture should not explode, due to omission of spark for speed regulation, then the miniature piston is not actuated, and the explosive charge is not exhausted and wasted, as with the usual gas engine construction.

JIGS AND FIXTURES.—1.*

EINAR MORIN.†

Einar Morin.‡

Jigs and fixtures may be defined as special devices made of cast iron, steel, or sometimes of wood, used in the manufacture of duplicate parts of machines, and intended to make possible interchangeable work at a reduced cost, as compared with the cost of producing each machine detail individually. The jigs and fixtures serve the purpose of holding and properly locating a piece of work, while being machined, and are provided with necessary appliances for guiding, supporting, setting, and gaging the tools in such a manner that all the work produced in the same jig or fixture will be alike in all respects, even with the employment of more or less unskilled labor. When using the expression "alike," it implies, of course, simply that the pieces will be near enough alike for the purposes for which the work being machined is intended. Thus, for certain classes of work, wider limits of variation will be permissible without affecting the proper use of the piece being machined, while in other cases, the limits of variation will be so small as to make the expression "perfectly alike" literally true.

Object of Jigs and Fixtures.

The main object of using jigs and fixtures is, of course, the reduction of the cost of machines or machine details being built or made in great number. This reduction of cost is obtained in consequence of the increased rapidity by which the machines may be built, and on account of the employment of cheaper labor, which is possible when using tools for interchangeable manufacturing. Another purpose, however, not less important, is the accuracy with which the work can be produced, making it possible to assemble the pieces produced in jigs without any great amount of work in the assembling department, thus also effecting a great saving in this respect.

The use of jigs and fixtures practically does away with the fitting, as this expression was understood in the old-time shop; it eliminates cut-and-try methods, and does away with the so-called patch work in the production of machinery. It makes it possible to have all the machines turned out in the shop according to the drawings, a thing which is rather difficult to accomplish if each individual machine in a large lot is built without reference to the other machines in the same lot.

The interchangeability obtained by the use of jigs and fixtures, makes it also an easy matter to quickly replace broken or worn-out parts without great additional cost and trouble. When machines are built on the individual plan, it is necessary to send somebody from the shop where the machine was built to the place where it is installed, in order to fit the part replacing the broken or worn-out piece, in place, and this would, in a great many cases, involve considerable extra expense, not to mention the delay and the difficulties occasioned thereby.

As previously mentioned, jigs and fixtures permit the employment of practically unskilled labor. There are a great many operations in the building of a machine, which, if each machine were built individually, without the use of special tools, would require the work of expert machinists and toolmakers. Special tools, in the form of jigs and fixtures, permit equally good, or, in some cases, even better results to be obtained by a much cheaper class of labor, provided the jigs and fixtures are properly designed and correctly made. Another possibility for saving, particularly in the case of drill and boring jigs, provided with guide bushings in the same plane, is met with in the fact that such jigs are particularly adapted to be used in multiple-spindle drills, thereby still more increasing the rapidity with which the work may be produced, and at the same time making the machine extremely productive, so as to reduce the shop cost of this machine to a minimum. In shops where a great amount of duplicate parts are made, containing a number of drilled holes, multiple spindle drills, of complicated design, which may be rather expensive as regards first cost, are really cheaper, by far, than ordinary simple drill presses.

Another point of advantage which has been gained by the use of jigs and fixtures, and which should not be lost sight of in the enumeration of the points in favor of building machinery by the use of special tools, is that the details of a machine that has been provided with a complete equipment of accurate and durable jigs and fixtures, can all be finished simultaneously in different departments of a large factory, without inconvenience, thus making it possible to assemble the machine at once after receiving the parts from the different departments; and there is no need of waiting for the completion of one part into which another is required to fit, before making this latter part. This gain in time means a great deal to a manufacturing concern in cases where the orders are coming in with great rapidity, so as to require the utmost speed in production. This rapidity was entirely impossible under the old-time system of machinery building, when each part had to be made in the order in which it went on the finished machine and each consecutive part had to be lined up with each one of the previously made and assembled details. Brackets, bearings, etc., had to be drilled in place, often with ratchet drills, which of course, was a slow and always inconvenient operation.

Difference between Jigs and Fixtures.

To exactly define the word "jig," as considered apart from the word "fixture," is rather difficult, as the difference between a jig and a fixture is oftentimes not very easy to decide. The word jig is frequently, although incorrectly, applied to any kind of a work-holding appliance used in the building of machinery, the same as, in some shops, the word fixture is applied to all kinds of special tools. As a general rule, however, we can say that a jig is a special tool, which, while it holds the work, or is held on the work, at the same time also contains guides for the respective tools to be used, while a fixture is only holding the work, while the cutting tools are performing the operation on the piece, without containing any special arrangements for guiding these tools. The fixture, therefore, must, itself, be securely held or fixed to the machine on which the operation is performed, hence the name. A fixture, however, may sometimes be provided with a number of gages and stops, although it does not contain any special devices for the guiding of the tools.

The definitions given, in a general way, would therefore define jigs as special tools used particularly in drilling and boring operations, while fixtures, in particular, would be those special tools used on milling machines, and in some cases, on planers, shapers, and slotting machines. Special tools used on the lathe may be either of the nature of jigs or fixtures, and sometimes the special tool is actually a combination of both, in which case the expression drilling fixture, boring fixture, etc., is in place.

Fundamental Principles of Jig Design.

Before entering upon a discussion of the minor details of the design of jigs and fixtures, we will briefly outline the fundamental principles of jig and fixture design. Whenever a special tool is made up for a component part of the machine, it is almost always required that a corresponding jig

* The following articles on the subject of jigs and fixtures have previously been published in MACHINERY: Milling Fixtures, November and December, 1905, January and February, 1906; Drill Jigs, November and December, 1906, January, 1907.

† Address: No. 833 W. Sixth St., Plainfield, N. J.

‡ Einar Nathanaël Morin was born in Norrbarkes County, Dalarne, Sweden, 1883. After having finished his high-school education he went to the Technical College of Boras, Sweden, where he graduated from the department of mechanical engineering in 1902. He served an apprenticeship in the mechanical department of the Domnarfvets Iron & Steel Works, Sweden, and in the spring of 1903, came to the United States where he obtained employment with the Pratt & Whitney Co., Hartford, Conn., afterwards being assigned to the Pond Machine Tool Co., Plainfield, N. J., branch of the Niles-Bement-Pond Co., which controls both concerns. He has worked as a machinist, toolmaker, tool and jig designer, and at present is head tool and jig designer of the Pond Machine Tool Co.

is made up for the place on the machine, or other part, where the first-mentioned detail is placed. It is, of course, absolutely necessary that these two jigs be perfectly alike, as to the location of guides and gage points. In order to get the holes and guides in the two jigs in perfect alignment, it is advisable, and almost always attended with less cost, and with a gain in time, to transfer the holes or the gage points from the first jig made, to the other. In many instances, it is possible to use the same jig for both parts. Instances where the one or the other of these principles is applicable will be shown later in the detailed descriptions of drill and boring jigs. There are also cases where it is not advisable to make up two jigs, one for each of the two parts, which are to fit together. It may be that it is impossible to properly locate the jig on one of the parts to be drilled, or it may be that if the jig were made, it would be so complicated that it would not be economical. Under such conditions the component part, itself, may be used as a jig, and the respective holes or slots in this part used as guides for the tools when machining the machine detail into which it fits. Guide bushings for the drills and boring bars may then be placed in the holes in the component part itself. In many cases, drilling and boring operations are also being done, to great advantage, by using the brackets and bearings already assembled and fastened onto the machine body as guides.

One of the most important questions to be decided before making a jig is to what extent it is permissible to expend money on a special tool for the operation required. In many cases, it is possible to get a highly efficient tool by making it more complicated and more expensive, whereas a less efficient tool may be produced at very small expense. To decide which of these two types of jigs and fixtures should be designed in each individual case depends entirely on the circumstances. In any well managed shop there should be a careful comparison of the present cost of carrying out a certain operation, the expected cost of carrying out the same operation with an efficient tool, and the cost of building that tool itself. Unless this is done, it is likely that the shop is burdened with a great amount of special tools and fixtures which, while they may be very useful for the production of the parts for which they are intended, actually involve a loss. It is readily seen how foolish it is to make up an expensive jig and fixture for a machine or a part of a machine, that would only have to be duplicated a few times. In some cases, of course, there may be a gain in using special devices in order to get extremely good and accurate results.

Regarding the design of the jig, the most important requirements are that good facilities are provided for locating the work, and that the piece to be machined may be easily inserted and quickly taken out of the jig, so that no unnecessary time is wasted in placing the work in position on the machine performing the work. In some cases, a longer time is required for locating and binding the piece to be worked upon, in place, than is required for the actual machine operation itself. In all such cases the machine performing the work is actually idle the greater part of the time, and, added to the loss of the operator's time, is the increased expense for shop cost, incurred by such a condition. For this reason, the question of locating and binding the work in place quickly, and at the same time accurately, should be carefully studied by the designer before any attempt to design the tool is made. In choosing the locating surface or points of the piece or part, consideration must be given to the facilities of locating the corresponding part of the machine in a similar manner. It is, of course, highly important that this be done, as otherwise, although the jigs may be alike, as far as their guiding appliances are concerned, there may be no facility for locating the corresponding part in the same manner as the one already drilled, and while the holes drilled thus may coincide, other surfaces also required to coincide may be considerably out of line. For this reason, one of the main principles of location is that two component parts of the machine should be located from corresponding points and surfaces.

If possible, special arrangements should be made in the design of the jig so that it is impossible to insert the piece in any but the correct way. Mistakes are often made on this account in shops where a great deal of cheap help is used, pieces being placed in jigs upside down, or in some way other than the correct one, and work that has been previously machined and a great deal of time spent on, is entirely spoiled. Therefore, whenever possible, a jig should be made "foolproof."

When the work to be machined varies in shape and size, as for instance in the case of rough castings, it is necessary to have at least some of the locating points adjustable, and placed so that they can be easily reached for adjustment, but, at the same time, so fastened that they are, to a certain extent, positive. In the following installments different kinds of adjustable locating points will be described in detail. The strapping or clamping arrangements should be as simple as possible, without sacrificing effectiveness, and the strength of the clamps should be such as to not only hold the piece firmly in place, but to take the strain of the cutting tools also without springing or "giving."

When designing the jig, the direction in which the strain of the tools or cutters act upon the work should always be considered, and the clamps so placed that they will have the highest degree of strength to resist the pressure of the cut.

A cardinal principle in the application of clamps to a jig or fixture is that they should be convenient for the operator, quickly operated, and when detached from the work still connected with the jig or fixture itself, so as to prevent the operator from losing them, or, at least, from losing time hunting for them. Many a time, looking for lost straps, clamps, screws, etc., causes more delay in shops than the extra cost sometimes incurred in designing a jig or fixture somewhat more complicated, in order to make the binding arrangement an integral part of the fixture itself. Great complication in the clamping arrangements, however, is not advisable. Usually clamping arrangements of this kind work very well when the fixture is new, but as the various parts become worn, complicated arrangements are more liable to get out of order and the extra cost incurred in repairing often outweighs the temporary gain in quickness of operation.

Some of the principles mentioned may seem contradictory, and in fact, they are. There is, therefore, all the more reason to refer to the fact that the judgment of the designer is, in every case, the most important point in the design of jigs and fixtures. Definite rules for all cases could not be given. General principles can be studied, but the efficiency of the individual tool will depend entirely upon the judgment of the tool designer in applying the general principles of tool design to the case in hand.

When designing the jig or fixture, the locating and bearing points for the work, and the location of the clamps must also be so selected that there is as little liability as possible of springing the piece or jig, or both, out of shape, when applying the clamps. Either the one or the other part being sprung, will, of course, cause incorrect results when the piece is taken out of the jig, as it will then spring back into its natural position, and its surfaces will be out of alignment with the holes drilled or the faces milled. The clamps or straps should, therefore, in as far as it is possible, be so placed that they are exactly opposite some bearing point or surface on the work.

The designer must use his judgment in regard to the amount of metal put into the jig or fixture. It is desirable to make these tools as light as possible in order that they may be easily handled, be of smaller size, and cost less in regard to the amount of material used for their making, but, at the same time, it is poor economy to sacrifice anything of the rigidity and stiffness of the tool, as this is one of the main considerations for efficient results. On large-sized jigs and fixtures, it is possible to core out the metal in a number of places, without decreasing, in the least, the strength of the jig itself. The corners of jigs and fixtures should always be well rounded, and all burrs and sharp edges filed off, so as to make them convenient and pleasant for handling. Smaller jigs should also be made with handles in proper places, so that they may be held in position while working, if it be a drilling jig, and also for convenience in moving the jig about.

Boring jigs and drill jigs should always be provided with feet on all sides which are opposite the holes for the bushings.

or other provisions for guiding the tools, so that the jig can be placed square on the table of the machine. These feet also greatly facilitate the making of the jig, making it much easier to lay out and plane the different finished surfaces. On the sides of the jig, where no feet are required, if the body is made from a casting, it is of advantage to have small lugs, projecting out, for bearing surfaces when laying out and planing. While jigs are most commonly provided with four feet on each side, in some cases it is sufficient to provide the tool with only three feet, but care should be taken in either case that all bushings and places where pressure will be applied to the tool are placed inside of the geometrical figure obtained by connecting, by lines, the points of location for the feet.

While it may seem that three feet are preferable to use, because the jig will then always obtain a bearing on all the three feet, which it would not with four feet, if the table of the machine were not absolutely plane, it is not quite safe to use the smaller number of supports, because a chip or some other object is liable to come under one foot, and throw the

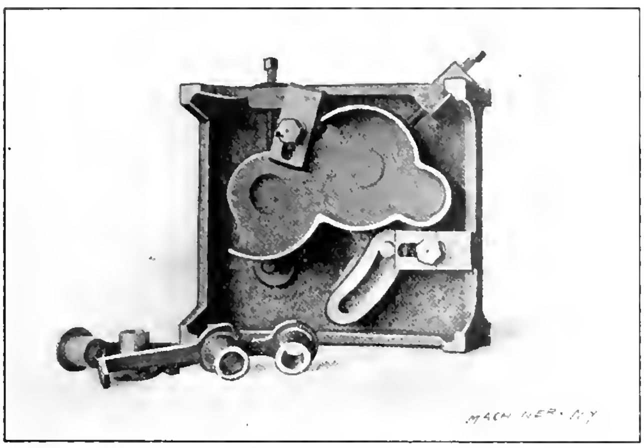

Fig. 1. Typical Open Drill Jig for Gear Guard.

Fig. 2. Open Drill Jig, showing Commonly Used Design.

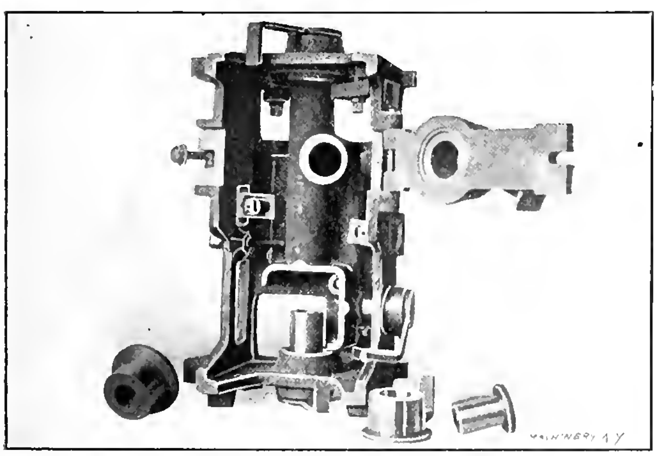

Fig. 3. Closed Drill Jig, showing Leaf Opened.

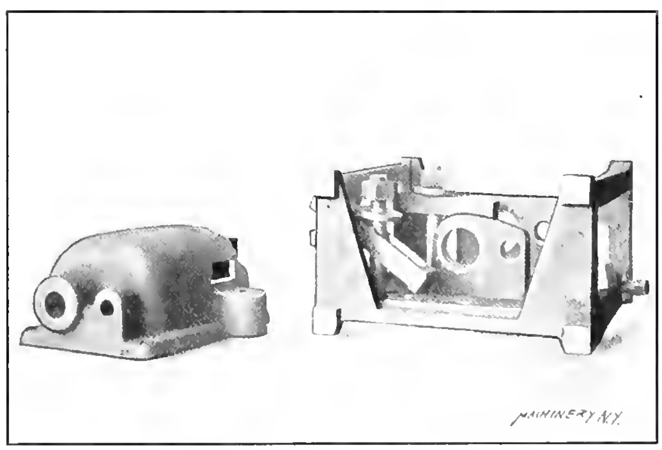

Fig 4 Combination Drill and Boring Jig.

jig and the piece out of line, without this being noticed by the operator. If the same thing happens to a jig with four feet, it will rock, and invariably cause the operator to notice the defect. If the table is out of true, this defect, too, will be noticed for the same reasons.

One mistake, quite frequently made, is giving too little clearance between the piece to be machined and the walls or sides of the jig used for it. Plenty of clearance should always be allowed, particularly when rough castings are being drilled or machined in the jigs; besides, those surfaces in the jig which do not actually bear upon the work, are likely to be made up with some slight variation from the dimensions on the drawing, particularly in a cast iron jig, and allowance ought to be made for such differences as well.

In regard to the locating points, it ought to be remarked that, in all instances, these should be visible to the operator when placing the work in position, so that he may be enabled to see that the work really is in its right place. At times the construction of the piece to be worked upon may prevent a full view of the locating points. In such a case a cored or drilled hole in the jig, near the locating seat, will enable a view of same, so that the operator may either see that the work rests upon the locating point, or, if the work be very particular, so that he can get a feeler or thickness gage between the work and the locating surface, to make sure that he has got the work in its correct position. Another point that should not be overlooked is that jigs and fixtures should be designed with a view to making them easily cleaned from the chips, and provision should also be made so that the chips, as far as possible, may fall out of the jig and not accumulate on or about the locating points, where they are liable to throw the work out of its correct position, and consequently spoil the piece.

The principles so far referred to have all been in relation to the holding of the work in the jig, and the general design of the jig for producing accurate work. Provisions, however, should also be made for clamping the jig or fixture to the table of the machine, in cases where it is necessary to have the tool fixed while in operation. Small drilling jigs, for instance, are not clamped to the table, but boring jigs, and milling and planing fixtures invariably have to be firmly secured to the machine on which they are employed. Usually plain lugs, projecting out in the same plane as the bottom of the jig, or lugs with a slot in them to fit the body of T-bolts, are the common means for clamping fixtures to the table. For boring jigs, it is unnecessary to provide more than three such clamping points, as a greater number is likely to cause some springing action in the fixture. Some springing effect is almost unavoidable, no matter how strong and heavy the jig is, but, by properly applying the clamps, it is possible to limit this springing to so small a limit as to permit it to be commercially disregarded.

When jigs are made, before they are used, they should always be tested so as to make sure that the guiding provisions are placed in the right relation to the locating points and in proper relation to each other.

Summary of Principles of Jig Design.

Summarizing the principles referred to in the previous discussion, we may state the following rules as being the main points to be considered in the designing of jigs and fixtures.

1. Before planning the design of a tool, compare the cost of production of the work with present tools, with the expected cost of production, using the tool to be made, and see that the cost of building is not in excess of expected gain.
2. Before laying out the jig or fixture, settle upon the locating points and outline a clamping arrangement.
3. Make all clamping and binding provisions as quick acting as possible.
4. In selecting locating points, see that two component parts of a machine can be located from corresponding points and surfaces.
5. Make the jig "fool-proof," that is, arrange it so that the work cannot be inserted except in the correct way.
6. For rough castings, make some of the locating points adjustable.
7. Locate clamps so that they will be in the best position to resist the pressure of the cutting tool, when at work.
8. Make, if possible, all clamps integral parts of the jig or fixture.
9. Avoid complicated clamping arrangements, which are liable to wear or get out of order.

Classes of Jigs and Fixtures.

The two principal classes of jigs are drill jigs and boring jigs. Fixtures may be grouped as milling, planing, and splining fixtures, although there are a number of special fixtures which could not be classified under any special head.

Drill Jigs.

Drill jigs are intended exclusively for drilling, reaming, tapping and facing. Whenever these four operations are required on a piece of work, it is usually possible to provide the necessary arrangements for all these operations being performed in one and the same jig. Sometimes separate jigs are made for each one of those operations, but it is doubtless more convenient and cheaper to have one jig do for all, as the design of the jig will not be much more complicated. Although it may be possible to make a distinction between a number of different types of drill jigs, it is almost impossible

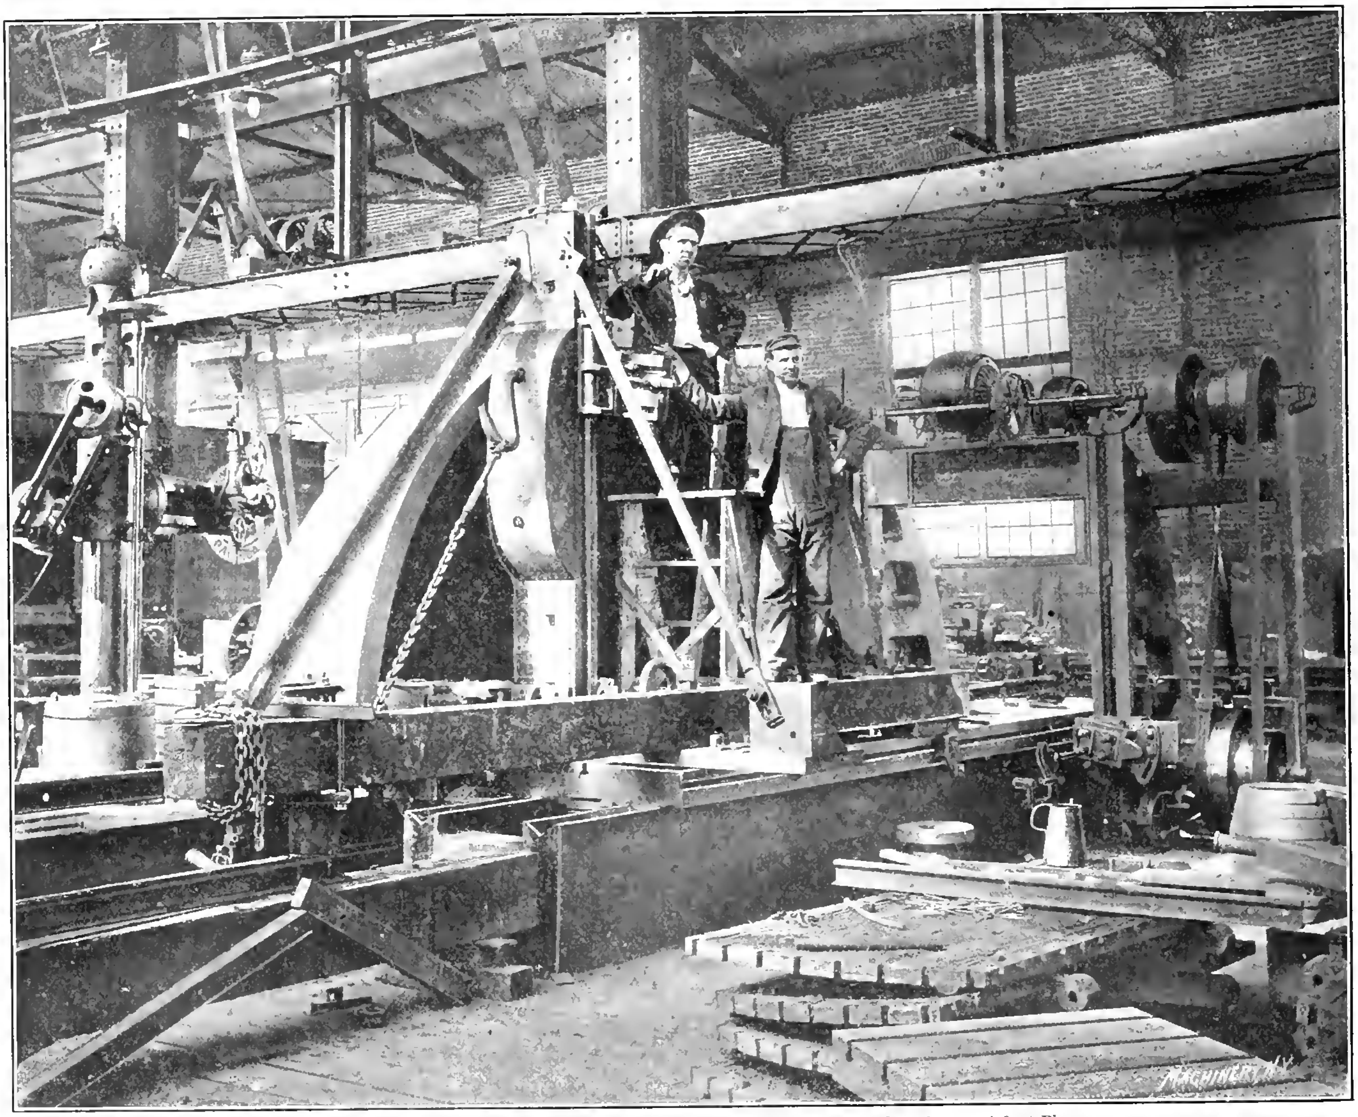

Fig 1 View showing how the Large Casting Illustrated in Fig 2 was planed on a 4-foot Planer.

10. Place all clamps as nearly opposite some bearing point of the work as possible, to avoid springing.
11. Cut out all unnecessary metal, making the tools as light as possible consistent with rigidity and stiffness.
12. Round all corners.
13. Provide handles wherever these will make the handling of the jig more convenient.
14. Provide feet, preferably four, opposite all surfaces containing guide bushings in drilling and boring jigs.
15. Place all bushings inside of the geometrical figure formed by connecting the points of location of the feet.
16. Provide abundant clearance, particularly for rough castings.
17. Make, if possible, all locating points visible to the operator when placing the work in position.
18. Provide holes or escapes for the chips.
19. Provide clamping lugs, located so as to prevent springing of the fixture, on all tools which must be held to the table of the machine while in use, and tongues for the slots in the tables in all milling and planing fixtures.
20. Before using in the shop, for commercial purposes, test all jigs as soon as made.

to define and to get proper names for the various classes, owing to the great variety of shapes of the work to be drilled. There are, however, two general types that are most commonly used, the difference between which is really very noticeable at sight. These types may be classified as open jigs and closed jigs, or box-jigs. Sometimes the open jigs are called clamping jigs, although it is difficult to see a good reason for this name. The open jigs usually have all the drill bushings in the same plane, parallel with one another, and are not provided with loose or removable walls or leaves, thereby making it possible to insert the piece to be drilled without any manipulation of the parts of the jig. These jigs are often of such a construction that they are applied to the work to be drilled, the jig being placed on the work, rather than the work being placed in the jig. The work is held to the jig (or the jig to the work) by straps, hook bolts or clamps. Figs. 1 and 2 show types of open drill jigs.

The closed drill jigs, or box-jigs, frequently resemble some form of a box, and are intended for pieces where the holes are to be drilled at various angles to one another. As a rule, the walls are solid with the face of the jig, and the piece to be drilled can be inserted only after a leaf or some leaves or covers have been swung out of the way. Sometimes it is necessary to remove a loose wall, which is held by screws and dowel pins, in order to locate the piece in the jig. The work in the closed drill jig is generally held in place by set-screws and sometimes by screw bushings, as well as by straps and hook bolts. Fig. 3 shows an example of a typical closed jig. Another type of closed jig is exemplified in a combination of drill and boring jigs, which are designed to serve both for drilling and boring operations.

Before designing a combination drill and boring jig, the relation between, and number of, the drilled and bored holes must be taken into consideration, and also the size of the piece to be machined. In case there is a great number of holes, it may be of advantage to have two or even more jigs for the same piece, because it makes it easier to design and make the jig, and very likely will give a better result. The holes drilled or bored in the first jig may be used as means for locating the piece in the jigs used later on. It is plain that combination drill and boring jigs are not very well adapted for pieces of large size. In Fig. 4 is shown a typical combination jig, where the bushings for guiding the drills are indicated in the bottom surface, the work upon which the operations are performed being shown at the left-hand side in the cut.

DIFFICULT PLANING JOB.

JOHN McLEOD.

The accompanying half-tone and line cut show how a difficult and unusual job was planed in the Payne & Jouberts shop, Birmingham, Ala. The work to be planed consisted of eight halves of four 14-foot sugar-pan domes, which were required to be planed where the faces of the two halves were fitted together. This planing job was carried out on a 4-foot Pond planer in the following manner: Two 24x24-inch angle

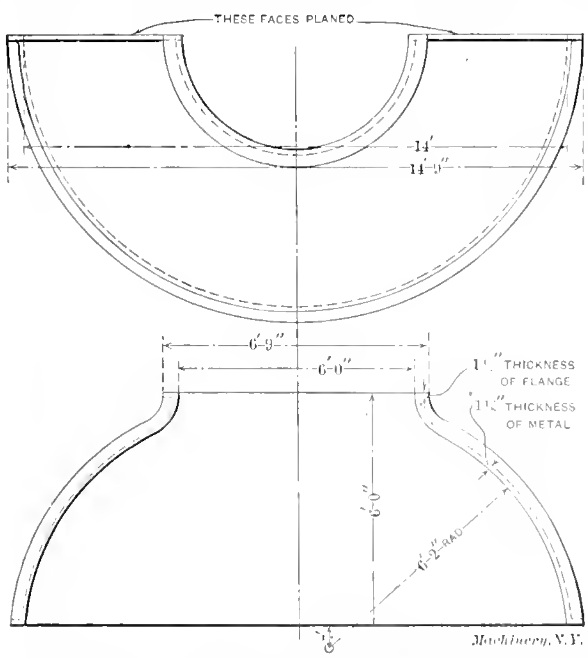

Fig. 2. Detail of the Casting which was planed as shown in Fig. 1.

plates were first bolted to the side of the planer bed, and the work then bolted to these angle plates, screw jacks supporting them at the other end, together with braces from the work to the planer housing. Then the cross-rail was taken off from its place, and securely bolted on end and braced on front and side, two foundry weights being clamped on the planer table for supports, as indicated in the half-tone, Fig. 1. In this manner the work was carried out to full satisfaction, and after the first half was finished, which, of course, took somewhat longer on account of the considerable rigging necessary, the balance of the work was finished at the rate of one-half of a dome in 12 hours.

THE LADY MANAGER AND THE FLY-WHEEL BID.

M. E. CANEK.

We read and hear much nowadays about the new woman and the wide swath she cuts in the business world. Personally, I think there is a good deal of nonsense written and talked about the matter. Most women are the same as their mothers and their grandmothers in preferring the quiet joys of housekeeping and domesticity to anything else. The hurly burly, trials and uncertainties of business life may be quite to the taste of a small percentage of women but not of the large majority. When a woman *does* take hold of a business job it is with deadly earnestness. She is "on the job" all the time, and woe to the unlucky chap who thinks that just because she is a woman he can play up monkeyshines instead of doing straight business. Now this story is not about a crooked business deal. On the contrary, it is about a gentleman general manager who pitted himself against a lady general manager in a straightforward business proposition, but who, nevertheless, felt very small after the deal had been consummated—entirely to the lady's liking. The incident occurred a few years ago in a thriving city not a thousand miles from New York.

Mr. Gray was the G. M. of the Snapshot Works, a concern noted for its enterprise, broad business policy and remarkable growth. Its handsome buildings, modern shop methods, fine business system and efficient selling department were the envy of would-be competitors the world over. Miss Brown was the G. M. of the Cog Works where cogs in all sorts of styles and shapes were whittled out of wood, brass, cast iron, steel or whatever material you wanted them made of. The "works" also made castings large and small, for all comers. I forgot to say that the cogs generally were on wheels. Some fastidious individuals may prefer to call them gears, and they are welcome to do so for all I care.

One morning late in September the engineer of the Snapshot Works discovered that the fly-wheel on the auxiliary engine used to run the lighting dynamo and to furnish power when part of the plant was working nights, had three spokes cracked. Though the wheel was in no immediate danger of breaking down, it was deemed advisable to get a new one as soon as possible. With characteristic energy and promptness, Mr. Gray issued calls to the large foundries of the city and the neighboring towns for bids on a new fly-wheel, fifteen feet diameter, weight about five tons, and *cast in one piece*. Now the only foundry in the home city that could or would handle the job was the Cog Works, and the G. M. of the Snapshot Works fully expected that this concern would get the job. The call for bids was more of a bluff to get a favorable price than anything else.

Well, a week passed and no bid was received from the Cog Works; in fact no acknowledgement was made of the letter asking for bids. Finally Mr. General Manager "called up" Miss General Manager, and in tones of some asperity demanded to know why no bid had been made on the fly-wheel.

"Is this Mr. Gray?"

"Yes."

"Well, Mr. Gray, we really haven't thought it worth while to make a bid on your fly-wheel."

"What! Don't you want the job?"

"I didn't say so. I simply said we didn't think it worth while to make a bid."

"How do you expect to get the job if you don't make a bid?"

"Can't you simply send the order over by a messenger, Mr. Gray?" (in sugary tones).

"Why, I tell you this job is going to be let to the lowest bidder."

"Yes, I know that, but aren't we just the same as the lowest bidder?"

"Why, how you talk. You haven't even made a bid, and you know that Jones of Pisgah and Smith of Ararat are just hot after such jobs."

"Yes, but they are not going to make your wheel. Now, Mr. Gray, have you thought of the fact that a fifteen-foot wheel is just a little too large to be carried on a railroad car?"

"Well, I'll be—er-er—excuse me, madam. Say, er-er—we'll send the order over this afternoon. Good-by."

"Good-by, Mr. Gray."

* * *

THE ARRANGEMENT OF FLOORING WITH REGARD TO SPRINKLERS.

The designs for the ordinary shop or mill are usually carried into material effect before the question of sprinklers is taken up. It may then be discovered that a different spacing of the timbers might have made a material change in the cost of the sprinkler system. Of course, prices will vary with localities, but taking a given case, an interesting comparison may be made. The fundamental rule of the insurance company was that no sprinklers should be called upon to serve a plain surface exceeding 100 square feet between timbers, and that for any less undivided space, unless a very small one, one sprinkler would be required. Fortunately the building was laid out on a 20-foot unit basis, and in the case of the roof, the timbers 20 feet long were spaced 10 feet on centers, keeping just within the limit, which called for two sprinklers for 200 square feet of space. But the main floors were planned for the spacing of timbers 20 feet long on 4-foot centers, leaving 3 feet between timbers, and establishing a plain surface under the floors measuring approximately 3 feet by 20 feet, or 60 square feet. As a result, five sprinklers were required instead of four in a given 20 feet square, an increase of 20 per cent in the sprinkler cost over what was required for the same total roof area. In this particular case, where the sprinkler equipment was installed on the basis of $3.00 per head, the cost for two floors was about $800.00 more than would have been necessary if it had been given an opportunity to serve the maximum area of 100 square feet. Here the expense of a framing arrangement to secure the minimum cost of sprinkler system per square foot would have increased the size of timbers through increasing their spacing on centers at a cost probably about equal to the saving in sprinklers. But in another building, in the same group, designed on different lines, the opportunity for a net saving was sufficiently manifest to attract attention, and suggest the necessity of giving thought to a matter not often considered.

* * *

Some interesting information regarding the over-supply of technically educated people in Germany, is furnished by the *Technik und Wirtschaft*, a supplement to the well-known *Zeitschrift des Vereines deutscher Ingenieure*. It appears that, at the present time, the German technical schools turn out a great many more well educated young men than there is actual demand for in the industries of the country. Even official opinions have been expressed in the matter, and the Bavarian press gives place to a statement from an official source, in which young men are discouraged, for the present, from entering into the technical field, as there is, at the present time, in the government service no opportunity for the great number of young men who have intended to enter into the service of the State Railways and the government Public Works department. Attention is also called to the comparatively small salaries received by technically educated men, caused, to a great extent, by the keen competition offered on account of the oversupply. In this connection, it may be of interest to mention the number of students at the ten highest German technical institutions. The total for the year 1907-1908 is 15,720, as compared with 15,453 in the previous year, the largest number of regular students being at the Hochschule at Munich, where there are 2,325, as compared with 2,291 regular students at the Berlin Hochschule.

A STUDY IN SPIRALS.

WALTER GRIBBEN.*

In cutting a spiral gear in a milling machine as ordinarily arranged, it is necessary to set the table to the helix angle in order that the sides of the cutter may not interfere, or drag in the cut. But the helix angle varies with the depth, being greatest at the top of the tooth, less at the pitch line, and still less at the bottom of the cut. In fact, if the cut were deep enough to reach all the way to the center of the piece being operated on, the helix angle would become zero, or parallel to

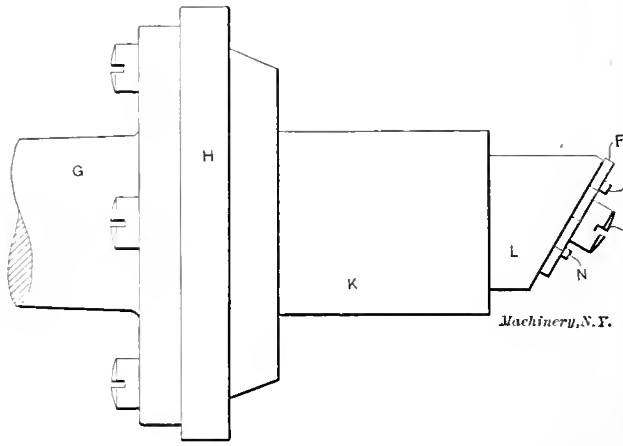

Fig. 1. Chuck for Mounting the Pieces shown in Fig. 2.

the center line. If the general run of mechanics were asked what would be the proper angle at which to set the table, I think they would say that the helix angle at the pitch line would be the one to determine the setting of the table, and I used to think so myself. This setting has the effect of making the width of the cut exactly right at the pitch line, but it does so at the expense of undercutting and weakening the teeth. For quite some time past I have thought that the helix angle at or near the bottom of the cut should be the one to set the table to in order to get a strong tooth, and to convince other mechanics of the correctness of this view I made the following experiments:

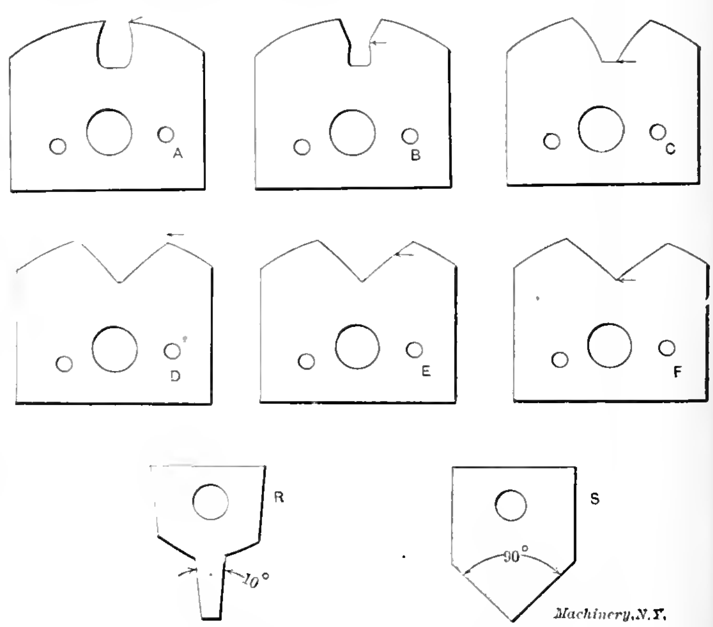

Fig. 2. Pieces milled on the Chuck, Fig. 1, with Fly-cutters R and S, showing the Effect of varying the Pitch Circle.

The piece *G*, Fig. 1, is a cast iron taper stem with a flange cast on, and fits in the dividing head of the milling machine. *H* is a brass chuck that was made for another job, and is fastened to *G* with four screws. *K* is a piece of 1¾-inch round brass, with the ends faced true, while *L* is a piece of scrap brass with two faces machined at an angle of 30 degrees, one of these faces being tapped for the screw *M*, and also containing the two dowel pins *N*. *H*, *K* and *L* are sweated together with soft solder.

* Address: 314 Halsey St., Brooklyn, N. Y.

The six pieces of sheet brass, A, B, C, D, E and F, Fig. 2, were drilled so they would fit onto the dowel pins in the 30-degree face of the improvised chuck, F being shown in place in the line cut, Fig. 1. These six pieces were placed in succession on this chuck and the curved edges of all turned to a diameter of 1.23 inch. I wanted to make a spiral cut in each of these six pieces, varying the setting of the table angle, and also the shape of the cutter, and compare the shape of the cut with that of the cutter that made it.

The lead used was 5.33 inches to one turn, and the depth of cut ¼ inch, both these elements being alike in all six cases. The pieces of sheet brass were intended to stand at right angles with the cut, but, of course, this was impossible, as the helix angle varied with the depth, so I made them stand at right angles with the helix at half depth. Assuming this helix angle to be 30 degrees ,we can find the diameter of the imaginary cylinder whose surface is at half the depth of the cut by multiplying the lead, 5.33 inches, by the tangent of 30 degrees, and dividing by 3.1416, which gives 0.98 inch. Adding 0.25 inch to this, we get 1.23 inch for the outside diameter, and also by subtracting 0.25 from 0.98 we get 0.73 inch for the diameter at the bottom of the cut.

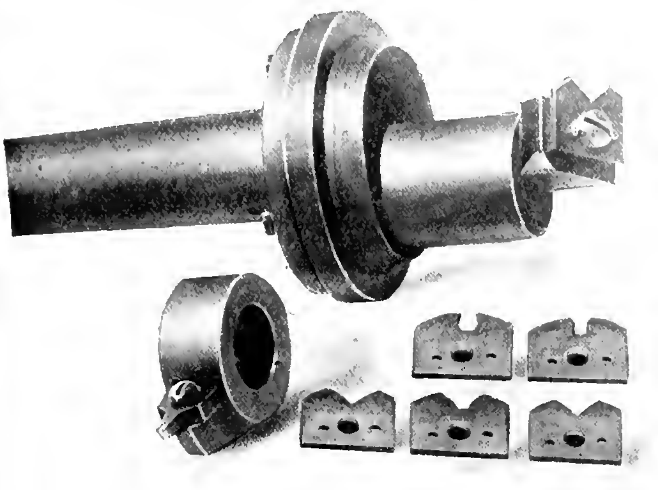

Fig. 3. Chuck, Fly-cutter, and Pieces milled in Experiments Described

Knowing the outside diameter to be 1.23 inch, we multiply this by 3.1416 and divide by 5.33 to get the tangent of the helix angle at the top, which we find to be 35 degrees 56 minutes. In a similar manner we multiply the bottom diameter, 0.73, by 3.1416 and divide by 5.33 to get the tangent of the helix angle at bottom of cut, which we find to be 23 degrees 17 minutes.

The cutter used in this job was a fly-cutter, the holder being shown in the half-tone illustration Fig. 3, while its blades, R and S, are shown in the line illustration Fig. 2. R was used to cut A, B and C, while S was used to cut D, E and F. The table setting was nearly 36 degrees for A and D, 30 degrees for B and E, and about 23¼ degrees for C and F.

The shapes of the cuts show that the width of the cutter is accurately reproduced only at the particular depth where the helix angle is the same as the table setting, this point being shown by the arrow heads at the sides of the various cuts. The shapes of the cuts also show that the departure from the true form of the cutter due to faulty table setting is less in the case of the more flaring cutter S than in the case of cutter R, whose sides come nearer to being parallel.

This demonstrates to my mind that the table setting for a spiral gear should be the same as the helix angle at or near the bottom of the cut, because at this point the sides of the cutter come closer to parallelism, while at the top of the cut they are more flaring, and the table setting not being correct for the helix angle at this point would produce a comparatively slight error.

This also suggests a slight modification in selecting a cutter to do the job, as the tops of the teeth would be rounded off somewhat more than in the case of a spur gear cut with the same cutter. Therefore, it would be well to select a cutter for a greater number of teeth than the spiral gear formula $T = \frac{N}{\cos^3 a}$ calls for.

Setting the table for a less angle than that of the pitch line helix also has the effect of slightly increasing the width of the cut at the pitch line, but not to the extent that a comparison of C and R would seem to indicate, as in the experiments here described the depth of the cut was purposely made a very large percentage of the diameter in order to accentuate the errors due to faulty setting of the table, and if the table is to be set correct for the bottom of the cut, it might be well to consider the normal circular pitch as slightly greater than that rightfully belonging to the cutter in use, and size the blank accordingly. These experiments were entirely of a qualitative nature, and were only intended to guide the judgment of the designer and the man who puts the design in material form in cold metal.

[Those not thoroughly familiar with universal milling machine use should carefully distinguish between the table angle and the helix angle produced by the gearing of the dividing head. The dividing head is geared to produce the required helix angle, measured on the pitch line the same as usual, of course. What Mr. Gribben advocates, in order to reduce interference, is simply setting the table to some helix angle between the pitch line and the dedendum or root circle rather than to the helix angle indicated by the pitch line. A point worth attention, also, is that the interference of a cutter increases with increase of diameter. Small cutters, therefore, tend to reproduce their outlines more accurately than large cutters, other things being equal.—EDITOR.]

NOTES ON HIGH-SPEED STEEL.

In a discussion regarding the manufacture and up-keep of milling cutters, at a meeting of the Institution of Mechanical Engineers, of Great Britain, one of the speakers called attention to one valuable property of high-speed steel, which he has not seen referred to, namely, that of withstanding shocks. In one of the railway shops in England, the output of the crank-turning lathes had been practically doubled by the use of high-speed steel tools. The forgings were never very accurate, there being perhaps ¼ inch to take off one side of the diameter, and 1½ inch off the other, and a tool suited to such wide variation was greatly appreciated. If the high-speed steel tool dug in, it did not break, as invariably happened with ordinary carbon steel.

Another speaker called attention to an important factor affecting the life of high-speed steel milling cutters. The teeth, besides being correctly relieved at the back should have a front rake of 5 degrees, as indicated in the accompanying cut. The number of teeth in milling cutters, particularly when made of high-speed steel, plays a very important part. A cutter made of this material with a large number of teeth, has a considerably shorter life than one with fewer but deeper teeth. In a certain case, two milling cutters, one with 16 teeth, and one with 32 teeth, had been made. The one with the coarser teeth, of helical shape, would finish an article with as good a finish as the one with the finer pitched teeth, but the cost of making the coarse-pitched cutter was 35 per cent less than the cost of making the one with the fine-pitched teeth, and the life of the coarse-pitched cutter was four or five times as long as that of the other.

* * *

Messrs. Gebrüder Sulzer, Winterthur, Switzerland, have recently devised a method of working internal combustion compressed air engines, which consists in one of the two ingredients of the charge required for burning, that is, either the air or the combustible gas alone, being introduced under pressure into the engine cylinder, and enclosed therein. The other ingredient is introduced in such a manner that the combustion process takes place during the whole of the time of the introduction, and is regulated according to the load. The temperature required for ignition is produced inside the working chamber, by any ignition device, without the fuel previously having been heated to its ignition temperature.

TAPER TAPS.—2.

ERIK OBERG.*

English Taper Pipe Taps.

English taper pipe taps constitute a special class of taper taps. These, most tap manufacturers in this country make exactly like the Briggs' standard pipe taps in regard to dimensions, the only difference being that the English taper pipe taps are provided with Whitworth form of thread, and with such a number of threads per inch as is called for by the standard for Whitworth standard gas and water pipe thread. It appears, however, that in England these taps are made with 1 inch taper per foot, instead of ¾ inch, and at least one firm in this country makes these taps with the taper according to this practice.

Pipe taps and taper taps in general are often made with the interrupted or Echols' thread shown in Fig. 6. A more

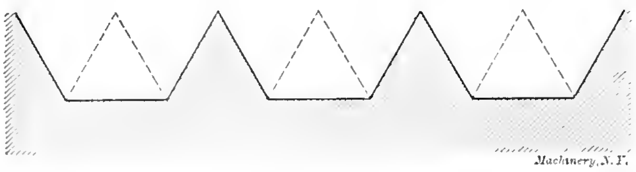

Fig. 6. Interrupted or Echols' Thread.

complete reference to this thread was made in an article entitled "Machine Taps," in the February, 1907, issue of MACHINERY. This form of thread is very well adapted for taper taps, and, in case of a very steep taper, is, in fact, almost essential if a smooth and perfect thread is to be cut. In hardening, pipe taps should be drawn to a somewhat higher temperature than ordinary hand taps of the same sizes. The correct temperature is about 470 degrees F.

Pipe Hobs.

Pipe hobs are used for sizing pipe dies, after the thread has been cut nearly to size either in a lathe or by a pipe tap. The length of the thread of a pipe hob is made longer than that of pipe taps, but there is not any very good reason why it should be so, excepting that it has become customary, and

TABLE V. DIMENSIONS OF PIPE HOBS.

established custom is as unyielding in tool making as in anything else. Outside of the longer length of thread, the only essential difference from the pipe tap is the number and the form of the flutes. These latter are cut with a 50-degree double-angle cutter, 25 degrees angle on each side, which is the same kind of a cutter as is used for ordinary straight hob taps. The number of the flutes may be approximately determined by the formula

$$8.5\,B = N$$

in which B equals the diameter at large end of thread of hob, and N equals the number of flutes.

With this formula, the width of each land is about 3/16 inch, and the width of the space or flute is the same amount. According to this formula the number of flutes for various sizes of pipe hobs are as follows:

TABLE VI. NUMBER OF FLUTES IN PIPE HOBS.

Size of Pipe Hob.	No. of Flutes.	Size of Pipe Hob.	No. of Flutes.
1/8	5	2	22
1/4	6	2½	26
3/8	6	3	32
1/2	8	3½	36
3/4	10	4	40
1	12	4½	44
1¼	16	5	48
1½	18	6	58

Dimensions of Pipe Hobs.

The dimensions for lengths and diameters of pipe hobs are given in Table V. The dimension A is given according to the established standard of the manufacturers of taps. This is the essential diameter and is located 1½ inch from the large end of the thread of the hob. The limit of error for the location of this diameter is the same as the limit for the location of the size line of pipe taps which was stated in the March issue, and the gaging is done in the same manner. It is evident that a separate set of ring gages are required, and that the length of the gage in this case always should be 1½ inch, the large diameter of the hole in the gage being diameter B in Fig. 7, and the small diameter the dimension A. The taper of pipe hobs is, of course, the regular pipe thread taper, ¾ inch per foot.

The more important dimensions in Table V are figured from the formulas:

$$C = \frac{N + 16}{8}, \qquad D = \frac{5\sqrt{N} + 11}{4},$$

$F = A - 1/16$, for pipe sizes up to and including 3 inches,

$F = \frac{N}{8} + 3\frac{1}{4}$, for 3½-inch pipe sizes and larger.

2	8 3/4	3 3/8	7/8	4 1/2	1 27/32	1 1/2	1 1/2

* Associate Editor of MACHINERY.

In these formulas:
A = size of hob 1½ inch from the large end of the thread,
N = nominal size of hob (pipe size),
C = length of shank,
D = length of thread, and
F = diameter of shank.

Relief.

Pipe hobs, being provided with a taper thread, must be relieved both in the angle and on the top of the thread. In this respect they differ from straight thread hobs, which are not relieved at all, except on the top of the thread of the short chamfer at the point.

Taper Boiler Taps.

Taper boiler taps, as the name indicates, are used in steam boiler work, and, like the pipe taps, are in this work used where a steam tight fit is desired. The taper of the taps is the same as the pipe tap taper, ¾ inch per foot. In regard to their construction there is nothing to say that has not already been said either in connection with pipe taps, or about taper taps in general. The size by which these taps are designated is located ¼ inch from the large end of the thread.

TABLE VIII. DIMENSIONS OF PATCH BOLT TAPS.

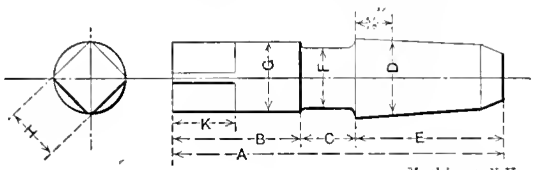

Fig. 9.

Diameter of Tap.	Total Length.	Length of Shank.	Length of Neck.	Length of Thread.	Diameter of Neck.	Diameter of Shank.	Size of Square.	Length of Square.
D	A	B	C	E	F	G	H	K

15/16	3 7/16	1 9/16	1/2	1 3/8	13/16	15/16	11/16	11/16
1	3 1/2	1 5/8	1/2	1 3/8	7/8	1	3/4	3/4
1 1/16	3 9/16	1 11/16	1/2	1 3/8	15/16	1 1/16	13/16	3/4
1 1/8	3 5/8	1 3/4	1/2	1 3/8	1	1 1/8	27/32	13/16
1 3/16	3 3/4	1 13/16	1/2	1 7/16	1 1/16	1 3/16	7/8	13/16
1 1/4	3 13/16	1 7/8	1/2	1 7/16	1 1/4	1 1/4	15/16	7/8
1 5/16	3 7/8	1 15/16	1/2	1 7/16	1 3/16	1 5/16	1	7/8
1 3/8	3 15/16	2	1/2	1 7/16	1 1/4	1 3/8	1 1/32	15/16
1 7/16	4	2 1/16	1/2	1 7/16	1 5/16	1 7/16	1 1/16	15/16
1 1/2	4 1/16	2 1/8	1/2	1 7/16	1 3/8	1 1/2	1 1/4	1

The permissible limits of error in regard to the location of the size line are the same as for pipe taps.

In Table VII dimensions are given for taper boiler taps. The most important of these are approximately figured from the following formulas:

$$A = 3D + 2\tfrac{3}{4} \text{ inches}, \qquad E = 2D + \tfrac{1}{2} \text{ inch}.$$

$$B = \frac{3D}{4} + 1\tfrac{7}{8} \text{ inch}, \qquad C = \frac{D}{4} + \tfrac{3}{8} \text{ inch}.$$

In these formulas:
A = total length of tap,
B = length of thread,
C = length of neck,
D = diameter of tap, measured ¼ inch from the large end of the thread.

These taps are provided with four flutes up to 1½ inch diameter, and with five flutes for sizes from 1⅝ to 2 inches. If made in sizes larger than 2 inches, six flutes should be given to the tap. Boiler taps are always provided with twelve sharp V-threads per inch, irrespective of the diameter of the tap.

Patch Bolt Taps.

Patch bolt taps are practically only a modified form of taper boiler taps. The taper is the same, but the threaded portion as well as the total length is shorter than the corresponding lengths of a taper boiler tap. The nominal size is measured ⅝ inch from the large end of the thread. These taps are used for purposes similar to the taper boiler taps, in boiler construction.

The dimensions for patch bolt taps are given in Table VIII. The essential dimensions are approximately figured from the formulas:

$$A = 1\ 3/16\ D + 2\ 5/16 \text{ inches}, \qquad B = D + \tfrac{5}{8} \text{ inch},$$

$$E = 3/16\ D + 1\ 3/16 \text{ inch}, \qquad F = D - \tfrac{1}{8} \text{ inch}.$$

TABLE IX. DIMENSIONS OF MUD OR WASHOUT TAPS.

TABLE X. DIMENSIONS OF BLACKSMITHS' TAPER TAPS.

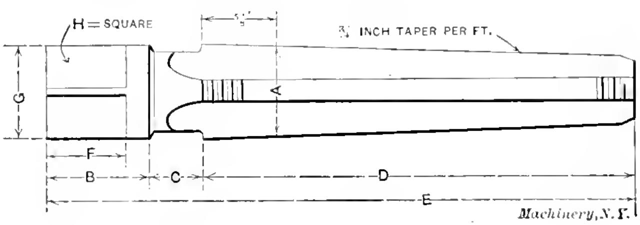

Fig. 11.

Nominal Diameter of Tap.	Length of Shank.	Length of Neck.	Length of Thread.	Total Length.	Length of Square.	Diameter of Shank.	Size of Square.
A	B	C	D	E	F	G	H
1/4	1/2	3/8	1 1/2	2 3/8	3/8	5/16	1/4
5/16	9/16	7/16	1 11/16	2 11/16	3/8	3/8	9/32
3/8	5/8	7/16	1 7/8	2 15/16	7/16	7/16	5/16
7/16	5/8	7/16	2 1/16	3 1/8	7/16	1/2	3/8
1/2	11/16	1/2	2 1/4	3 7/16	1/2	9/16	7/16
9/16	3/4	1/2	2 7/16	3 11/16	1/2	5/8	15/32
5/8	13/16	1/2	2 5/8	3 15/16	9/16	11/16	1/2
11/16	13/16	1/2	2 13/16	4 1/8	9/16	3/4	9/16
3/4	7/8	9/16	3	4 7/16	5/8	13/16	5/8
13/16	15/16	9/16	3 3/16	4 11/16	5/8	7/8	11/16
7/8	1	9/16	3 3/8	4 15/16	11/16	15/16	11/16
15/16	1	5/8	3 9/16	5 3/16	11/16	1	3/4
1	1 1/16	5/8	3 3/4	5 7/16	3/4	1 1/16	13/16
1 1/8	1 3/16	11/16	4 1/8	6	13/16	1 3/16	7/8
1 1/4	1 1/4	11/16	4 1/2	6 7/16	7/8	1 5/16	1
1 3/8	1 3/8	3/4	4 7/8	7	15/16	1 7/16	1 1/16
1 1/2	1 7/16	3/4	5 1/4	7 7/16	1	1 9/16	1 3/16

In these formulas,
D = diameter of tap (measured ⅝ inch from the large end of the thread),
A = total length of tap,
B = length of shank,
E = length of thread, and
F = diameter of neck.

The diameter of the shank equals the nominal diameter of the tap.

Patch bolt taps are always provided with twelve threads per inch, V form, irrespective of diameter. All sizes are fluted with four flutes up to 1½ inch diameter. Patch bolt taps are not manufactured in larger sizes.

Mud and Washout Taps.

Mud and washout taps are used in boiler work the same as the taps previously referred to. These taps are sometimes referred to as "arch pipe taps," but the former name is by far the most common. They are made in six sizes, usually known by the numbers as stated in Table IX. These taps taper 1¼ inch per foot and have twelve sharp V-threads per inch. The dimensions, as given in Table IX, conform in all essential details with the practice of the manufacturers of these taps. Number 0 tap is provided with five flutes, No. 1 with six, No. 2 with seven, and the remaining ones with eight flutes.

Blacksmiths' Taper Taps.

We have but one more class of taper taps generally manufactured, the blacksmith's taper tap. This tap has a long taper thread, and a very short shank, only sufficiently long for a square and a collar to prevent the tap wrench from slipping from the square down upon the body of the tap. The taper of the thread is ¾ inch per foot, and the size by which the tap is known is measured ⅝ inch from the large end of the thread. These taps are generally made with the standard number of V-threads per inch corresponding to their nominal diameter. The sizes given in Table X are the sizes generally made; these sizes all have four flutes.

Pipe Taps and Drill Combined.

Pipe taps are sometimes provided with a drill point, as shown in Fig. 12, for drilling the hole previous to tapping. Instead of a square for a wrench, they are then usually provided with square taper shank for a taper drill socket. The dimensions of the shank must, of course, suit the requirements. The threaded portion is an exact duplicate of the threaded part of a pipe tap. The drill part has two flutes like a twist drill, and the point is ground to the same angle, 59 degrees with the center line, as are ordinary twist drills. The diameter and the length of the drill point are the only dimensions necessary to state in this connection.

TABLE XI. LENGTH AND DIAMETERS OF DRILL POINTS IN COMBINED PIPE TAPS AND DRILLS.

¾	1⅜	29/32	2½	2	2 ⅝

* * *

Some interesting facts about alloys of silicon are reported in *Engineering*. Alloys containing from 5 to 15 per cent of silicon can, like nickel, be forged cold, but not when at a red heat. When the percentage of silicon exceeds 22, the hardness of the alloy increases. A regulus with 25 per cent of silicon cleaves like mica in sheets, and alloys containing more than 50 per cent of silicon can be powdered. It is interesting that an alloy containing 20 per cent of silicon is much harder when slowly cooled than when suddenly chilled.

* * *

The growth of the motor car industry, in which aluminum is now extensively used, has greatly increased the use of this metal. The present output of aluminum is between 15,000 and 20,000 tons yearly. In America there are at present 56 installations using aluminum wire for electric power transmission purposes, some of these being in connection with schemes of considerable magnitude and importance. This application of the metal has not been followed up in Europe, where doubts exist in the minds of engineers as to its suitability for outside work involving long-continued exposure to a humid atmosphere.

GRINDING AND GRINDING MACHINES.*

CARL OLSON.

The development of the grinding machine has made rapid progress during the last few years, and the process of grinding is more and more recognized as having both economical and technical advantages, as compared with the old methods of obtaining finish. This is especially true regarding plain cylindrical grinding, and this is due chiefly to the fact that the machines for this kind of grinding are easier to build, and in general more efficient than machines for other kinds of grinding.

It has often been claimed, by people who have had long and thorough experience in regard to this subject, and whose testimony, therefore, must be considered as having weight, that time can be saved in finishing a cylindrical piece of work by taking a roughing cut with an ordinary cutting tool, leaving about from 0.008 to 0.010 inch, and grinding off this amount, instead of taking a second cut in the lathe, and finishing the piece by filing. One great advantage of the grinding machine is the closer finish that can be obtained.

In some special cases, when the steel to be finished is so hard that it cannot be cut by means of a cutting tool, the grinding machine has to take the place of the lathe entirely. Of course, the work in this case cannot be done so cheaply as in the case of ordinary kinds of steel, but still it can be done with fair economy. As the piece is taken entirely rough and put up in the grinding machine, there is, considering the errors in casting, about ⅛ inch up to 3/16 inch on the diameter, that has to be ground off. When so large an amount of metal has to be removed by grinding, another problem than that dealt with when only 0.008 to 0.010 inch has to be ground off presents itself. The writer has recently designed three special grinding machines, two for external and one for internal work, all for very heavy duty. Herein are given a few of the conclusions arrived at while designing these machines. Being, as mentioned, mostly used for heavy grinding, the machines may differ some from the common light grinding machines, but the principles remain, in general, the same.

Any machine tool must, of course, be designed heavy enough not only to take all the strains produced by the action of the cutting tool or wheel, but to prevent all, or nearly all, vibration and chattering of the machine itself. This is true of the grinding machine more than of any other machine tool. Rigidity is a very important factor in the efficiency of the machine, both in regard to heavy grinding and grinding for very exact sizes and high finish.

Influence of Vibrations on Action of Grinding Machines.

The grinding wheel rotating at a high speed tends to jar its bearing and supports. Vibrations of this kind would result in an oscillating motion of the grinding wheel perpendicular to its own axis of rotation and along the line connecting the center of work with the center of the wheel. The frequency of these vibrations depends entirely upon the weight of the oscillating parts. The cause of the vibrations is that the center of gravity of the rotating parts, grinding wheel, shaft, pulley, etc., is not entirely the same as the center line of rotation. This is partly due to the uneven structure of the material. It is very plain to everybody, that the oscillating grinding wheel cannot cut to its full capacity. The length of the oscillations might not be large, perhaps only one-thousandth of an inch or a fraction thereof, but the cut will be just so much deeper one moment than the next following. Only at one moment, when the wheel is furthest in, will it cut to its full capacity.

It is very important, in order to secure nice running of the wheel, to have the belts in good order, and to have the boxes closely adjusted, even though they run a trifle warm. Because of the high speed of the shaft, the boxes ought to be made with ring-oiling devices. This would allow a closer adjustment, and secure a better running of shaft. However, as far as the writer knows, there are no grinding machines

* The following articles on this and kindred subjects have previously been published in MACHINERY: A Talk on the Disk Grinder, June, 1904; The Grinding of Thread Gages, October, 1904; The Cost of Grinding, October, 1906; Grinding Crank-shafts, March, 1907; and Grinding a Large Crank-shaft, April, 1907.

on the market equipped with ring-oiling boxes. The slides should, for the same reason as the boxes, be adjusted closely, even though they slide hard.

Speed of Grinding Wheels.

The peripheral speed of the grinding wheel should be approximately from 5,000 to 5,500 feet per minute. There are occasionally cases when higher speed is desirable, but with higher speed there is danger of the wheel breaking. The wheel should, however, never be run slower than 5,000 feet per minute, because it becomes less efficient at slower speeds.

Below will be found a table which gives the number of revolutions per minute for specified diameters of wheels to cause them to run at the respective periphery rates of 5,000 and 6,000 feet per minute.

TABLE OF SPEEDS OF EMERY WHEELS.

Diameter of Wheel, inches.	R. P. M. for Surface speed of 5,000 feet.	R. P. M. for Surface Speed of 6,000 feet.
1	19,099	22,918
2	9,549	11,459
4	4,775	5,730
6	3,183	3,820
8	2,387	2,865
10	1,910	2,292
12	1,592	1,910
14	1,364	1,637
16	1,194	1,432
18	1,061	1,273
20	955	1,146
24	796	955
30	637	764

Experience has shown that for grinding work with fairly large diameter, better results are obtained by using a comparatively small wheel than by using one with too large a diameter. The explanation of this fact is that the wheel of smaller diameter clears itself faster from the work, while the larger one has a larger contact surface, and, therefore, the specific pressure between wheel and work becomes reduced, and the metal removed by the wheel stays too long a time between the wheel and work, and prevents the particles of the wheel from cutting properly into the work. The peripheral speed must, however, be the same for the smaller wheel as for the larger one.

Surface Speed of Work.

The proper surface speed of the work varies somewhat with the material and kind of work to be done. The grinding machine builders recommend 15 to 30 feet as a good average speed range for ordinary kind of work. For cast iron this can be slightly increased. The writer has had experience in grinding a very tough and hard steel (manganese steel), and has found the right surface speed in this special case to be as low as 6 to 8 feet a minute for rough grinding. For finishing grinding, the speed should be somewhat higher than for rough grinding. For delicate work the speed should be slow, because the work could easily be damaged by forced grinding.

As a general rule, for determining the surface speed for a certain kind of material, one can say that a brittle material, as cast iron, takes a high speed, while a tough and hard material, as the best tool steel, takes a slow speed. For grinding close to size and for high finish, the depth of the cut must be small, and higher surface speed can consequently be used.

Many of the grinding machines on the market are built so as to have the work revolving on two dead centers. This is done more for the sake of being able to obtain accuracy than for the sake of increasing the cutting efficiency of the machine.

Traverse Speed of Grinding Wheel.

The traverse speed of the grinding wheel should for ordinary grinding be three-fourths of the width of the wheel, that is, for one revolution of the work the wheel should travel three-fourths of the width of the face. If the wheel be traversed slower, the new cut is overlapping the old one more than necessary, and too large a part of the wheel is idle. It is, however, necessary that the new cut overlaps the old one with about one-fourth of the width of the face, because the edges of the face easily become rounded off, and, if the travel be too rapid, the result is an uneven surface.

The capacity of the wheel, within certain limits, of course, is proportional to the width of the face. A certain specific pressure between wheel and work is required for the highest cutting capacity. A wider wheel requires consequently a larger total pressure. But many of the machines now on the market are not rigid nor heavy enough to stand the pressure needed for a fairly wide wheel, cutting at full load, without vibration and chatter. The grinding machines on the market have not, in the writer's opinion, yet reached their full capacity. Wider wheels should be used, and the machines be designed and built heavier in order to take the load of the cutting wheel, without perceptible vibration of the machine.

For the final smooth finish, a slower traverse speed should be used, especially if the face of the wheel is not kept a perfectly straight line. A smoother surface is obtained by using a slower traverse speed. The part of the wheel which is overlapping, while theoretically it does not cut, still wears away the unevennesses left from the first cut, and, by this, to some extent polishes the surfaces.

While grinding a plain cylindrical piece of work, the grinding wheel should not be allowed to travel too far past the ends of the piece before reversing; it is only waste of time. The wheel should be reversed when three-fourths of its width is past the end of the work.

Depth of Cut.

The depth of the cut to be taken depends upon the material, kind of wheel, and of work done. It should be deep enough to permit the wheel to do its utmost. This is, of course, true only about pieces that are rigid enough to stand a heavy cut. The grinding operator himself will have to determine the depth of cut for each individual case, judging it by the prevailing conditions of work, machine, and wheel.

When the piece to be ground, owing to the hardness of the material, cannot be roughly finished by a cutting tool before being placed in the grinding machine for the final finish, there is often up to 3/16 inch on the diameter to be removed by grinding. Employing the same principle as when the piece is previously to the grinding operation roughly turned in a lathe, the work should first be put up in a machine equipped with a coarse and wide grinding wheel. A wheel of this kind is capable of removing stock rapidly. The piece should be finished to within about 0.005 inch of the finish diameter in this machine, and then moved to a machine equipped with a finer grain wheel, and the final finish given to it. A fairly high grade of economy is thus obtained.

The Grinding Wheel.

For heavy grinding, the alundum wheel is the best for removing stock rapidly. The carborundum wheel will give a smoother finish, and is to be recommended for the large majority of other classes of grinding. Emery is less abrasive, but gives a higher polish. Most grinding wheel manufacturers recommend their medium grade, *M*.

TABLE OF GRADE OF WHEEL TO USE FOR DIFFERENT MATERIALS.

Material.	Grit No.	Grade.
Soft steel — Ordinary shafts	24 to 60	Medium.
Soft steel — Steel tubing or very light shafts	24 to 60	Two or three grades softer than medium.
Tool steel or cast iron. ...	24 to 60	Medium or one grade softer.
Internal grinding	30 to 36	Medium or several grades softer.

The question as to what is the very best wheel for finishing any particular piece cannot be definitely answered. Above will be found a table, giving wheels which can with advantage be used in the cases mentioned. This table is recommended by one of the largest grinding machine manufacturers.

Grit No. 24 may be too coarse for any but rough classes of work, but if mixed with No. 36 it gives a fair result. No. 30 used separately is capable of a very fair commercial finish, but if mixed with No. 16 will give as fine a finish as is

desired by the majority of the grinding machine users, and at the same time it retains the rapid cutting capacity. Nos. 46 and 60 are as fine as is necessary for almost any manufacture, although finer than these are used by some concerns who require a very high gloss finish.

A satisfactory grinding wheel is an important factor in the production of good work. In machine grinding, it is desirable, in order that the cut may be constant, and give the least possible pressure and heat, to break away the particles of the wheel after they have become dulled by the act of grinding. It is the faculty of yielding to or resisting the breaking out of the particles which is called grade. The wheel from which the particles can be easily broken out is called soft, and the one that retains its particles longer is called hard. It is evident that the longer the particles are retained the duller they

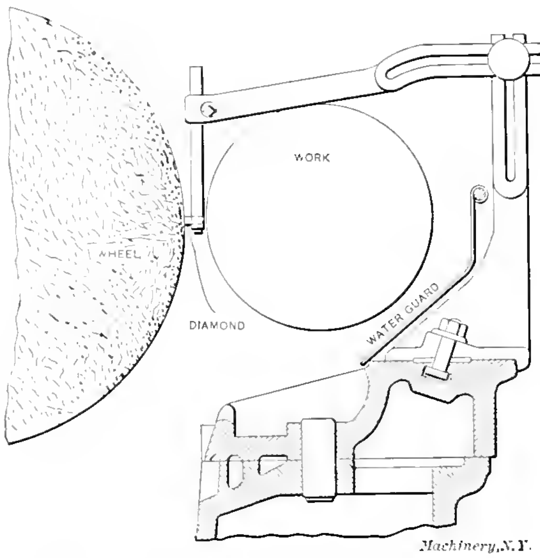

Fig. 1. Fixture for Truing Emery Wheel with Diamond

will become, and the more pressure will be required to make the wheel cut. Retaining the particles too long causes what is familiarly known as glazing. A wheel should cut with the least possible pressure, to effect which it must always be sharp. This is maintained by the breaking out of particles. Therefore, a wheel of proper grade cutting at a given speed of the work possesses "sizing power," or ability to reduce its size uniformly without breaking away its own particles too rapidly; obviously if the work is revolved at a higher speed, the particles will be torn away too fast, and the wheel will lose its sizing power.

The properties of toughness and hardness of the material to be ground has a retarding influence on the grinding because it makes the material stick to or clog the wheel. The ground-off material, instead of being thrown away from the wheel by the centrifugal force, gets in between the particles of the grinding wheel. It is self-evident that this has a greatly retarding effect on the cutting quality of the wheel. A brittle material, on the contrary, does not have the tendency of clogging the wheel, but the stock ground off is immediately thrown away from the wheel, leaving the particles free to cut without the retarding action of undue friction, and generation of more than the due amount of heat. If we take into consideration only these properties of the material to be ground, the tough or leady material requires a soft wheel, because the particles must break away fast enough to prevent the wheel from being clogged. In this case, the particles do not wear enough to become dull, but must break away before this. When grinding a brittle or hard material, on the contrary, the wheel is less liable to be clogged, the particles do not need to break away so soon, and, therefore, a harder wheel should be used. However, the wheel must not be so hard that the particles get too dull and become inefficient as cutting agents before they break away.

Importance of Wheel Running True.

In order to obtain the full efficiency of the grinding wheel, it must be run perfectly true; that is, cut evenly all the way around. The grinding wheel detects its own errors. A slight difference in the sparks indicates that the wheel is out of true. The eccentric wheel has about the same kind of action as the one which is vibrating because of too weak supports. Furthermore, the edge of the grinding wheel should be kept perfectly straight. If the edge be curved, however slightly, a curved cut will be the consequence. Many grinding machines give inefficient results because the edge of the wheel is not kept in a true straight line. The operator seldom appreciates the great importance of this, and, therefore, the foreman should watch the man closely in regard to this point.

The best tool for truing the wheel is the diamond, but, this being rather expensive for shops where not very much grinding is done, the usual emery wheel dresser can be used with good advantage. In truing the wheel, the dressing tool should be kept stationary and rigidly supported, and the wheel should be traversed back and forth, until the true edge is obtained. Fig. 1 shows a fixture and arrangement for wheel truing with a diamond.

Wet and Dry External Grinding.

Nearly all plain cylindrical grinding is now done wet. There are many reasons why the wet method is to be preferred to the dry. Because of the friction between the grinding wheel particles and the work, as well as between the cut-off material before it leaves the wheel and the work, more or less heat is generated. If this heat is not carried away, the work will be burned. Besides, the edge of the grinding wheel would be highly heated, but the center would still remain comparatively cool, the outer part would expand and there would be danger of the wheel breaking. It is found that the water has a softening effect upon the wheel, therefore a harder wheel is required for wet grinding than for dry.

Machines with Two Grinding Wheels.

The grinding machines on the market are equipped with only one grinding wheel, but there is no reason why two grinding wheels cannot be employed to advantage. In this case one wheel is to operate on each side of the work. As both of the wheels are to throw the sparks and the water down, one of the wheels has to cut with the revolving of the work, that is, the peripheries of the wheel and the work are going downwards. This is, of course, not the ideal condition, but, when the work is revolving at a slow peripheral speed, there is not much difference in the cutting capacity of the two wheels.

It is self-evident that, when employing two wheels, one at each side of the work and right opposite each other, the traverse speed of the wheels must be twice as fast as in the case of only one wheel, or three-fourths of the width of the wheel for one-half revolution of the work. Otherwise one wheel will overlap the cut of the other.

The two machines for external grinding which the writer has recently designed, and of which one is in operation and one being built, have two wheels working according to the principle previously described, and the machine already in operation is giving entire satisfaction. Fig. 2 gives an idea of the arrangement used on one of these machines. The principal features of the design can be studied direct from the cut without any further comments.

One new feature of these machines is that each grinding wheel is driven independently by a motor. This motor is mounted above the wheel spindle, and is belted directly to same. Special attention has been paid to designing the support of the motor in order to prevent the vibrations of the motor from being transferred to the grinding wheel.

Internal Grinding.

The development of internal grinding is not, by far, so advanced as that of external grinding. To be sure, there are a few machines and fixtures on the market that are designed and built for the internal grinding of holes of various kinds, but the machines suffer from lack of rigidity, and some of the most conscientious grinding machine builders do not recommend them very highly, but admit their inefficiency for removing any comparatively large amount of stock. It has even gone so far that one man holding a prominent position with one of the largest grinding machine manufacturing concerns in the country has said, that in his opinion, the internal

grinding machine is a mistake from start to finish, and that it will never be made a success.

This state of affairs has not come about without good reason. As we already have seen, the rigidity of the arrangement for supporting the grinding wheel is a very important factor for all efficient grinding. But the internal grinding machine does not very well lend itself to the employment of any rigid and heavy fixtures, and the grinding wheel must necessarily be small, and therefore lacks the strength to stand a heavy cut. The designer, when designing the fixtures for internal grinding, has an entirely different problem to solve than when designing those for external grinding, where it is comparatively easy to obtain ample rigidity. The internal grinding wheel must be mounted at the end of a small spindle which projects past the bearing far enough to enable the wheel to reach past the end of the hole to be ground. Such a spindle rotating at a high speed is liable to vibrate, especially if a pressure be applied at the end of it, as is here the case.

Sometimes, however, it becomes absolutely necessary to grind, internally, even a comparatively large amount of stock.

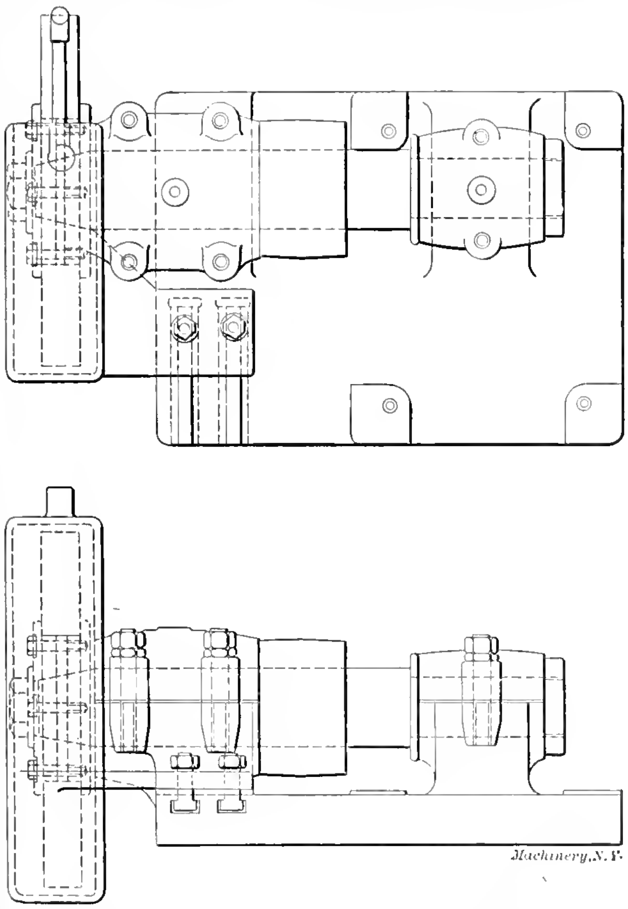

Fig. 2. Grinding Head for External Grinding Machine.

This is the case, when finishing manganese steel, this material being so hard that it cannot be cut by any kind of tool steel. Take the case of bores of manganese steel car wheels. As the grinding of the bores must be done without any stock having previously been removed from the rough casting, on the average, about one-eighth inch of metal must be ground off from the hole. All the errors in the cored hole, as eccentricity in reference to the circumference of the wheel, etc., must be corrected by grinding. A hole cored in a manganese steel casting is always comparatively much rougher than a hole cored in cast iron, and all this must be taken into consideration, when determining the amount of stock to leave for the grinding process.

The old method for finishing the bores of these wheels was to cast an ordinary steel bushing in the hole. This then was bored in the usual manner in a lathe or boring mill. But this method had several objectionable features, and, besides, it was too expensive.

Design of Fixtures for Internal Grinding.

The fixture used in the internal grinding machine designed for grinding these wheels is shown in Fig. 3. Internal grinding fixtures, generally have a long extension bearing, as shown in Fig. 4. This serves to support the spindle as near to the grinding wheel as possible; but the diameter at the root of this extension, that is, nearest to the box, cannot exceed the diameter of the grinding wheel.

The spindle, shown in Fig. 3, is made solid, and has the largest diameter possible for the size of the grinding wheel. An increased amount of rigidity and a greatly increased simplicity is gained by this design.

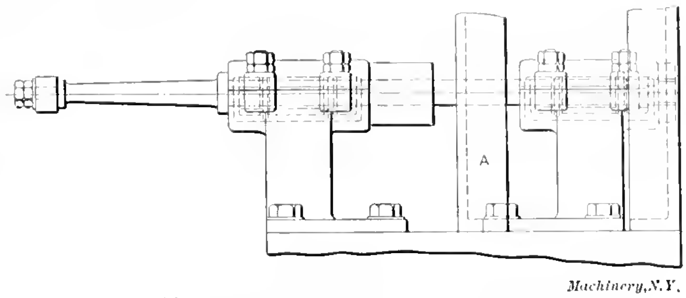

Fig. 3. Grinding Head for Internal Grinding.

When working, the grinding wheel produces, especially in dry grinding, very much dust. When inside a hole the dust cannot very easily get away, but whirls about in the hole. If the spindle has a bearing near to the grinding wheel, the dust will find its way into the journal. This drawback is entirely eliminated by having a large solid spindle without a bearing near to the grinding wheel.

As to the relation between the overhanging part of the spindle and the distance between centers of the boxes, there are many factors that come into consideration in regard to this relation, such as the design of the boxes, the diameter of the spindle, how close the spindle can be allowed to run in the boxes, etc. However, the distance between the centers of the boxes should be made as large as the general design conveniently permits.

The cut shows at *A* the support for the motor. This support is placed on the top of the top rest. The driving pulley is placed between the bearings, so that the support could be made as rigid as possible.

It was found by actual experience with these fixtures, that when the grinding wheel was taking a fairly heavy cut the spindle did not vibrate nearly so much as when the wheel was running idle. The springing quality of the spindle, and the pressure between work and wheel, made the wheel cut without any chattering worth mentioning.

Regarding the peripheral speed of the grinding wheel, what has already been said with reference to external grinding is equally applicable to internal grinding.

Because of the lighter fixtures the speed of the work should be slower than for external grinding. The writer has found the right cutting speed for manganese steel to be, for heavy grinding, about seven feet a minute. For the finishing, the speed can, with advantage, be somewhat higher. Because of the combined hardness and toughness of this steel, the cutting speed is exceptionally low in this case. Regarding the

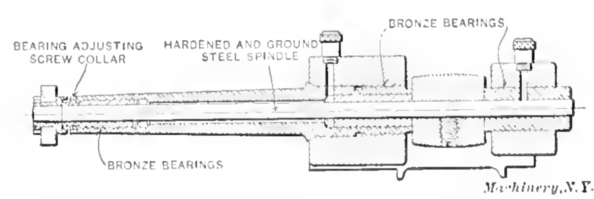

Fig. 4. Common Construction of Grinding Heads for Internal Grinding.

traverse speed of the wheel, it should travel three-fourths of its width for one revolution of the work, the same as for external grinding.

Wet and Dry Internal Grinding.

One point that has been much discussed in regard to internal grinding, is whether it shall be conducted wet or dry. Some grinding machine designers have advanced the opinion that it, by all means, must be done dry, but others claim the wet method to be superior. For light finishing grinding one method might be considered as good as the other, because so small an amount of heat is generated that there is no danger of burning the material or breaking the wheel. But, for

heavier grinding, a considerable amount of heat is generated, and it becomes necessary to carry it off by water. At least, such is the writer's own experience on this subject. At a test recently conducted to find out the actual difference between dry and wet internal grinding, it was found that the cutting quality of the grinding wheel was about the same in both cases, but, with a heavy feed and dry grinding, the work was highly heated, and the wheel broke after about half an hour's run, while, with wet grinding, the wheel stood the heavy cut continuously without breaking.

The water can be injected into the hole in a stream about one-sixteenth inch in diameter. In addition to carrying away the heat, the water serves to wash away the removed stock from the hole.

The writer conducted, a short time ago, a test on the above mentioned internal grinding machines, in order to find out and supply the sales department with a figure of the time required to grind the bores of a certain kind of manganese steel car wheels. Two different kinds of wheels were tested. The first one, a 20-inch diameter wheel, had a bore 2⅞ inches in diameter and 5⅞ inches long, and it was to be ground for a press fit. The second one, an 18-inch diameter wheel, had a bore 3¼ inches in diameter and 4½ inches long, and was also to be ground for a press fit. Four wheels of each kind were ground during the course of the test, and it was found that the actual time for the grinding operation, not including the time required for putting up the work in the machine, was, for the first kind of wheels 1 hour and 23 minutes for all four, and for the second kind, 1 hour and 9 minutes for four wheels. Considering that the bores of the wheels were not previously turned, but entirely rough, as the wheels were taken directly from the foundry, and considering the hardness and toughness of the steel, the results obtained were considered good. The time of putting up the work in the machine was about 6 to 8 minutes for each wheel. As the machines work automatically, one man is able to run three machines. Counting 8 minutes for the putting up of each wheel, the man is able to grind one wheel in 30 minutes of the first kind, and one wheel in 26 minutes of the second kind.

The work was revolved at a speed of 7.7 revolutions per minute. This makes a peripheral speed, for the first case, of 5.8 feet a minute, and for the second case, of 6.6 feet a minute. The grinding wheel used was a 2-inch diameter, 1-inch face, No. 46 grit, O grade alundum wheel. It was run at a speed of 4,750 feet a minute.

The traverse speed of the work was as high as 0.84 inch per revolution of work. This allowed the wheel to overlap the old cut by only 0.16 inch but, as the grinding wheel was trued very carefully, this was found to be all there was required for obtaining a nice smooth surface. The traverse feed was not slowed down, but remained the same while doing the final finishing, and a very satisfactory finished hole was obtained. The test was made throughout with wet grinding.

For heavy cylindrical grinding, that which I especially referred to, the width of the wheel used varies between 1½ and 2½ inches, regardless of the diameter. In some special cases narrower wheels than 1½ inch are used, but these special cases are exceptions to the general practice, and must be recognized as such by the machine builders and users. Although larger wheels are used, it is my opinion that the best range of diameters of wheels is between 12 and 18 inches. For how wide a wheel the grinding machine in the future can be designed, has yet to be decided; but, wider wheels and heavier machines point the direction of the road which the designer and machine builder should follow for the development of the grinding machine.

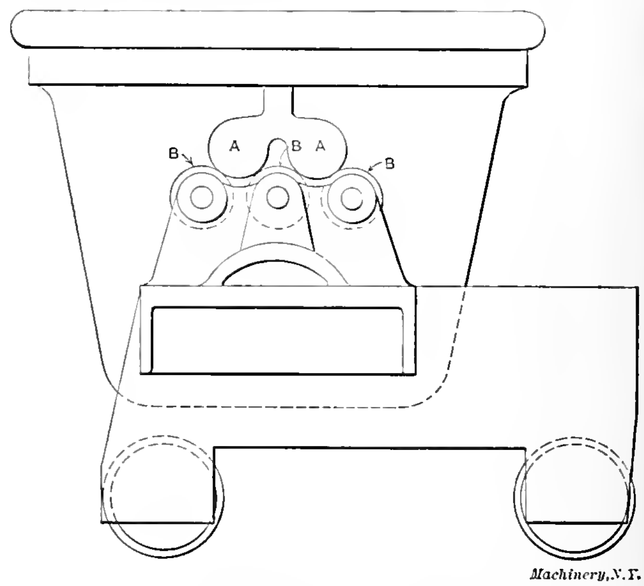
* * *

The output of the world's shipyards for the year 1907 was 1,930 vessels of over 100 tons displacement, with an aggregate of 3,099,299 tons. The tonnage of the vessels built in the United States amounted to 474,675 tons, which is 33,400 tons greater than the output for the previous year. Of the total tonnage of the vessels built in this country, considerably more than half was constructed for the Great Lakes.

ITEMS OF MECHANICAL INTEREST.

UNIQUE BEARING FOR END-TIPPING SLAG LADLE.

Another interesting application of roller bearings is shown in the diagrammatical sketch, herewith, of an end-tipping slag ladle made by the Dewhurst's Engineering Company, Ltd., Attercliffe Road, Sheffield, England. In this design double trunnions *A* are cast on each side of the ladle, and are located slightly above its center of gravity so that the ladle will right

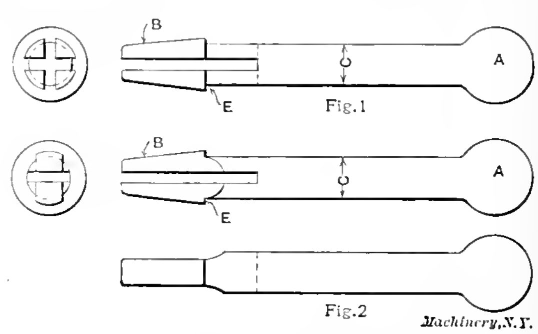


End-tipping Slag Ladle with Roller Bearings.

itself from any point to which it may be tipped. Roller bearings *B* are provided on the carriage on which these trunnions rest, and this greatly reduces the power required for tipping, as the trunnions roll easily along the surface of the rollers. The principle exhibited is a very interesting one, and shows how simple means may be adopted for solving a rather difficult problem of machine design, and indicates the possibility of the efficiency of the least elaborate devices which are not likely to get out of order, and which hardly need any attendance whatever.

SUBSTITUTE FOR COTTER PINS.

The accompanying cut shows an interesting little appliance, used instead of the common split cotter pin. The pin shown is manufactured by a Swedish firm, Aktiebolaget Bofors-Gullspang, Bofors, Sweden. Its simplicity and general usefulness of application seem to warrant that attention be called to it. As will be seen, the pin in Fig. 1 simply consists of a round piece of stock, provided with a ball-shaped head *A* at one end, and a tapering head *B*, at the other, the corner *E* being quite sharp. The pin is split, as shown, crosswise, so that when pushed into a hole, it will spring sufficiently to



Figs 1 and 2. Showing Pins which take the Place of the Common Split Cotter Pin.

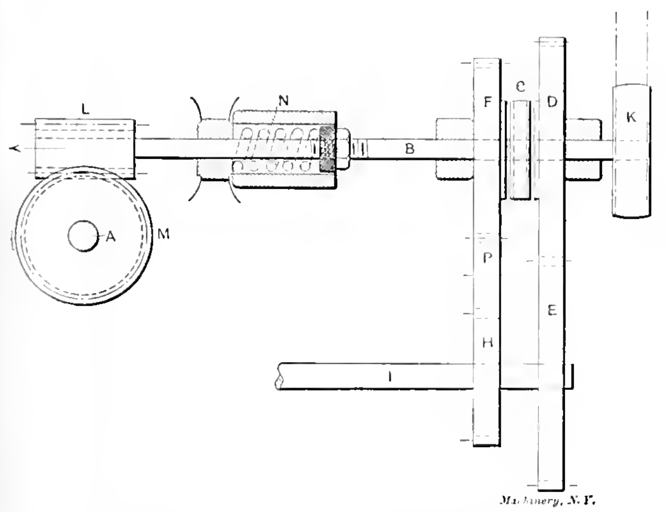
permit being pushed through, but as soon as part *B* has passed through the hole, it will spring out again, and on account of the sharp corner at *E*, it is not possible for the pin to slip out of the hole again, excepting if a special tool (a socket with a hole in it of the same diameter as the body *C* of the pin) is applied at the end to force the prongs together, so as to make the head small enough to enter the hole. These pins are also made by simply having one slot through them,

and then flatted on the two sides a trifle below the diameter of the central portion C, of the pin, as shown in Fig. 2. In applying these pins, nothing is necessary but to put the tapered end into the hole, and gently press with the hand on the top of the head A, until the pin is in place.

DEVICE FOR ADJUSTING THE FEED OF A ROTATING CUTTING TOOL IN PROPORTION TO THE WORKING PRESSURE.

The *Zeitschrift für Werkzeugmaschinen und Werkzeuge*, shows, in its issue for December 5, 1907, an interesting mechanism for automatic adjustment of the feed in proportion to the working pressure on the cutting edges of a rotating cutting tool. The principle of the device is shown in the diagrammatical view in the accompanying cut. This device is intended to make it possible to automatically throw out the feed, when the pressure on the cutting edges of the tool becomes heavier than normal, and to completely reverse the feed in case this pressure still continues to be abnormally high when the feed is thrown out.

Referring to the cut, A represents the spindle of the machine to which the cutting tool, say a drill, is attached. This spindle is driven through worm gear M and worm L from the driving shaft B, which, in turn, receives its motion from the counter-shaft through the belt on pulley K. The driving shaft B is free to move in its axial direction, within certain limits. The clutch C is keyed to the shaft B, so that it will rotate and also move axially with the shaft. On each side of clutch C gears D and F are mounted on shaft B, in such a manner that they remain stationary in the axial direction. These gears are not keyed to the shaft B, but turn freely, and motion is imparted to them from clutch C, one of the gears being engaged at a time. The sides of gears D and F, which face toward the clutch C, are themselves provided with clutch teeth, so that the clutch can engage with either of the gears. The gear D in turn engages with gear E, on the feed-shaft I, so that if clutch C is driving gear D, motion will be imparted to the feed-shaft I, and the tool will be fed forward. If, again, the clutch disengages gear D, and



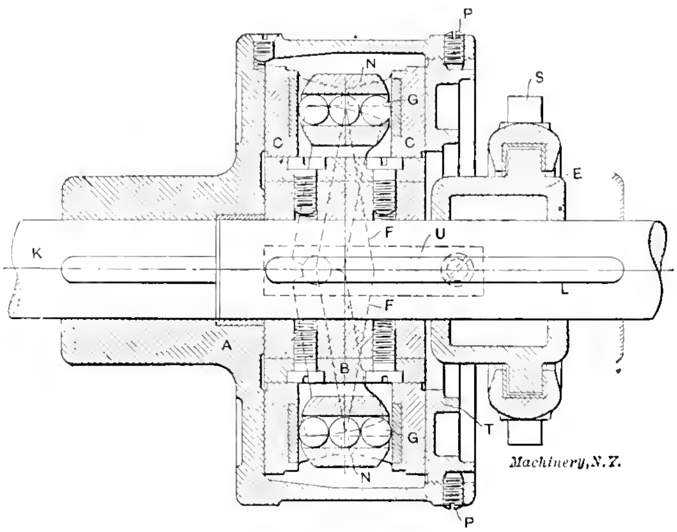
Diagrammatical View of Device for Automatically Adjusting Feed in Proportion to Pressure on Cutting Edge of Tool.

occupies a neutral position, no motion whatever will be imparted to the feed-shaft I. If, again, clutch C engages with the gear F, then the feed-shaft I will be driven through an intermediate gear P and gear H, thereby reversing the motion of feed-shaft I, as compared with the direction when receiving motion directly through gears D and E.

The engagement or disengagement of the clutch C with the clutches on gears D and F is accomplished as follows: Spring N is, through the nuts shown, adjusted to the proper tension, so that it will normally hold the driving shaft B in such a position that clutch C engages with the clutch on gear D, when, as we have seen, the feed shaft feeds forward. In case the load on the cutting edges of the tool should exceed the normal load, however, the worm-wheel will exert such a pressure on the teeth of the worm as to pull the worm in the direction of the arrow, shown at the end of the worm, thereby compressing the spring N, and pulling the clutch C out of engagement with the clutch on gear D. Clutch C then takes a central position and the feed is stopped. Should the resistance to the rotation of the cutting tool still continue to be strong enough to compress the spring still further, the clutch will enter into engagement with the clutch on gear F, in which case motion will be transmitted to the feed-screw I through the gears P and H, as mentioned before, which then reverses the feed motion.

HAEBERLIN FRICTION COUPLING.

The accompanying cut shows an interesting and ingenious friction coupling for transmitting power from one shaft to another, if these are situated in a straight line with one another. Of course, the design may be applied to almost any kind of a friction coupling, if suitably modified. If we assume that the shaft K is the driving shaft, and the shaft L the driven shaft, power is transmitted from the one to the other through the medium of rollers G. The construction is, briefly, as follows: The flanged sleeve A is keyed to the shaft K, but is independent of the shaft L. To the outside of this sleeve, a pulley, spur gear, or other means for trans-



Friction Coupling of Ingenious Design

mitting power, may be attached. The action of the device, of course, is the same whether the shaft K or the shaft L is the driving shaft.

The driver B is attached to the shaft L and is also keyed to friction disks C C, so that if the friction disks are actuated by the power, and rotate, they will carry with them the driver B and the shaft L. The friction disks C rotate with the sleeve B, but are still free to move in a longitudinal direction. The opening of the sleeve A is closed at the right-hand end by the cover T, which is prevented from turning by the set-screws P. The threads on the cover permit a fine adjustment, so that the inside width of the sleeve, between the outside of rings C, can be adjusted within very small limits, and the transmission of power can thus be controlled.

The characteristic feature of this design is to be found in the simple and practical mechanism for producing pressure on the friction disks C, so that these will be carried around with the sleeve A and its cover T. This arrangement consists, in general, simply of two levers N, provided with hardened steel rollers G. When the mutual center line of these three rollers is parallel with the axis of the shaft, which is the case when the coupling is in the driving position, then the distance between the friction disks C, and also the pressure on the friction surfaces, are the greatest. When the levers N, by pulling out sleeve E, which is attached to the ring S for its operation, are pulled from the position shown, and brought into the position indicated by the center lines F, shown by the dotted lines, the center lines through the rollers G will form an acute angle with the axis of the shaft, and the pressure between the surfaces C C and the sleeve A or the cover is released. The link u combines the sleeve E with the levers N, which are operated through this connection. These friction couplings are made by Düsseldorfer Maschinenbau-Aktiengesellschaft, Düsseldorf-Grafenberg, Germany.

REGISTERED IN UNITED STATES PATENT OFFICE.

DESIGN—CONSTRUCTION—OPERATION.

PUBLISHED MONTHLY BY

THE INDUSTRIAL PRESS,

49-55 LAFAYETTE STREET, CORNER OF LEONARD, NEW YORK CITY.

Alexander Luchars, President and Treasurer.
Matthew J. O'Neill, Secretary.

Fred E. Rogers, Editor.
Ralph E. Flanders, Erik Oberg, Franklin D. Jones, Associate Editors.

The receipt of a subscription is acknowledged by sending the current issue. Checks and money orders should be made to THE INDUSTRIAL PRESS. Money enclosed in letters is at the risk of the sender. Changes of address must reach us by the 15th to take effect on the following month; give old address as well as new. Single copies can be obtained through any newsdealer.

We solicit communications from practical men on subjects pertaining to machinery, for which the necessary illustrations will be made at our expense. All copy must reach us by the 5th of the month preceding publication.

APRIL, 1908.

PAID CIRCULATION FOR MARCH, 1908, 22,507 COPIES.

MACHINERY is published in four editions. The practical work of the shop is thoroughly covered in the Shop Edition—$1.00 a year, comprising more than 430 reading pages and 36 Shop Operation Sheets, containing step-by-step illustrated directions for performing 36 different shop operations. The Engineering Edition—$2.00 a year, coated paper $2.50—contains all the matter in the Shop Edition, including Shop Operation Sheets, and about 250 pages a year of additional matter, which includes a review of mechanical literature, and forty-eight 6 x 9 data sheets filled with condensed data on machine design, engineering practice and shop work. The Foreign Edition, $3.00 a year, comprises the same matter as the Engineering. RAILWAY MACHINERY, $2.00 a year, is a special edition, including a variety of matter for railway shop work—same size as Engineering and same number of data sheets.

DIVIDENDS AND FOUL AIR.

If there is in the dictionary a stronger word of its kind than "asinine," we would like to use it to describe the mental caliber of those responsible for the heating and ventilating arrangements in some shops and drafting-rooms with which we are acquainted. In the absence of a stronger word, perhaps the one we have used will do. Good air and an equable temperature have come to be recognized as necessary to the proper accomplishment of physical or mental labor, and the neglect of these provisions is the exception rather than the rule; but there are still shops in which the proprietor handicaps his workmen and diminishes his own profits by the unsanitary condition of his plant.

We were reminded of this recently by a visit to a large drafting-room, connected with a plant the responsible heads of which are surely old enough to know better, and prosperous enough to act on their knowledge without even temporary financial embarrassment. The air was thick and heavy and foul, and listlessness and sluggishness were apparent everywhere in the faces and actions of the draftsmen. It would seem as though a single clear-eyed glance at the room and its occupants (assisted perhaps by an analytical sniff of the tainted atmosphere) would have been enough to show the proprietors on which side their bread was buttered.

* * *

AN ASPECT OF PATENT RIGHTS.

The daily newspapers recently gave considerable space to an alleged wonderful improvement in firearms, made by the son of a well-known inventor of rapid-fire guns. The invention is in the nature of an automatic valve placed transversely in the barrel near the muzzle, which is required to close immediately following the passing of the bullet so as to divert the gases to the atmosphere through small side openings. The object is to prevent the sudden expansion of the gases, and thus render the firing of the piece noiseless. The principle of action is somewhat similar to that of the gas engine muffler in breaking up and dispersing the gases, and so destroying the sharp reports of the explosions.

An examination of the patent specification (No. 880,386) discloses a curious fact. The invention is covered by a basic patent of twenty-three claims, but it is, as described and illustrated, practically inoperative. In fact, we very much doubt the practicability of the idea as outlined by the inventor—for one reason, because of the inertia of the necessary moving parts, but the patent has suggestive value and it may eventually lead to the solution of the problem. The field for following inventors is what we are concerned about.

The patent is basic, and no matter how ingeniously some really practical intercepting valve scheme for rendering firearms noiseless is worked out, its inventor is barred from its use by an impracticable invention which has been awarded basic claims. To say the least, this seems unfair to future genius. It is not quite just, that, because an inventor had a lucky thought, but apparently not the ability to devise a working model, he should be given such sweeping rights. It is analogous to giving the discoverer of a new country title to all the land that he found, simply because he first saw it. The simplest general remedy for such abuses in patent practice would appear to be to limit the life of all patents to a short period, say two or three years, provided the inventor does not reduce his invention to actual working shape, and then enter into its manufacture. Such a provision of patent law would also tend to discourage the buying up of patents by corporations to stifle competition.

* * *

THE ESSENTIAL AND UNESSENTIAL.

When an industrial plant grows, so that the final product is lost sight of in the production of each detail, it is a great temptation to forget the relation between one's own work and the final result arrived at. The essential feature in producing a machine is that it shall possess productive qualities when placed in the hands of the user. The drawings for the machine, for instance, are only a means to an end, and are essential only inasmuch as they aid the economical and accurate making of the machine. The outside finish and polish of the machine is not essential in itself, excepting as it aids in attracting customers who may not be able to judge so much of quality as of appearance.

The whole shop system of a plant is unessential in itself, and is of value only to the extent to which it aids the production. Yet—and here is the fatal danger in the growth of a large undertaking—when we get used to certain ways of doing work, and to certain shop systems, these seem essential in themselves, and the final end of the work is lost sight of. A draftsman finishes his drawings without judgment as to the actual purpose of his work. He lays down a great deal of work on fancy lettering and wonderful border lines, when these things are entirely unnecessary for the purpose of the drawing. A simple, correct, distinct drawing, giving the directions for the work in a clear-cut manner, is the best drawing, no matter if it looks plain to the artistic eye. The same is true of the shop and its methods. A certain foreman has a hobby that all parts shall be finished in a certain way, regardless of the final use of the part made. Many of the men get into the same habits; they complete their details of the machine often not with a view to the ultimate object of the work, but simply thinking of delivering a "nice job" to the next department. The tool-maker is, in common with the draftsman, often the worst offender. Jigs and fixtures are finished all over, an entirely wasted amount of work is laid down on dimensions not essential, and the work, while carefully done, does not show good judgment.

The success of an individual as well as of a firm depends largely on this judgment of essential and unessential features of work. Careful work does not mean unnecessary work. The greatest care should be taken with the necessary parts, and no time wasted which involves a useless expense. It is gratifying to see that our latest designs of machine tools show no machined surfaces excepting the working surfaces. Fifteen or twenty years ago many machines were practically finished all over, excepting the bed and legs, and this involved a double waste of labor as it increased the work of keeping the machines clean. The tendency of to-day is toward greater economy by means of *new methods*, but there is a great deal to be gained in the *elimination of the waste of the old methods* as well.

COMPRESSED AIR VS. ELECTRICAL TOOLS.

A great deal has been written in the engineering press regarding the relative superiority of compressed air and electricity for driving portable machine tools. Some writers have attempted to prove with figures and calculations that electricity is the cheaper, while others have presented arguments equally good on the face that compressed air is the better of the two motive powers. Very likely, however, an unbiased view of the subject would disclose the fact that either the one or the other of the motive powers may, at times, be the preferable one. For such purposes as riveting and calking, the use of compressed air is a foregone conclusion, but for almost all other small portable tools, electricity has gained on compressed air in popularity. It cannot be denied that in point of weight, the compressed air motor has advantages over the electric motor. The electrically-driven tools, are, as yet, considerably heavier, and their repair bills are higher than for their pneumatic competitors. The electric drive, however, is more efficient. Some experiments carried out by an English engineer indicate that 1¾-inch holes drilled in steel would take only 2 horse-power at the dynamo, while a compressed air drill on the same size of hole, at the same speed, takes 9 horse-power at the air compressor, so that the use of compressed air for motive power is rather more expensive, even if the repair bills for the electric tools are, say, twice as heavy as for pneumatic appliances. It seems then, in general, that the electric motor possesses advantages over its competitor, but in establishments where riveting and calking have to be done, compressed air is able to hold its own. There are in the market some fairly good electric riveting machines, but they do not possess the convenience and portability of the pneumatic hammer. In shops where an air compressor is required for some pneumatic tools for the purposes mentioned, it may be advantageous to use the air for other operations as well.

RAPID LOCOMOTIVE TIRE TURNING.

The development of powerful locomotive driving-wheel lathes during the past few years is well worth attention. The time when it required from one and one-half to two days to turn a pair of locomotive driver tires is not long ago, and to most of us it seems but yesterday when the turning of a pair of hard tires in four or five hours was considered a feat worth mention. The advent of high-speed steel revealed the general inadequacy of machine tools in power and rigidity, and the driving-wheel lathe was one of the first machines to be re-designed so as to work the new tool steels to the limit of capacity. What is the result? Within the past three years we have seen the notable exploit of turning ten completely finished pairs of locomotive tires in ten hours, or at the rate of one pair per hour. This feat has since been outdone, and now it appears commercially possible to turn a pair of badly-worn tires for, say, 56-inch wheel centers, in forty minutes, counting in the time required for putting in and removing the wheels from the lathe.

But there is quite obviously a chance for further reduction of time, if we are willing to provide still greater power and strength in the lathe. At the present time, the tire is broken down with a round-nose roughing tool which removes the worn tread and the top of the flange. Then follow three forming tools, the first removing the corners of the flange, the second forming the flange and the tread, and the third forming the outer coned part of the tread and rounding the edge.

These forming tool cuts require enormous driving power, but progress will require that the operations of turning a tire shall be reduced to two, these being the roughing cut made by round-nose tool, and the finishing operation, which will be done by a broad-faced tool of exact contour of the tire, forming the tread, edge and flange to the required shape all at the same time. The immediate objections raised will be the great power required of the lathe and the expense of keeping up the forming tools. The first objection will be valid so long only as it can be shown that the interest on the increased investment is not more than offset by the greater earning capacity, and the second objection already has been met by the proved durability of existing tire forming tools. When it can be shown that a forming tool will last for some weeks of constant use, its economy is proved.

With the two-operation wheel lathes fully developed, we may expect to see 60-inch tires turned in twenty minutes, counting the time required for putting in and removing the pair from the lathe. We fully expect to see twenty pairs of average locomotive tires turned in a day of ten hours. This will be increasing productive capacity with a vengeance. The first question that the individual thinks of is: "What good will it do labor?" That question is one that the twentieth century must answer.

* * *

ECONOMY OF NON-PRODUCTIVE LABOR.

It seems difficult for many persons in charge of industrial undertakings to comprehend that so-called productive labor, *i. e.*, labor directly or manually engaged in making the actual product sold, is not the only part of the organization actually profitable or productive. While, of course, it is recognized that the non-productive labor is a necessity, it is by a great many considered as a necessary evil, and any contemplated increase of a non-productive department is viewed with distrust and with the fear that its expense may mount so high as to devour the profits of the productive departments. An example of substantial economy effected by increasing the "non-productive" labor cost may be cited.

In a certain shop, where a great part of the work consisted in making certain tools to order, the customers ordering such tools often simply sent in samples, and requested that one or more tools be made exactly like the sample. The manufacture was of such a varied character that often many different machine operations were performed before the parts were finished, so that they had to pass through, say, six or seven different departments before completion. It was the custom, until lately, to send these samples directly into the shop, without making any drawing or sketch from them, and to let the men work directly to the samples, reproducing them as closely as possible. It is evident that, as the sample passed from department to department, the same dimensions were measured over and over again, perhaps half a dozen times. If the machinist working on the parts did not note down the dimensions at the time when measured, it might occur that each machinist working on a part had to measure the same dimension two or more times. The waste is evident; still, the time was charged as *productive* labor.

Later, somebody suggested that the proper thing would be to hire one more draftsman who would make sketches of all these samples, as they came in, and to have another man check the figures on the sketches from the samples before the sketch was sent in the shop. This necessitated that each tool be measured twice. The sample tool was then sent with the sketch into the shop, but the machinists were required to work to the sketch, the sample merely giving them an idea of the general appearance of the tool required. Now, the additional cost of another draftsman and the cost of checking by a more expensive man was, of course, charged as *unproductive* labor, and considered practically as a loss, but there is no doubt that a great saving was accomplished on each particular tool sketched up in this manner, inasmuch as the necessity of measuring the sample in every department, and in some departments several times, was avoided. At the same time, many mistakes that had previously occurred when one man had measured the sample and then worked to an incorrect figure, were also avoided by the checking before the sketch of the sample left the drafting-room. A permanent record of the tool made was also provided by this method.

The system referred to, is one of the very simplest kind, of course, but it is undoubtedly true that in hundreds of different cases the same principle can be applied in a great many shops to-day. Work is constantly done in a wasteful way by so-called productive labor, which, if properly systematized, could be done by so-called unproductive labor in less time, with greater accuracy, and with the possibility of saving considerable in the running shop charges. Let it not be forgotten then when men running machines do "unproductive" labor, their machines are idle, but the interest account on the cost of these machines runs along just the same.

ENGINEERING REVIEW.

CURRENT MECHANICAL EVENTS—LEADING ARTICLES OF THE TECHNICAL PRESS.

According to the *Mechanical World*, the Marconi Wireless Telegraphy Co., on February 3, commenced to accept messages from the public for transmission between London and Montreal. The charge is 15 cents a word, including land rates.

Notwithstanding the financial depression which prevailed during the last months of the past year, the trade and industry of the United States during 1907 exceeded all previous records. According to a table of summaries issued by the Bureau of Statistics, the production of anthracite and coke pig iron in 1907 exceeded 25,315,000 tons, while in 1906 the figure was 24,808,000 tons. Shipments of all kinds of products in nearly every case exceeded by from 5 to 12 per cent those of the previous year.

In the January issue of MACHINERY, engineering edition, we mentioned that the German government has taken considerable interest in the question of airships. How serious this interest really is is shown by the fact that, according to *Engineering*, the German Reichstag, after having granted the sum of $125,000 for the erection of a balloon shed, and for other incidental expenses, has made another supplementary allowance of $100,000 for the building of a second airship for experiments.

Not only is the large Krupp Works, in Essen, Germany, the largest industrial establishment anywhere in the world, but it also appears to be one of the best paying of all large industrial undertakings. It is reported that the dividend for the year 1906-7 was maintained at 10 per cent, the same as the year previous, the net profits for the year amounting to $6,250,000, after taxes, interest and all similar expenses had been paid. The capital of the concern was increased, during the year, from $40,000,000 to $45,000,000.

An interesting method, taken from a German source, for sharpening files when worn is given in *Industritidningen Norden*. The file is connected with the positive pole of a battery, consisting of 12 Bunsen elements, and is then placed in a bath consisting of 40 parts sulphuric acid, to 1,000 parts water. The negative electrode consists of a copper wire, coiled in a spiral around the file, but not touching it. The file is then exposed to the action of the current for about ten minutes. It is stated that files treated in this manner can be sharpened so that they are nearly as good as new.

An International Industrial Exhibition is to be held at Toulouse, France, beginning May 1, and continuing until September 20, 1908. American firms are invited to exhibit, and the directory of the exhibition has offered to undertake to receive their exhibits, and to send them back at the end of the exhibition. Applications for admittance are to be made either to the American Consul, or to the Directory of the Exhibition (Commissariat-General, Exposition Industrielle, Toulouse, France). The goods will be transported back to the French sea-port, free of charge, by the French railway companies.

A practical test of reinforced concrete to determine whether it is safe to remove the forms and supports, was, according to *Engineering News*, given by Mr. C. A. P. Turner, in the course of an address to the Northwestern Cement Products' Association, at Chicago, Ill. The speaker said that it was difficult to formulate a comprehensive rule, covering the variable conditions entering into the problem of the setting of concrete, but it is easy to demand that concrete not frozen shall be set sufficiently hard, so that, if tested by driving a 20-penny wire spike into it, with an ordinary carpenter's hammer, the spike shall double up after penetrating approximately one inch, and if the concrete is not sufficiently good to withstand this test, after having had ample time to set, it is not good enough to remain and do business in a structure that may be deemed safe.

The *Engineering Record* mentions some interesting tests which have been made by Mr. A. E. Outerbridge some time ago for establishing the amount of swelling of cast iron by subsequent heating and cooling. These tests proved that it is possible to increase the volume of cast-iron bars as much as 40 per cent. A bar measuring one inch square by 14 13/16 inches long was heated in a gas furnace to 1,450 degrees F., and then cooled 27 times, after which careful measurements showed that the bar had increased in length to 16½ inches, and to a cross section 1⅛ inch square. Further heatings, however, increased the size of the bar only slightly. As this action is identical with the action of cast iron in super-heating steam fittings, it is quite generally thought that the difficulties experienced with such fittings are direct results of the many variations of temperature rather than the high temperatures themselves.

It has been stated by several authorities that high-speed steel milling cutters are not very successful in cutting hard materials. Messrs. Armstrong's Arms factory, England, however, constantly employ high-speed steel milling cutters for cutting nickel-chrome steel armor-plate, using a cutting speed of 75 feet per minute. Experience with high-speed steel cutters, used for cutting the teeth of gears for motor cars, which are made of a very hard material, putting a severe strain on the cutters, has shown that, under such circumstances, high-speed steel milling cutters will last three and one-half days, without grinding, as compared with one day when ordinary carbon steel milling cutters are used, and at the same time, the feed per revolution could be increased 1/3, so that the high-speed steel cutter, in addition to cutting at a higher speed, and lasting a greater length of time, without being ground or recut, would stand a greater strain as well.

An Italian correspondent to the *Times Engineering Supplement* states that at a meeting of naval and mechanical engineers, held in Genoa early this year Signor L. d'Adda, an Italian naval engineer, presented a proposition for the protection of armored war vessels with reinforced concrete instead of steel plates. This system, he stated, has been used with excellent results for land fortifications. While following the operations of the Russo-Japanese war in the Far East, he had been impressed by the resistance offered by reinforced concrete against heavy projectiles. The weight of plates made of this material would be about the same as of plates made from steel, and the space required was not more than of a metal armor, while the cost would be very considerably less. It is stated that the Ministry of Marine of Italy has directed that some of this concrete protection shall be thoroughly tested at one of the naval stations.

In a paper, read some time ago, before an English engineering society on the subject of illumination, the speaker called attention to the false economy of requiring people to work by poor light. In comparison with the cost of labor, the cost of light is but trifling. He took the illustration of a man receiving from $2.00 to $2.50 a day, or about 25 cents an hour, and compared this labor cost with the cost of a 16 candle-power lamp, burning 10 hours, which he estimated to be only about 1½ cent. Yet there are thousands of skilled mechanics, who are handicapped in their work by insufficient and ill-directed light. In the case of bad light in a factory or shop, the personal inconvenience caused thereby means a reduction both in the quality and quantity of the output, thus producing a loss, in comparison with which the cost of illumination is trifling. One must bear in mind that most men, engaged in mechanical work, are guided almost exclusively by the sense of sight, and the importance of furnishing good illumination ought to be apparent, although it cannot be denied that this question, in many cases, is sadly overlooked. To furnish up-to-date machinery and tools, to pay good wages for skilled labor, and then to handicap the men by insufficient, or improperly placed, light, ought to be so apparent a fallacy that it would hardly be necessary to call attention to it.

The following interesting information regarding the influence of variable load on iron beams, is taken from *Industritidningen Norden*. It is usually assumed that variable load, that is, continued loading and unloading of iron beams, diminishes their strength, but it is claimed that at the laboratory for the testing of materials in Grosslichterfelde, near Berlin, it has been found that this assumption is not based on actual facts. On application of a department of the Government Railroads, 24 beams taken from an old railway viaduct, which had been built in 1856, were tested. Investigations were made to establish the relationship between the original and the present strength of the iron, by comparing the beams from the heaviest loaded and the less heavy loaded portions of the bridge, and also by comparing the strength of two identical parts of the same beam, of which one had been annealed, while the other had been left in its original condition. As is well known, the reduced strength and elasticity of iron, caused by too heavy stresses, can be regained by annealing. If then, by the variable load, the strength of the iron had been reduced, the annealed beams would have shown a greater strength, when tested, than those which had not been annealed. The testing of the strength of the materials, however, showed that the strength of the iron had not been decreased by the variable load, which, for 51 years, had been applied to the bridge. On the other hand, in nearly all cases, it was proved that the parts which had been most heavily loaded showed greater strength than those which had been exposed to less heavy loads.

STORING COAL UNDER WATER.

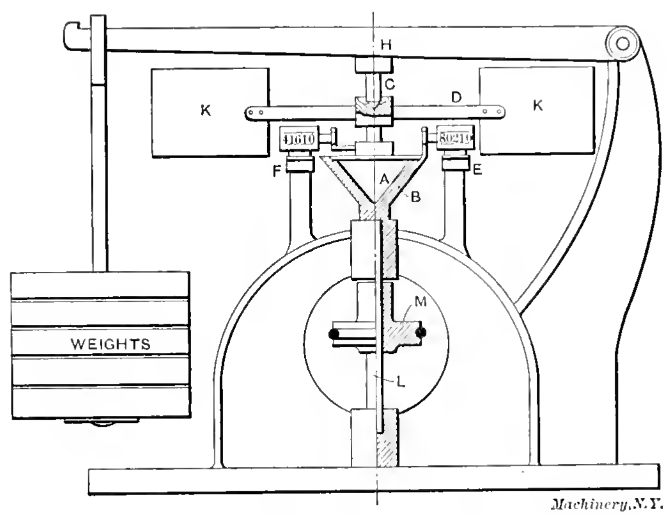
In our July and December, 1906, issues, we referred to the practice of the Western Electric Company of storing coal under water. This is admittedly the best way known for minimizing deterioration, as well as of avoiding spontaneous combustion or accidental ignition. The advantages of this method of storage, says the *Railroad Gazette*, have been determined by experiments in Great Britain within the past five years. The British Admiralty has been the most noted as well as the most extensive investigator, although the studies were antedated by individual experimenters, who were able to record definite and conclusive results. That the idea has been in use in this country since about the time attention was first drawn to it in England, may, however, be new to many, for already in 1902 the Western Electric Company, having had much trouble from spontaneous combustion with Illinois coal stored in quantity, determined on water storage as the simplest and most effective preventive. A large hole was dug in the ground, the coal dumped in, and flooded. When the large new plant at Hawthorne was built about two years ago, the scheme was elaborated to its present proportions. A concrete pit to hold 10,000 tons was built, with tracks across on concrete arches, and the reserve supply of coal is kept in the bins thus formed. To deposit the coal in these submerged bins costs about 5 cents a ton. It is removed by a locomotive crane with a grab bucket. The water for the bins comes from the roofs of nearby buildings. The cost of the pit, which is 310 feet by 114 feet by 15 feet deep, was at the rate of $7,000 per 1,000 tons of capacity. When the coal is used, it is loaded into cars, allowed to stand 24 hours to drain, and then put into the overhead bunkers of the power station, from which it feeds to the stokers. It is therefore used within 48 hours after coming from the pit, and burns well. Since the water removes all of the finely pulverized material, it is equivalent to using washed coal. The British experiments included storage in both sea and fresh water, and in the former instance the quality of the coal actually was improved, presumably from its permeation by the salt. The effect of salting the water has not been tried at the Western Electric Company's pit.

APPARATUS FOR TESTING THE LUBRICATING QUALITIES OF OIL.

Engineering, February, 1908.

An interesting little apparatus intended for testing the lubricating qualities of oils, made by Messrs. John Blake, Ltd., Accrington, England, is shown in the cut below. The apparatus, in general, consists of a vertical shaft *L*, driven by a belt on pulley *M*. At the upper end of the shaft *L* is mounted a conical cup *B*. Into this cup is accurately fitted a metal cone *A*, on which, in turn, is mounted a vertical spindle *C*, carrying two horizontal arms *D*, provided with two vanes *K*. When the spindle *C* is revolving, the air resistance on the vanes *K* will tend to retard the movement. A revolution counter or speedometer *E* is connected to the revolving cup *B*, and one speedometer *F* to the revolving cone *A* inside of the cup. The action of this device is as follows:

A small quantity of the oil or lubricant to be tested is placed in the cup *B*, and the loose cone *A* with its vertical spindle and vanes is placed in the cup. The cone has a groove in its side, in which a small quantity of oil may remain, so as to prevent all the oil being pressed out of the cup *B*, when the cone *A* is placed in position. The lower spindle, with the



Apparatus for Testing the Lubricating Qualities of Oil.

cup attached, is then revolved by means of its belt and pulley, at a speed of about three hundred revolutions per minute, and as the cup revolves with the cone inside it, the friction between the cup and the cone causes the latter to revolve also, but at a lower speed than the cup, on account of the resistance offered by the vanes, when passing through the atmosphere. After the machine has been running for a given time, say a couple of hours, the number of revolutions made by the cup and those made by the cone are noted. Then a second oil or lubricant may be put in, after first removing completely all traces of the one previously tested, and a note made of the number of revolutions made respectively by the cup and cone during the same period of time as in the first

TESTS OF LUBRICANTS.

Sample Number.	Quality of Oil.	Duration of Test.	Revolutions of Cup.	Revolutions of Cone.	Percentage of Cone Revolutions to Cup Revolutions.
1	Sperm	2 hours	36,540	12,300	33.6
2	Mineral	2 hours	36,800	14,800	40.2
3	Mineral	2 hours	36,300	16,100	44.4
4	Mineral	2 hours	36,350	17,400	47.8
5	Mineral	2 hours	36,580	18,600	50.8
6	Mineral	2 hours	36,280	22,100	60.9

test. If the number of revolutions made by the cone be less with the second oil or lubricant than with the first, it naturally follows that the friction between the cup and the cone has been less, and therefore that the second oil or lubricant is better. Many oils can be compared in this way, and their lubricating value can be put down in the exact order of merit. The accompanying table gives the results of a few tests which have been made on a number of different kinds of oils with this device.

When heavy oils are tested, the lever *H*, having weights hung on its end, as shown in the cut, is used for producing the required pressure between the cone and the cup.

THE STUB-TOOTH GEAR.

Abstract of pamphlet entitled "The Stub-Tooth Gear," published by the Fellows Gear Shaper Co., Springfield, Vt.

This little pamphlet deals with the advantages of the "stub-tooth" gear, a form of shortened and strengthened involute tooth cut with stub-tooth cutters. The pamphlet states the case for short teeth of greater obliquity than 14½ degrees standard so conveniently that it seems worth while to make the following condensed abstract of it, largely in the words of the original:

With the constantly increasing use of gears for transmitting power in widely varying quantities, the question of the correct shape and size of gear teeth becomes of far greater importance than ever before. It is not sufficient that a gear be well cut and the teeth properly spaced, but the shape and proportions of the tooth itself must be carefully considered.

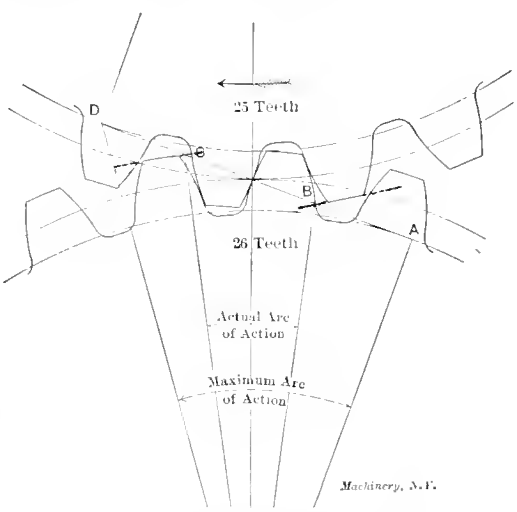


Fig. 1. Comparison of Actual with Maximum Arc of Action in the 14 1-2 Degree System.

The two most important features are the securing of the nearest approach to a rolling action that it is possible to obtain and the strongest tooth that will meet this condition. The first includes easy running, reduces the friction to the lowest point, and consequently has the least wear in action.

In the matter of length, it is a fallacy to argue that teeth should be made as long as possible in order to have two or more teeth in contact at once. An equal division of the load is never possible between two contact points, and it can be shown that the lengthening of the tooth to produce more points of contact gives an excessive sliding action at certain portions of the tooth action, especially with gears 14½

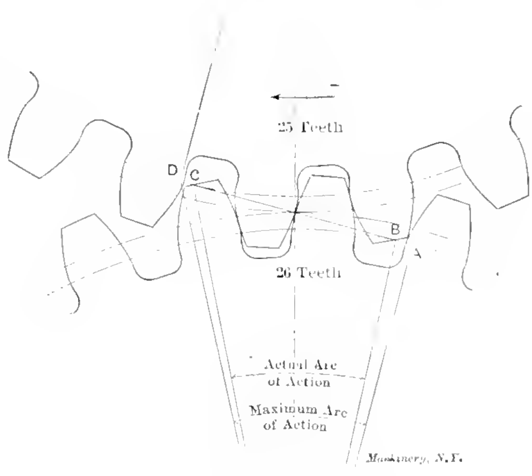

Fig. 2. Comparison of Actual with Maximum Arc of Action in the Stub-tooth System.

degrees of standard angle. By increasing this angle, the teeth may be shortened so that only such portions of the curve are used as will give nearly a complete rolling action. This increase in obliquity has been advocated before, but its advantages are very limited, if a tooth of the standard length is retained.

In Figs. 1 and 2 are shown comparisons of the tooth form of a gear of the standard and of the stub-tooth, the driver having 25 and the driven 26 teeth. If, in the diagrams, the gears are supposed to rotate in the direction of the arrow, the theoretical action begins at A and ends at D, the line $A\,D$ being termed the "line of action." It is obvious, however,

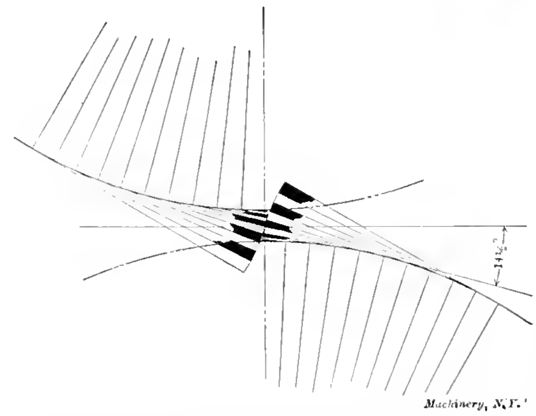

Fig. 3. The Involutes are those of Fig. 1. The Alternate Shaded Divisions show the Portions of Each which are in Contact with the Corresponding Portions of its Mate during Equal Angular Movements.

that the actual action can only begin at B, where the outside diameter of the upper gear intersects the line $A\,D$, and ends at the corresponding point C. Drawing the radial lines from these points to the center O (not shown) the triangle $A\,O\,D$ defines the maximum or the greatest possible arc of action, and $B\,O\,C$ the actual arc of action.

In Fig. 3 is shown an involute curve of 14½ degrees obliquity of each of the gears, the curves being of sufficient length to cover the maximum arc of action, and drawn to the same scale as Figs. 1 and 2. The alternately shaded divisions of the curves show the portion of each that is in contact with its mate during an equal angular movement of the gears. In Fig. 4 is seen a similar diagram for a tooth having an angle of obliquity of 20 degrees.

In Figs. 5 and 6 the involute curves of Figs. 3 and 4 are developed into straight lines, marked off into divisions corresponding with the divisions on the involutes. These division

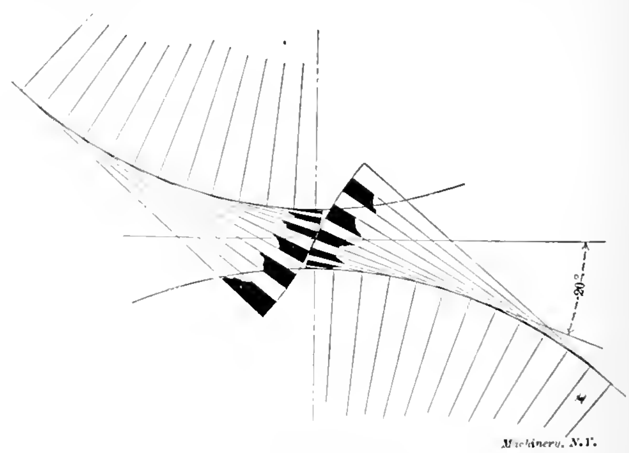

Fig. 4. The Involute of the Stub-tooth Gear in Fig. 2, treated as in the Preceding Figure.

points are connected by cross lines. It will at once be seen that the angularity of these cross lines may be taken as a measure of sliding that takes place at any given point, since a large division on one involute making contact with a small division on the other involves an amount of rubbing measured by the difference between the two distances. To any one who has labored under the impression that if the involute curves of a pair of gears are correct, the action is nearly a rolling one, a comparison of these diagrams will be both interesting and instructive. Two points will be noted.

First, on account of the greater angle of the line of action of the stub-tooth, the maximum arc of action is much increased.

Second, the ratio of the *actual* to the *maximum* arc of action of the stub-tooth is much less than in the standard.

This latter point is a very important one, as we thus eliminate contact at both ends of the line of action. When we

realize that this is the portion of the action in which the greater part of the sliding takes place, with its inevitable wear, we see that it is a good thing to cut it out if possible. The point of the tooth which wears out the flank of its mate is removed with the adoption of the stub-tooth, and this reduces the friction while increasing the efficiency. A comparison of Figs. 5 and 6 shows that the action of the stub-tooth is as nearly a rolling one as it is possible to obtain. The action of the standard tooth at the base line is that of a stone-boat being dragged over the ground, while the action of the stub-tooth can be compared with the same stone-boat mounted on wheels.

It is, of course, impossible to entirely eliminate the wear between the teeth of gears working under a load. But if the wear can be evenly distributed over the entire working face of the tooth, the correct form of tooth is retained indefinitely, and a worn-out gear should, aside from the excessive back-

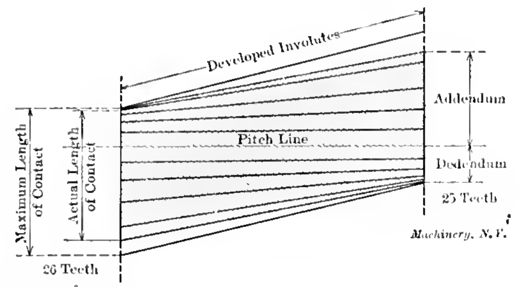

Fig. 5. The Involutes of Fig. 3 Separated and Developed into Straight Lines with the Division Points Connected as shown. The Angularity of the Connecting Lines is a Measure of the Rubbing.

lash, run as well as a new gear. And, if this wear can be evenly distributed, the durability of any gear will be increased many times.

We have so far discussed only the points of efficiency and durability, but there is another advantage of the stub-tooth over the standard form, and one which some might think entitled to first consideration, especially in the transmission of any considerable amounts of power; this is the advantage of greatly increased strength.

A comparison of the two diagrams in Fig. 7 (drawn according to the well-known method proposed by Mr. Wilfred Lewis) shows an increase in strength for the stub-tooth form of 80 per cent. It will be noted by comparing different combina-

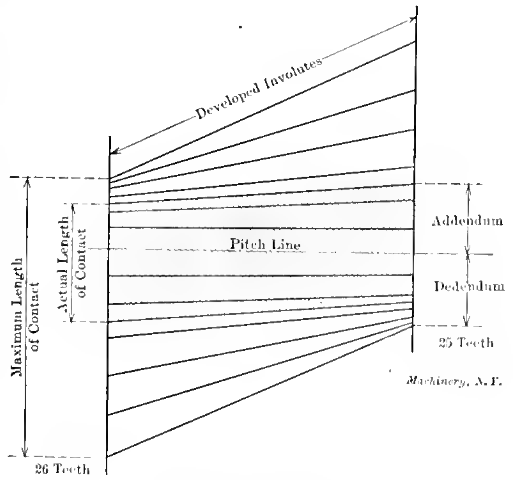

Fig. 6. The Involutes of the Stub-tooth Gear in Fig. 4 treated as in the Preceding Figure.

tions of gears that the increase in strength is greatest for pinions, which are almost invariably weaker than the gears they run with.

To understand the importance of this consideration of strength, it may be mentioned that if comparisons are made between a 15-tooth 6-pitch 14½-degree gear and one with 20 teeth 8/10 pitch of the stub-tooth standard, both having the same diameter, it can be shown that the stub-tooth, though shorter and of finer pitch, has 20 per cent greater strength, and while the bearing surface per tooth is shorter, the total area of bearing surface is 6 per cent greater.

Some of those who are not entirely familiar with this system of gear teeth have made the mistake of thinking that it consists simply of the shorter tooth than the standard form, while retaining the same pressure angle, and have therefore opposed it on the ground that the arc of action, in the case of a small pinion, is not equal to the pitch arc, and that the action is therefore not continuous, because one tooth is out of action before the next tooth takes up the load.

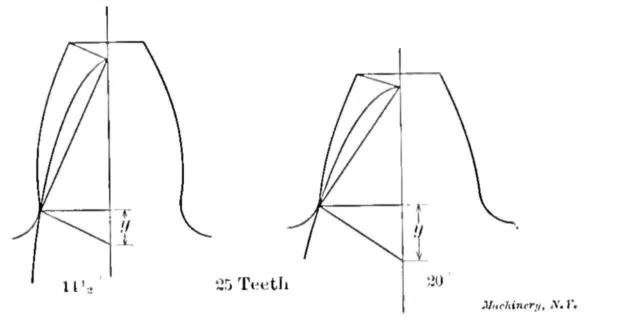

Fig. 7. The Strength of a 14 1-2 Degree Tooth and a Stub Tooth Compared by the Wilfred Lewis Method; the Strength is measured by Dimension y.

It should be thoroughly understood, and we wish to emphasize the fact as much as possible, that the increased angle of obliquity is an essential and vital part of the stub-tooth system, and that with this increased angle, the arc of action is as long as that of the 14½-degree tooth.

Fully one-third of the cutters made by the Fellows Gear Shaper Co. are now of the stub-tooth form.

[We have described the method of sizing the stub-tooth gear in a previous issue of MACHINERY. See "How and Why" in the July, 1907, issue. This method of sizing the teeth is very convenient for use with the Fellows gear shaper, in which the depth of cut is obtained by referring to graduations numbered to correspond with the diametral pitch used. We cannot escape the belief, however, that it is a serious error to inaugurate a system in which the addendum of the tooth bears no definite relation to the pitch. While the convenience of the operator is worth consideration, we believe it could have been obtained in other ways that would not have involved the irregular determination of the addendum, as now practiced.

The argument for shortened addendum and increased pressure angle, given in this pamphlet, seems to us worthy of the serious attention of mechanics. The conclusions are, we believe, inescapable, and perhaps even more might be said from the standpoints of efficiency and durability in behalf of a change from the old standard form.—EDITOR.]

FRICTION AND LUBRICATION.

Abstract of paper read by Dr. J. T. Nicolson before the Manchester, England, Association of Engineers, November 23, 1907.

The present paper does not give much attention to dry friction, or to the laws of resistance when one solid moves over another. Its chief aim is to attempt to give some definite ideas about the resistance offered to the relative motion of lubricated surfaces, and, in particular, relates to journals and bearings as used in engineering practice. Experimental results obtained by Stribeck, Dettmar, Heimann, Lasche, and others, have been utilized for framing rules which indicate that some views commonly held in regard to bearings are not correct. In particular, the idea that the length of the bearing should increase in proportion to the speed, is shown to be erroneous.

Dry Friction.

When one solid rubs upon another without any lubricant, the resistance offered to relative motion is due either to actual abrasion or to molecular interference between the two surfaces. Even though a metallic surface may appear to be perfectly smooth to the eye, its real condition, if viewed with a powerful microscope, resembles that of a rugged mountain system. When one surface is slid upon another, these surfaces exercise a resisting force. The following laws may be considered as generally covering the question of dry friction:

1. Within certain limits, the frictional resistance may be said to be proportional to the load, and to be independent of

the extent of the surface over which the load is distributed; but when the pressure or load per unit area is large, the friction increases at a greater rate than the load, or, in other words, the coefficient of friction increases with the pressure.

2. The coefficient of friction varies with the speed of motion. It is greatest when the motion is slowest, and when one body is just commencing to move relative to another, we have what is called friction of repose. This friction has been found by experiments to be from 0.3 to 0.4 for iron upon iron; for moderate speeds, the friction varies from 0.15 to 0.25 for the same material; and for speeds from 10 to 90 feet per second, the coefficients of from 0.10 to 0.20 have been found by experiments.

3. The friction of solids with no lubricant interposed has been found to diminish as the temperature increases. This is due to the fact that abrasion is easier at high temperatures.

Friction with Lubrication.

When some lubricant is placed between moving bodies, the valleys or the uneven surfaces are leveled up, and the intensity of the molecular action is diminished. For the frictional work when a shaft rotates in a well-lubricated bearing, we may state the following formula, expressing the frictional work done per revolution:

$$\text{Frictional work per revolution} = \frac{\pi\, d\, u\, W}{12} \text{ foot-pounds.}$$

In this formula,

d = diameter of shaft, in inches,

u = coefficient of friction (0.15 on an average),

W = load on the bearing in pounds.

This formula holds true when there is plenty of oil, so long as the speed is small. If we take as an example the case of the spindle for a 10-inch lathe, running slowly, with a weight of 3,000 pounds carried by the front bearing, which is $3\frac{1}{2}$ inches in diameter, then the friction work per revolution is

$$\frac{\pi \times 3.5 \times 0.15 \times 3{,}000}{12} = 412 \text{ foot-pounds per revolution.}$$

If a cut were ¼ inch × 1/16 inch on soft steel, the cutting force would be, say, 3,500 pounds, and on a 20-inch face-plate diameter the work spent in cutting per revolution would be

$$3{,}500 \times \frac{20\,\pi}{12} = 18{,}300 \text{ foot-pounds.}$$

The work lost in friction by the journal is therefore 2.26 per cent of the useful work. A similar calculation for a 48-inch lathe would show a loss of about 10 per cent. These great frictional losses constantly occur with lathe spindles or other rotating shafts, revolving slowly, even when abundantly fed with oil, and indicate the necessity for using measures to preserve a separating film of oil between the shaft and bearing, and not to allow them to run in metallic contact. This is more difficult to accomplish at slow than at high speeds.

Automatic Lubrication.

The following rules for supplying bearings with oil will give the best results in practice: If the oil is fed in by the ordinary cup and syphon, or by a ring or centrifugal method of supply, it should be made to flow onto the journal at the place where the pressure is least. The oil should therefore be fed from a point situated in the top rear quadrant of the bearing when the journal is loaded by gravity only, and the point should be further back the slower the speed. This applies, then, especially to the large lathes. If the loading of the journal is principally due to cutting force acting upward upon it, the feed should be placed in the bottom front quadrant, and nearer the front, the slower the speed of rotation. This meets the case of the smaller-sized lathes.

The compromise ordinarily effected to enable the lubricant to enter, whatever may be the direction of the loading, is the simple one of fitting the oil cup on the top of the bearing. This seems almost the only thing to do in the case of automatic lubrication, but it is the correct position only when the resultant force upon the journal, due to gravity and cutting force, etc., acts nearly horizontally and from front to rear.

Forced Lubrication.

When the lubricant is supplied by mechanical means at a fixed rate and at any required pressure, it must be fed in at the points of greatest oil pressure in the bearing. For large lathes, where gravity is more important, the region of greatest pressure lies in the rear bottom quadrant. For small lathes, on the other hand, in which the force on the spindle acts upward, owing to the cutting force being relatively greater, the maximum oil pressures occur in the front top quadrant. To meet all contingencies, it would appear on the whole best, in the case of forced lubrication, either to force the oil in at the back of the bearing, well below the center, or preferably to fit three alternative branches from the oil pressure supply pipe to the back, top, and front, any one of which may be turned on at will to suit the conditions of working.

Frictional Resistance Due to Viscosity.

In describing the phenomena occurring when a journal rotates in a bearing, we have, so far, not alluded to the nature or magnitude of the frictional resistance experienced when there is an abundant supply of lubricant completely separating the former from the latter, and preventing any metal-to-metal contact. It is frequently stated that "there is no friction without abrasion," or, in other words, that unless two metals rub against each other, there can be no resistance due to relative motion. This, however, is not the case. When a film of lubricant is interposed between two metallic surfaces, there is a resistance to relative motion of these surfaces due to the shearing or transverse distortion of the oil film.

This resistance does not depend on the load. It is governed only by the area of viscous fluid to be sheared, and the viscosity of the oil, *i. e.*, the kind of oil and its temperature (with which the viscosity greatly alters), and it also gets greater the smaller the thickness of the film, so that if the shaft is a close fit within its bearing, the resistance to motion will be greater than if the fit is an easy one.

There are very few cases in engineering practice where a journal rotates with a uniform thickness of oil around it, and it is only at very high speeds that this takes place. At moderate and low speeds, the shaft moves to one side an amount depending on the speed of the load, the eccentricity for any given load becoming less, the greater the speed. We have already said that the frictional resistance depends on the thickness of the oil film. Experiments have shown, however, that the thickening of the film on one side of the shaft is more than counteracted by the thinning of the film on the other, so that, in general, the friction gets greater when the journal becomes more eccentric.

Considering, therefore, the bearing running slowly, in which a lubricant has just formed a complete film all around the shaft, it will have its maximum amount of eccentricity, and the frictional resistance will, on this account, be large. As the speed increases, the eccentricity diminishes. The friction increases with the speed, but it diminishes, on the other hand, with the eccentricity. Experiments show that at first there is a diminishing and then an increase, so that the coefficient of friction attains a minimum value which depends on the circumstances in each case. With further increase in speed, the diminishing of friction, due to the lessening eccentricity, becomes insignificant, and after a certain interval, the simple law of friction is followed, whereby friction increases in proportion to the velocity of rubbing.

For speeds greater than at from 20 to 80 feet per minute, the temperature of the oil film also exerts its influence. This temperature rises above that of the bearing, and its viscosity becomes reduced. The frictional resistance then increases less rapidly than in exact proportion to the speed. The faster the journal runs, the more the temperature of the oil film rises above that of the bearing, and the thinner or less viscous becomes the oil. Thus, for speeds from 50 to 90 up to about 450 feet per minute, the coefficient of friction is proportional to the square root of the speed of rubbing. For speeds between 450 feet and 800 feet per minute, the friction increases more slowly, and varies as the fifth root of the velocity. For speeds as high as 3,600 feet per minute and upward, the influence of the speed disappears altogether, and the conclusion is arrived at that for bearings of high speed generators, for

instance, driven by steam turbines, whose rubbing speeds are nearly a mile a minute, the coefficient of friction is the same, whatever be the speed.

Application of Results of Experiments to the Design of Bearings.

In endeavoring to apply the theoretical explanations and the experimentally found formulas, the question arises: What is the proper proportion of length to diameter, under any given condition, as to load, speed and kind of lubrication? According to hitherto accepted rules, the length of the bearing should increase with the load and with the number of revolutions. The experiments and formulas arrived at by the author, indicate, however, that the heat developed in the bearing depends only upon the rubbing velocity, and is quite independent of the length of the journal. We cannot, therefore, hope to lower the temperature by lengthening the bearing. The heat generated increases as fast as the area for dissipating it increases, and, although by lengthening the journal, the bearing pressure is diminished, the frictional resistance and the heat generated are increased. On the other hand, we know from experience that journals must be made long for high speeds, and the above calculations seem, at first sight, to be in conflict with accepted practice. The explanation of this is as follows: While it is true that the final temperature to which the bearing will rise after a long run, under a given load, and with a given lubricant, depends only on the diameter of the spindle and the speed of revolution, that is, only upon the rubbing velocity, and not at all upon the length of the journal, we have to remember that if the finally attained temperature be too high, the lubricant will be squeezed out unless the bearing pressure is low.

Another conclusion arrived at by these experiments, contrary to the view usually accepted, is that the length of the bearing must be greater, the slower the speed. This, however, is clearly correct, for the slower the speed, the greater difficulty has the shaft in dragging in its supply of oil to meet the required demand, in opposition to the bearing pressure which is squeezing it out, and consequently the unit bearing pressure should accordingly be lower in order to enable the journal to maintain its oil film unbroken.

Journals for Heavy Loads at Slow Speed.

One kind of bearing which presents special conditions, and which is frequently met with and has to be dealt with in practice, is that in which a journal has to run under a heavy load at a very slow speed. What we have here to guard against is the entire collapse or tearing asunder of the film of lubricant, owing to the slow speed at which the bearing is being worked; and when once the tearing of the oil film begins, the journal is unable to bring up a fresh supply, owing to its small surface speed.

Calculations and experiments show that it is impossible to give the large dimensions to the front bearing of a heavy lathe that would be necessary to prevent the oil film from being broken at such slow speeds; and, as a matter of fact, lathe spindles turning at the slow speeds used for heavy cuts inevitably run metal-to-metal with their bearings, giving rise to the high frictional resistance corresponding to the coefficient of friction of 0.15 for greasy metals. The work thus spent and wasted on friction and wear may amount to from 2 per cent to 10 per cent of the total useful work expended on cutting. From 1/4 to 9 (according to size) horse-power is, therefore, wasted on the friction of the front journal alone when the lathe is running at these slow rates with a heavy job between centers. Even if the working pressure is light, and the thrust on the front journal is due to the standard cut only, it can be shown that 2 1/2 per cent of the useful work is spent on friction on any size of lathe when the speeds are so low as to squeeze out the oil film.

We are here face to face with a very serious loss of power, and a correspondingly large amount of wear of the spindle and in the front bearing, not at all due to high speeds of rotation of the spindle; and it is owing to this that the elaborate arrangements for adjustment of the spindle in a lathe headstock have to be provided.

It is impossible to give enough area in the front bearing of a lathe head-stock to prevent metallic contact of journal and brass at the slower speeds, if dependence is placed upon the lubricant being carried in by the ordinary action of the shaft's rotation, the supply being automatic. By using a force pump, however, and injecting a stream of moderately heavy oil into the bearing at the place where the pressure is greatest, it is possible to raise the journal off the brass even when at rest, and to keep it floating with a film of oil interposed between itself and the bearing when in motion, be that motion as slow and the load as high as it may. If metal-to-metal contact can in this way be prevented at slow, and by the ordinary methods at high speeds, there seems to be a possibility that wear may be entirely eliminated. If this be so, it follows that adjustments for wear are unnecessary, and instead of the elaborate and expensive designs of front and back bearings which are now used, we may expect that a simple solid bush of ample thickness will meet every requirement. Such a solid bush, of hard bronze round the steel spindle, has a great deal to recommend it from the point of view of accuracy of fit, solidity, and stiffness, as compared with the intricate methods of adjustments now common.

Modern Practice for Lubricating Bearings.

The chief distinction between the modern and the older methods of lubricating bearings lies in that the oil is no longer supplied drop by drop, as formerly, but in an abundant stream, the oil serving the purpose not only of lubrication, but of carrying away the heat.

For high speed bearings, the principle most often adopted is that of the "closed circuit," that is, the oil is used over and over again; after dropping off the journal into a collecting reservoir, it is filtered and used anew, being automatically supplied to the journal at any suitable point. A cooling arrangement is sometimes fitted in the reservoir so as to remove the heat from the oil, and consequently also from the bearings. The system of forced lubrication is also adopted to a great extent. The oil is then, by means of a pump or other suitable device, pressed in between the rubbing surfaces so that the journal floats on the heavy film of lubricant.

Lubricating Horizontal Bearings.

The most common method of lubrication for horizontal journals running at high speed is the ring-oiled bearing, in which a loose ring, resting on the shaft, turns with it, dipping into the oil reservoir at the lower side, and bringing up the oil to the top surfaces of the journal, from where it flows over into the oil grooves. No ribs or other projections should be fitted on the rings, as such arrangements produce a resistance to their passage through the oil bath, and bring them to a stand-still. At high speeds, the centrifugal force renders the flow of oil from the ring to the journal difficult, and scrapers are used for diverting the oil into the oil channels. These, however, should never touch the ring, as they will then stop its motion.

Self-oiling bearings having rings fast on the shaft are not much used. The fast ring cannot stick, but it requires a longer design of bearing. The ring may act as a collar where end-wise motion is to be prevented; but as such motion is usually an advantage, the ring should ordinarily be attached to the shaft so that it can slide on its key. For high speeds, the scraper may be used with fast rings, to overcome the centrifugal force.

Forced Lubrication.

By the use of a pump to force the oil drawn from the reservoir into the bearing, to the point of maximum pressure, the length of the bearing can be very much diminished even for the slowest speeds, especially for journals whose load and rotation direction do not change. For such bearings, the length need, in all probability, not be more than equal to the diameter of the shaft. With such bearings there ought hardly to be any wear at all. The system is extensively used in high speed steam engines and gas engines.

DERIVATION OF FORMULA FOR DETERMINING SPUR GEAR CUTTER NUMBER FOR SPIRAL GEARS.*

H. W. HENES.†

The formula $N_c = \dfrac{N}{\cos^3 a}$ is generally accepted as the correct one for determining the proper spur gear cutter to be used in cutting a desired spiral gear. In this article is given the derivation of the formula. The following notation is used:

N_c = number of teeth in spur gear for which cutter is intended.

N = number of teeth in the desired spiral gear.

a = the angle which the direction of the spiral makes with the axis of the gear.

Let P_n be the perpendicular distance between two consecutive teeth on the spiral gear, and let D_1 be the diameter of the spiral gear. Let the gear be represented as in the cut, and pass a plane through it perpendicular to the direction of the teeth. The section will be an ellipse as shown in *CEDF*. Designate the semi-major and semi-minor axes by a and b respectively.

Now, N_c is the number of teeth which a spur gear would have if its radius were equal to the radius of curvature of

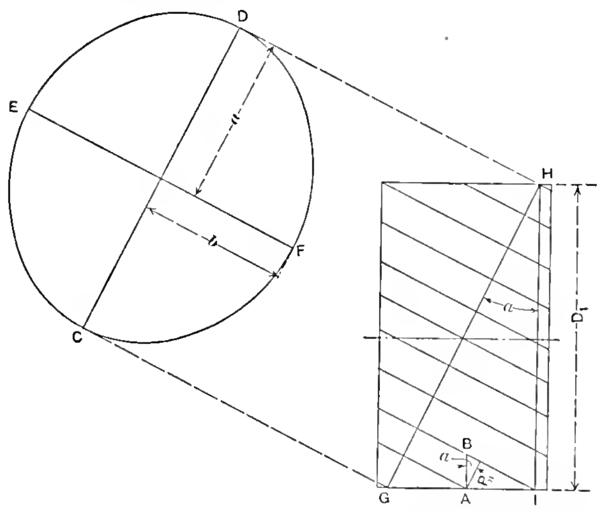

Diagram for Deriving the Formula for Determining Spur Gear Cutter Number for Cutting Spiral Gears.

the ellipse at E. Therefore, it is required to determine the radius of this curvature of the ellipse. This is done as follows:

From the figure we have:

$$2b = \text{axis } EF = D_1 \tag{1}$$

$$2a = \text{axis } CD = GH = \frac{HI}{\cos a} = \frac{D_1}{\cos a} \tag{2}$$

From (1) and (2) we have for a and b,

$$b = \frac{D_1}{2} \tag{3}$$

and

$$a = \frac{D_1}{2 \cos a} \tag{4}$$

It is known, and shown by the methods of calculus, that the minimum curvature of an ellipse, that is the curvature at E or F, equals $\dfrac{b}{a^2}$. Taking the values of a and b found in (3) and (4), we have as the curvature at E:

$$\text{Curvature} = \frac{b}{a^2} = \frac{\dfrac{D_1}{2}}{\dfrac{D_1^2}{4 \cos^2 a}} = \frac{4 D_1 \cos^2 a}{2 D_1^2} = \frac{2 \cos^2 a}{D_1} \tag{5}$$

It is also shown in calculus that the *curvature* is equal to $\dfrac{1}{R}$, where R is the *radius of curvature* at the point E. Therefore from (5) we have:

$$\frac{1}{R} = \frac{2 \cos^2 a}{D_1}, \text{ whence } R = \frac{D_1}{2 \cos^2 a} \tag{6}$$

[Formula (6) could have been arrived at directly, without reference to the minimum curvature of the ellipse, by introducing the formula for the radius of curvature in the first place. The curvature is simply the reciprocal value of the radius of curvature, and is only a comparative means of measurement. The radius of curvature of an ellipse at the end of its short axis is $\dfrac{a^2}{b}$, from which formula (6) may be derived directly by introducing the values of a and b from equations (3) and (4).—EDITOR.]

Having now found the radius of curvature of the ellipse at E, we proceed to find the number of teeth which a spur gear of that radius would have. From the figure we have:

$$AB = \frac{P_n}{\cos a} \tag{7}$$

Now, if AB be multiplied by the number of teeth of the spiral gear, we shall obtain a quantity equal to the circumference of the gear; that is:

$$AB \times N = \pi D_1, \text{ and, since } AB = \frac{P_n}{\cos a} \text{ from (7),}$$

$$\frac{P_n}{\cos a} \times N = \pi D_1 \tag{8}$$

Since N_c is the number of teeth which a spur gear of radius R would have, then,

$$N_c = \frac{2 \pi R}{P_n} \tag{9}$$

In equation (9) the numerator of the fraction is the circumference of the spur gear whose radius is R, and the denominator is the circular pitch corresponding to the cutter.

From equation (6) we have:

$$R = \frac{D_1}{2 \cos^2 a}$$

Substituting this value of R in (9), we have:

$$N_c = \frac{2 \pi D_1}{P_n \times 2 \cos^2 a} \tag{10}$$

From equation (8) we have:

$$D_1 = \frac{N P_n}{\pi \cos a} \tag{11}$$

Substitute this value of D_1 in equation (10) and we have:

$$N_c = \frac{2 \pi N P_n}{2 P_n \pi \cos^3 a}$$

or

$$N_c = \frac{N}{\cos^3 a} \tag{12}$$

* * *

The use of wind-mills for electric power generation for agricultural and industrial purposes has greatly increased in Denmark during the past years. The Danish Government conducts experiments to ascertain the best forms of installments, and since 1897 has spent about $28,000 for such experiments, and has lately erected an experimental station for determining the best means for generation of electricity by means of wind-mills. Wind-mills with four wings, have been found to be the most economical, because of giving the most power. The results have shown that out of a wing surface of about 65 square feet one horse-power is developed at a wind velocity of 20 feet per second. At a velocity of 26 feet, one horse-power is developed from about one-half of this wing surface. It is stated that 30 larger and smaller wind-power electrical installations are now in operation in Denmark.

RACK-CUTTING MACHINES IN THE SHOPS OF THE R. K. LE BLOND MACHINE TOOL CO.

One of the lines of manufacture of the R. K. LeBlond Machine Tool Co., Cincinnati, Ohio, is the cutting of racks for the trade. Though the machines for this work have been built at home, they do not display any of the usual crudities of home-made tools, being first-class examples of machine design, presenting a number of points of novelty and interest in their construction. Through the kindness of Mr. Wm. F. Groene, the chief draftsman of the firm, we are enabled to show photographs and details of the latest of these machines, which have recently been completed and put in operation.

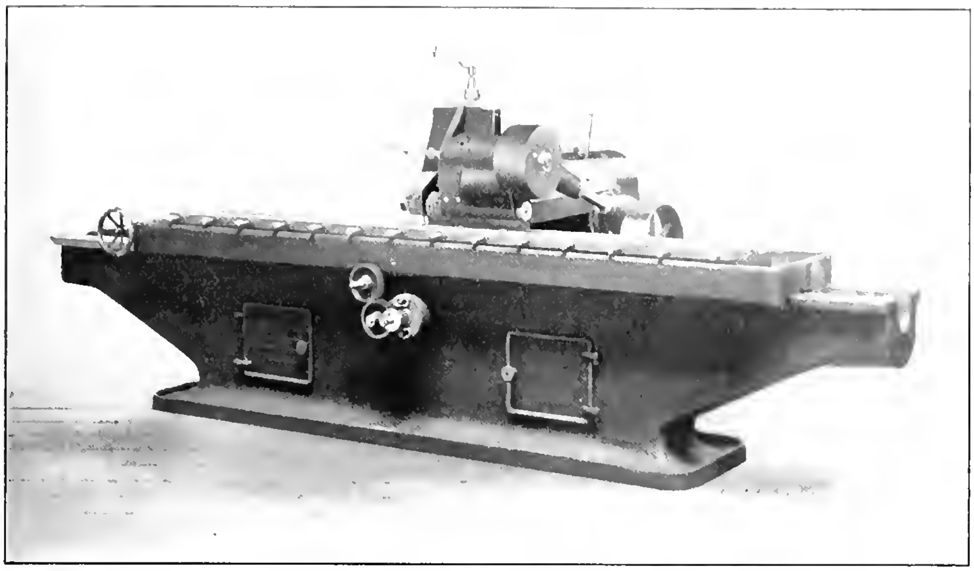

Fig. 1. Rack-cutting Machine built in the Shops of the R. K. Le Blond Machine Tool Co.

General Construction.

As may be seen in Figs. 1 and 2, the machine is of the type derived from the shaper, so far as its structural features are concerned. The cutter spindle and driving gears are carried in a head which is vertically adjustable on the front of a horizontal ram. This vertical adjustment is used for setting the cutters to depth. The horizontal ram is fed slowly forward for the cut, and is then rapidly returned while the work is indexed to a new position. The work is held in a long vise attached to the top of a work table, sliding on dove-tail ways on the long base of the machine. This base, as may be best seen in Fig. 2, is of T-form, having a rearward extension to support the ram, and it is cast solid in one piece. The machine is fully automatic in all its actions.

A 5-horse-power motor, mounted on the ceiling, drives the machine through a single speed pulley, shown best in Fig. 2. The single speed shaft, through change gearing in the case at the right of the ram in Fig. 2, drives a second shaft, connected by bevel gears with the splined shaft shown, running diagonally upward to the cutter slide, where the motion is transmitted to the cutter spindle through bevel and twisted tooth gears. This arrangement of splined shaft and bevel gears transmits the power without interfering with the movements of the cutter ram. The automatic slow forward feed and quick return of the ram is effected by mechanism in the casing at the rear of the column, as shown in Fig. 2, controlled by the handle projecting through the back end of the ram. The indexing is controlled by change gears at the front of the bed.

The work table is indexed by change gears mounted at the front of the bed. The movement of the table for indexing is effected by a stationary lead-screw carried by the table, and a revolving nut operated by the indexing mechanism. The machine will cut racks 10 feet long at one setting. Racks longer than this can be cut by resetting in the chuck, the table being provided with a fine micrometer adjustment by means of the hand-wheel shown at the left in Fig. 1, whereby it can be moved independently by the indexing mechanism, for matching the teeth. The return of the table for the next setting of the rack, and all other movements of the machine, are power operated, relieving the operator of all physical effort. These provisions make it possible for one man to run four machines.

To insure the maximum of productiveness from the machine, provision has been made in its design to furnish an abundant supply of oil to the cutters, so that the work and the cutters are flooded with a stream of lard oil. The inside of the column forms a reservoir from which the oil is pumped to the work. The machine has the necessary arrangements for straining and returning the oil to the reservoir.

Spindle Driving Mechanism.

Details of the spindle drive are shown in Fig. 3. The driving bevel pinion, mounted on the end of the splined driving shaft shown in Figs. 1 and 2, drives a bevel gear keyed with a taper fit to the driving pinion shaft. This shaft has teeth formed integrally with it, meshing with the intermediate gear shown, which, in turn, meshes with the pinion teeth formed integrally with the cutter spindle. This gearing has helical teeth, to give a smooth, even drive to the cutter spindle. The difficulty of driving the spindle of the rack-cutter is well known. The difficulty arises from the fact that the driving pinion of the cutter spindle must be smaller in diameter than the cutters which it drives, so that it must necessarily have very few teeth and be subjected to great strain. This makes it difficult to make it strong enough, and at the same time give a smooth, steady drive. In this case the teeth are made strong enough

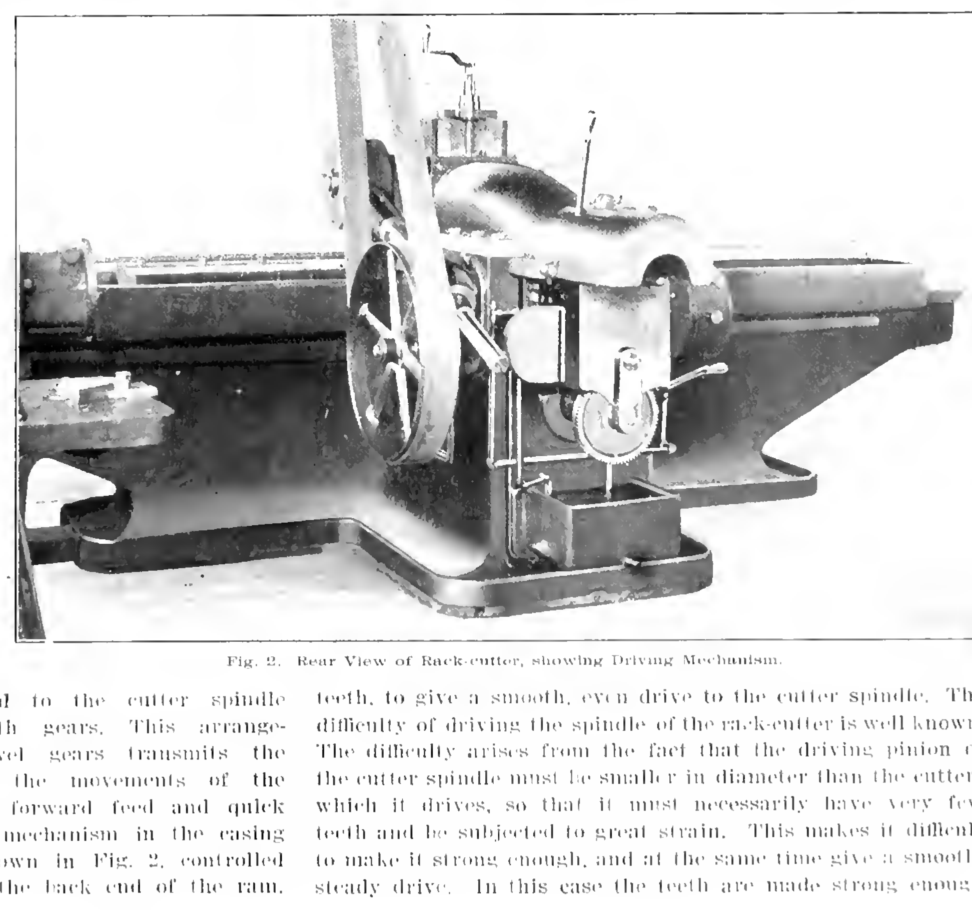

Fig. 2. Rear View of Rack-cutter, showing Driving Mechanism.

by being given a very wide face (5 inches), and the required smoothness of drive with the large pitch used is effected by making the gears with twisted teeth, the helix angle being 14 degrees. The end pressure produced by these twisted teeth is taken care of by suitable thrust washers, the direction of pressure being toward the left for the driving pinion and the cutter spindle, and toward the right for the intermediate gear stud.

The bearings for the cutter spindle on each side of the pinion are tapered, as shown. The one at the left, which takes the thrust, is held in the cutter slide by taper dowel pins. The one at the right may be screwed in or out of the cutter slide cup to take up end play. At the extreme left, the spindle is supported by a removable outboard bearing, which

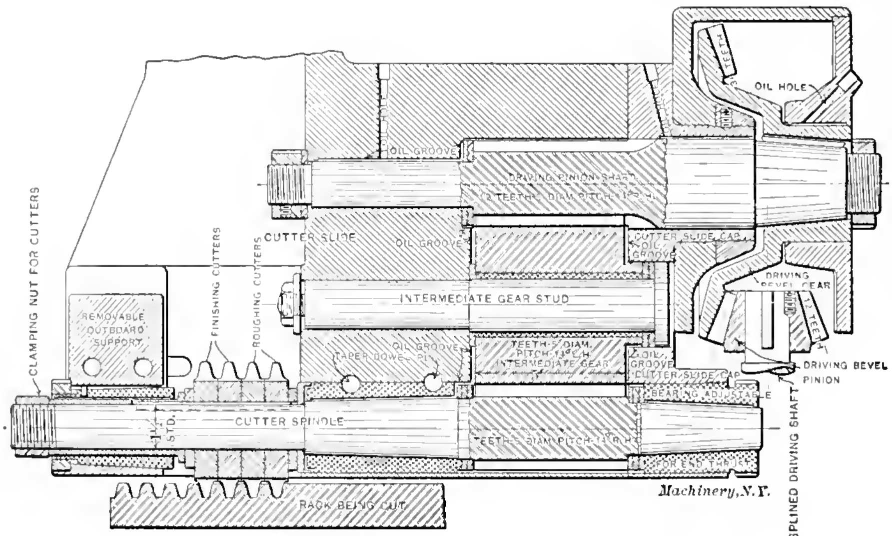

Fig. 3. Vertical Section through Cutter Spindle and Driving Gears.

slides off endwise, and may be adjusted longitudinally to accommodate the width of cutter space required for the cutters used. In the drawing, four cutters are shown in place, two of which rough the tooth spaces while the other two finish them, thus completing two teeth complete at each feeding stroke of the ram. These cutters are keyed to the spindle and are clamped by the nut at the outer end of the spindle, through the journal bushing shown. This bushing has a bearing in the outboard support. The box for this bearing is tapered and split so that it may be adjusted for wear.

Accuracy of Product.

Special attention has been paid to the accuracy of the product. The automatic indexing of the table gives more accurate and uniform results than hand indexing, and this accuracy is still further assured by the mechanism provided for locking the table in position after it is indexed. The great weight (about six tons) and stiffness of the machine also tend in the same direction.

Tests of the accuracy of the indexing were made by placing a 10-foot length of stock in the machine and milling teeth in it for its full length. The cutter used, to facilitate testing, was an ordinary half-inch slotting mill, cutting square teeth. The machine was set to index three diametral pitch, which is about 1.0472 inch circular pitch. The rack was then measured for every 6 inches throughout its length with a Brown & Sharpe 24-inch vernier caliper, set to cover 22½ teeth; that is, 22 teeth plus the thickness of a tooth. The space being 0.5000 inch thick, and the tooth 0.5472 inch thick, this gave a calculated distance of 23.5856 inches for the calculated setting of the vernier. In the 16 measurements made throughout the length of the 10-foot rack, the actual settings obtained varied from the theoretical by from 0.007 inch above to 0.0025 inch below, these amounts being the error in about 2 feet. It is believed that these tests show accuracy meeting every commercial requirement.

One source of error ordinarily met with in rack-cutting machines has been avoided in this tool. Ordinarily, the lead-screw is of some even number of threads or turns per inch. This makes it possible to figure out the gearing for circumferential pitches very easily. For diametral pitch racks, however (which constitute by far the greater part of the product of any such machine), translating gears have to be used to take care of the factor π, which must be used in obtaining diametral pitch from circular pitch measurements. The usual ratio used is 22 : 7, which, carried out, gives a value for π of 3.1429, considerably larger than the true value. From this it follows that racks cut with this gearing are uniformly longer for a given number of teeth than they should be, the error amounting to about 0.0046 inch per foot in length—not enough to create any serious difficulty, of course.

In the present machine this error has been avoided by making the screw with a special lead of $\pi/3 = 1.0472$ inch. The gearing for cutting this special lead was very carefully calculated, the actual calculated pitch for the gearing used being 1.04724 inch lead. This makes the screw nearly correct for diametral pitch gears, while the translating error involved in using the 22/7 ratio will come in cutting circular pitch gears, which form but a small part of the machine's output. The fact that the pitch in the test showed average measurements slightly greater than the standard, is perhaps due to heating, or some other similar cause.

The cold rolled stock ordinarily used for racks comes from the rack-cutting machine somewhat bowed, owing to the removal of the skin tension on the outer surface by the cutting operation. These racks are straightened by passing them several times through a machine which rolls them back to their proper shape. This machine has been specially designed for the purpose, and the straightening is accomplished without impairing the accuracy of the teeth in any way. This straightening machine was illustrated and described in the December, 1906, issue of MACHINERY.

CONCRETE FOUNDATIONS FOR DROP HAMMERS.

At a recent visit to the Pratt & Whitney Co.'s shops at Hartford, Conn., the writer had an opportunity to see some very interesting drop hammer foundations, made from solid concrete. The blacksmith shop is located on what one might say is the second floor of the building, there being a basement about 11 feet high under the blacksmith shop, which is used as a stock-room and where the case-hardening furnaces are located. The foundations for the drop hammers in the blacksmith shop must therefore be carried down clear through the basement, and then down approximately another 11 feet to hard pan. The construction of these concrete foundations is shown in Fig. 1. At *A* is shown a cast iron base-plate, into which the base of the drop hammer sets. This plate is bolted to the concrete column by four 1¼-inch anchor bolts. Between the cast iron plate and the top of the column a double layer of wood and also a thick layer of tar paper are interposed, the purpose of which will be referred to later. The column, as shown, reaches nearly up to the ceiling of the basement, *C* being the floor line of the blacksmith shop. At *D* is shown a line representing the floor of the basement. As will be seen, reinforcements have been placed around the concrete column in the form of heavy planks *B*, having one-inch bolts through the concrete to clamp them up against the concrete surface. It has been found later, however, that this reinforcement was not necessary, and that the foundations would have served their purpose fully as well had the column been left plain all the way down.

The installation of these concrete foundations, as compared with the wooden foundations previously used, has proved to be a very economical move. While previously, with hammers working on wooden foundations, it was not possible to make the drop forgings shown in Fig. 2 on anything but a 200-pound

hammer, since these foundations were put in, it has proved possible to make them on a 100-pound hammer, and, at the same time, the rapidity of completing the drop forgings has been increased, so that a saving in time of 20 per cent has resulted in the making of these forgings. Other elements of saving in comparing the making of these forgings on a 200- or a 100-pound hammer are that the tools cost more for a larger machine, and it consumes a great deal more power. The reason why there is a saving in the making of these forgings, even in regard to the time consumed, is because the strokes, even on a smaller hammer, can now be made shorter, so that a greater number can be struck in the same time, the blows, however, having an equally good, or better, effect, on account of the solid foundations under the base of the hammer. In the case of drop hammers, where the hammer was previously raised three feet, it is now not necessary to raise it more than two feet, in order to accomplish the same results.

When the foundations were first put in, the cast iron plate *A*, already mentioned, was laid directly on a surface of cement, three inches thick, placed on the top of the concrete foundations. The cast iron base-plate, of course, was not finished on the bottom, but was more or less rough. The cement itself did not have a perfectly plane surface, and it was found that, after the hammer had been used for some time, the top layer of the cement would be ground to powder, on account of the rough surfaces coming in contact, constantly cutting and grinding the surface of the cement. In

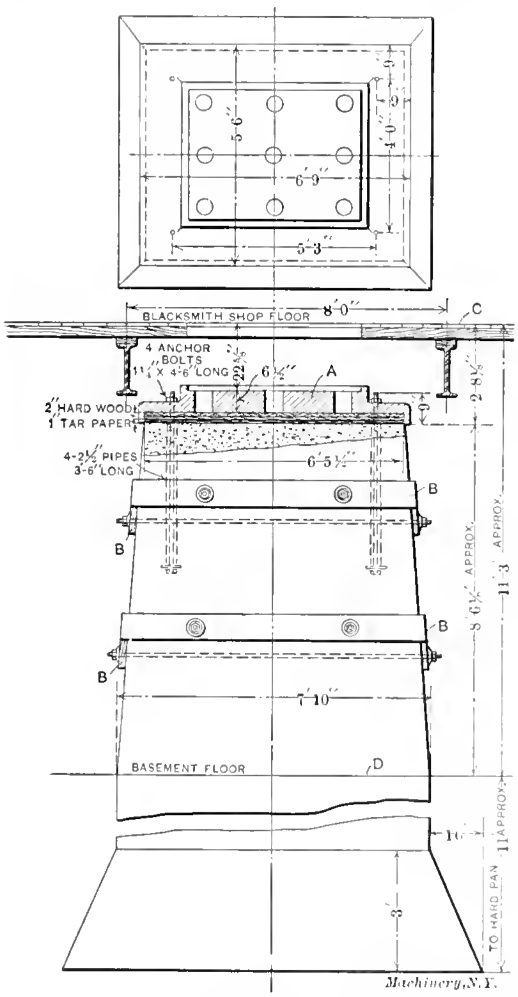

Fig. 1. Concrete Foundations for Drop Hammers in the Pratt & Whitney Co.'s Blacksmith Shop

order to prevent this, a layer of tar paper, one inch thick, was first placed on the top of the concrete foundation, and on top of this, two layers of hard wood, each one inch thick, were laid diagonally, the cast iron base-plate being placed directly on the hard wood, after which the anchor bolts were tightened down, clamping tho base-plate tightly against the wood and the tar paper, and consequently pressing the latter firmly against the top of the concrete. The tar paper would fill in all crevices and rough places on the top of the concrete, and the impact of the hammer blows would be distributed equally over the whole surface. After this improvement had been made, no more troubles were experienced with the top of the concrete being pulverized by the blows of the hammer.

At first it was feared that these solid foundations, having practically no springing action whatever, would cause trouble in regard to the dies, so that a greater cost would be incurred in regard to the replacing of broken dies, but this apprehen-

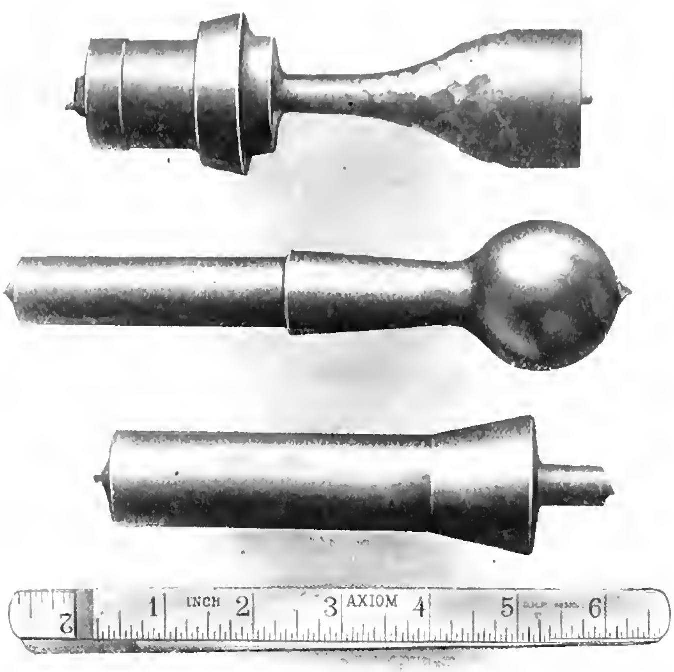

Fig. 2. Examples of Work formerly done on a 200-pound Hammer, but with Concrete Foundations completed on a 100-pound Hammer.

sion proved to have no foundation; the dies seemed to stand up fully as well now as with the old wooden foundations.

The concrete used for these foundations is what is known as 1—3—5 mixture. This mixture consists of one bag of cement, one barrel of heaped sand, and two barrels of stone.

In conclusion, it may be well to remark that the examples of drop forging shown in Fig. 2 do not, by any means, represent the limit of what could be made under the 100-pound hammer since the concrete foundations were put in, but the dimensions of these pieces are now limited by the size of the dies that can be placed on the hammer. As far as the power of the hammer is concerned, it would be possible to forge pieces probably 25 per cent larger than those shown.

The type of foundation used before these concrete columns were put in is shown in Fig. 3. On these foundations the base-plate was first laid on a few layers of plank, each layer being placed crosswise in relation to the next layer above, and this, in turn, was carried by timber, standing on end, to reach through the basement of the building. This timber, in its turn, was placed on foundations in the basement floor. Iron bands reinforced and held the timber together. This built-up foundation, however, acted as a buffer, and the timber standing on end was actually compressed several inches yearly, due to the force of the blows of the hammers.

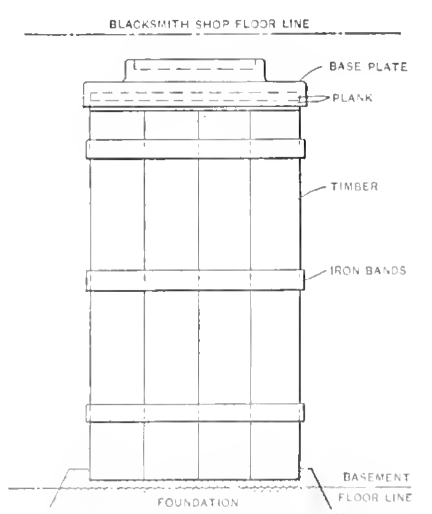

Fig. 3. Old-style Wooden Foundations which have been replaced by the Concrete Column shown in Fig. 1.

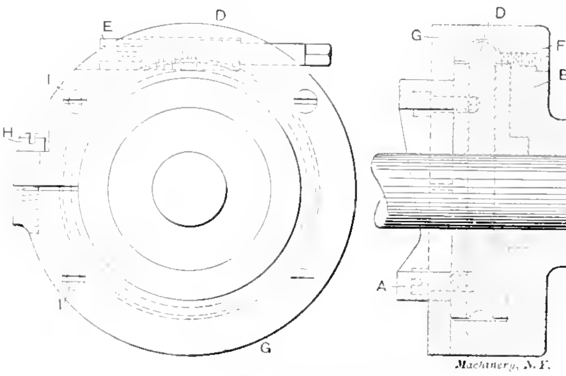
LETTERS UPON PRACTICAL SUBJECTS.

CAM ADJUSTING DEVICE.

Some time ago we had a great deal of trouble with the setting of the cams on our automatic roughers. Sometimes it was but a matter of a few minutes to get them just right, and again it would take over an hour of hard work and strong language. To remedy this state of affairs, we installed a series of cams such as shown in the accompanying cut. The cam proper is shown at *A*, enclosed by the circular housing *B*, which is secured to the shaft by the set-screw *C*. The housing *B* is provided with bearings for the worm *D* which engages with the worm threads cut on the cam member *A*, as shown. The worm *D* butts against a shoulder in the housing *B*, and is held in place by a plug bushing *E* driven in at the other end as shown. This plug is held tightly in place by the screw *F*. At *G*, finally, is a split steel ring fastened to the housing *B*, thus holding cam *A* firmly in place.



Cam Adjusting Device.

After the cam has been approximately set in place and secured by tightening the screw *C*, the next step is to loosen the binder *H* and the two screws *I*. These two screws work in slightly elongated slots, and when loosened allow the ring *G* to spring open a trifle. This leaves cam *A* free to revolve, and it is then adjusted accurately by means of a socket wrench fitting on the squared end of the worm shaft *D*. When the adjustment has been satisfactorily made, the binder *H* is tightened, thus drawing the ring *G* around *A* and clamping it. Screws *I* are then screwed down, and this serves as a further lock against the ring loosening. The cam is then in condition for service. With this arrangement it was possible to adjust the cams to the finest required degree of accuracy, and since placing them on the machines we have had no further trouble along this line. F. B.

MILLING ATTACHMENT FOR THE LATHE.

The accompanying half-tones, Figs. 1 to 3, show a simple but efficient milling attachment for the lathe. This device

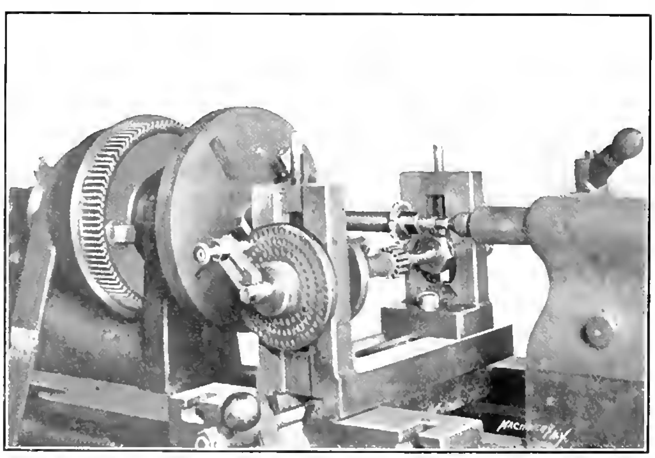


Fig. 1 Front View of the Milling Attachment.

is in use on a foot-power lathe in the private little workshop of Anton Schuermann, of Decatur, Ill., fitted up in the garret of his home.

Fig. 1 shows the front view of the milling attachment, and Fig. 2 shows a rear view of the device, both when in place in the lathe. The gear shown on the arbor between the centers of the device has actually been milled in the foot-power lathe with this device. As will be seen from the cuts, the attachment is placed on the cross slide, in place of the tool carriage. The general design of the device is most plainly

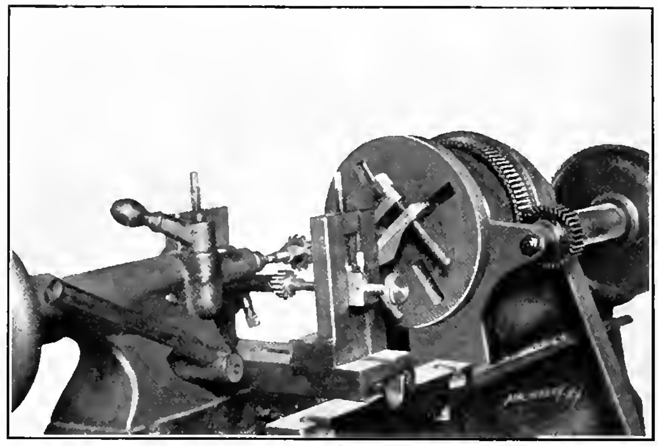

Fig. 2. Rear View of the Milling Attachment.

shown in Fig. 3. The screws *A* are adjusting screws, used for raising and lowering the head- and tail-centers, working on the same principle as does the Lincoln milling machine. The nuts *B* are lock nuts, which are loosened before the screws *A* are turned for adjusting the heads. The tail-center *F* simply slides back and forth in its bearing in the tail-stock, and is held in place by a set-screw *G*. The whole tail-stock may be moved in and out by loosening the screw *K*. The index dial is shown at *D*, three different dials being used

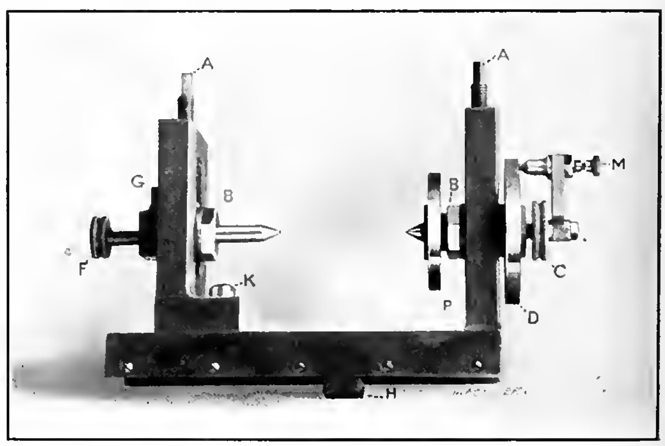

Fig. 3. View showing the Simplicity of the Design.

with the device. The spacing arm *M* is securely locked wherever set by the knurled thumb-nut *C*. The nut by which this fixture engages the cross-slide screw, is shown at *H*. In order to prevent play when an arbor is held between the centers, the tail of the dog used is made tapered where it enters the slot of the driving plate *P*, so that it will fit snugly.

The writer has seen a number of milling attachments adapted to lathes, but this one has several features which are superior to any that he has seen so far. ETHAN VIALL.

Decatur, Ill.

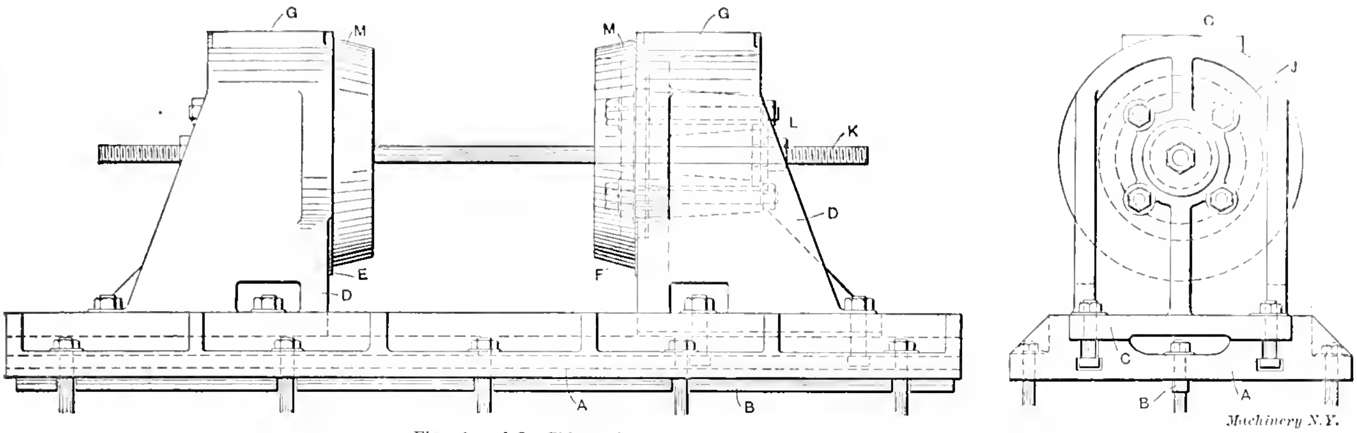
PLANER CHUCK.

Some time ago it became necessary to do some very accurate planer work on a number of cylinders, insuring that the seats outside be true with the center of the bore, and therefore an improvement was necessary on the chuck originally used for that purpose. The outcome of the redesigning was the chuck shown in the accompanying cuts.

The original form of chuck for this class of work consisted of two standards which were bolted to the table of the planer and provided with a series of interchangeable cones, each held by a central bolt to its own standard. This form of chuck rendered it very difficult to get the axes of the two cones

in the same straight line. The chuck, as shown in the cuts herewith, was found upon trial to entirely obviate this difficulty.

The first point at which it was found necessary to change the construction was that a false table had to be constructed to fit upon the planer table. This table is indicated by the letter *A*, Figs. 1 and 2. The rough casting for this table was first of all planed true on the bottom surface. The table of the planer to be used was planed off and the center slot of the table cut out parallel throughout its length by a tool held directly in the tool-post. The false bed was provided with a rib *B*, Figs. 1 and 2, which was accurately finished to fit the slot in the planer table. The false bed was then securely bolted in its permanent position on the table, and a way planed as shown at *C*. This way was carefully finished both on the bottom surface and on the two sides, so as to be of even width throughout.



Figs. 1 and 2. Side and End Elevations of the Planer Chuck.

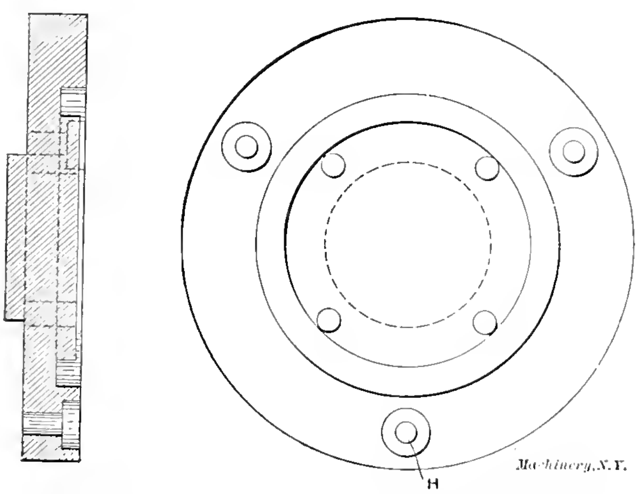


Fig. 3. False Face-plate used for Turning Cones of Various Sizes.

The standards *D* had their feet finished accurately to fit this way, both standards and way being scraped to a sliding fit. When the standards were placed on the way, the centers for the cones were very carefully laid out and tested to insure the two centers being exactly in line. The standards were then removed, chucked in a lathe so that the center was truly central with the spindle of the lathe, faced, and the annular groove *F*, Fig. 1 and 4, accurately turned. The standards were then replaced on the planer and a spot planed at *G*, Figs. 1 and 2, on each one, this spot being an even number of inches above the center line of the cones and center of the annular groove *F*.

Since the cylinders which were to be faced in this chuck were of varying sizes, it was essential that a number of different sized cones should be used to accommodate the various bores. For this purpose the face-plate on a heavy lathe was bored out to receive the boss of the false plate shown in Fig. 3. This false plate was provided with three tapped holes *H* to agree with holes near the rim of the regular face-plate. The false face-plate was made by chucking it with the boss outward in the lathe, and facing off the back, and forming the boss. The face-plate was then turned over and the annular recess shown was cut in it to agree accurately with the recesses *F* formed in the standards. The holes *H* which are countersunk for tapped bolts to enter tapped holes in the regular face-plate should not be spaced evenly, as it is essential that the false plate should have the same position on the regular face-plate every time it is used.

The cones *M*, Fig. 1, were prepared from the rough casting by having an annular rib accurately turned on the back and the back faced off while the casting was held in an ordinary chuck, the rib being made to templet so as to fit either the false face-plate, or the standard. The cone was then bolted to the false face-plate in position on the lathe, and the conical surface carefully turned. It will be seen that an exact center was thus obtained with the center of the false face-plate, which in turn was truly central with the lathe centers, and it was thus possible to get out any number of various sized cones, the centers of all of which when applied to the standards would lie in the same line.

It will be noted in Fig. 4 showing a horizontal section through one of the standards and its cone, that clearance is allowed between the annular rib and the recess receiving it, and that clearance is also allowed between the face of the standard and that part of the back of the cone lying inside of the annular rib. The purpose of this was to obviate the necessity of finishing the back of these portions, as the surfaces obtained by the sides of the rib and the back of the cone outside of that rib are amply sufficient to carry all the stress arising from the weight of the cylinder when in position.

By reference to Fig. 4, it will be seen that the central part of the standard is cast with a large opening clear through;

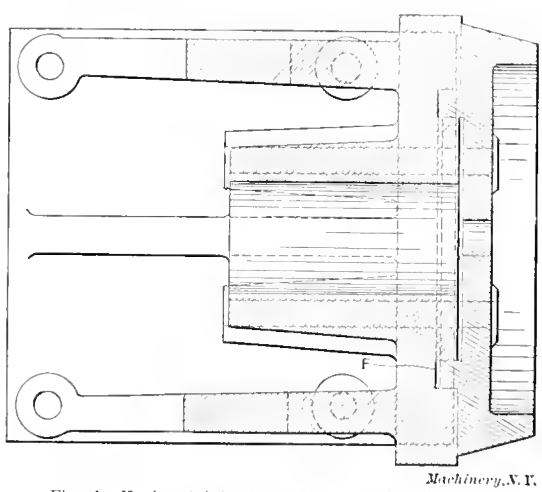

Fig. 4. Horizontal Section of Standard and Cone.

this is merely for lightness, and because in this particular case the cylinders to be carried were very heavy, these standards, if cast solid, would be very difficult to move. The cone is held to the standards by four bolts *J*, Fig. 2, and when in position on the false face-plate for turning, four tapped holes are provided in that face-plate to receive bolts to hold the cone securely. Adjustment for length is made by means of the threaded bar *K*, provided with necessary nuts, and having washers *L* fitting the openings above referred to in the standard.

After having tried this fixture, it was decided to provide means whereby two cylinders could be planed at the same time. A standard having two faces and with two cones was placed between the other two standards, and the bar *K* lengthened. As the construction of this standard, however, is so nearly the same as the ones described, it is not deemed necessary to go into the detail of it.

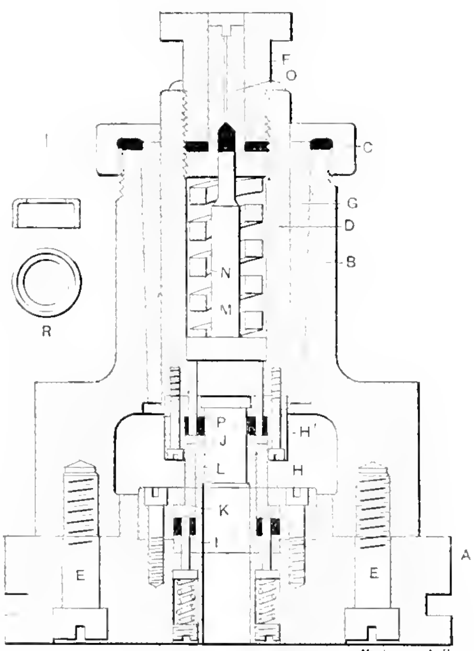
The face *G* is used for leveling up the cylinder cross ways, only the longitudinal leveling being accomplished by the cones. This, of course, is easily done by means of a surface gage, since the face *G* is horizontal both transversely and longitudinally, and is also parallel to the center line of the cone. It is, of course, obvious that the bolts may be changed to suit the planer on which this device is to be used and it is also plain that if a center slot is not obtainable in the planer table, two side slots may be used and two ribs like *B* provided.

Richmond, Va. L. N. GILLIS.

PUNCH AND DIE FOR BLANKING AND FORMING COPPER CUPS.

The subject of punches and dies has been gone over so thoroughly, and is so well understood, that it may seem a bit superfluous to add anything to it; nevertheless the accompanying illustration may be of interest to those who come in contact with such tools.

This die is designed to blank and form up a copper cup or capsule used in the manufacture of balance wheels for watches. The copper strip is fed into the press, which then blanks out and draws the metal into the shape shown at *R*, at the same time punching the center hole. Referring to the



Punch and Die for Blanking, Piercing, and Forming the Copper Capsule shown at R.

illustration, *A* is the base of the sub-press, *B* the body, *C* the cap, and *D* the plunger; all these being of cast iron machined to size. The body and base are held together by two screws *E* after the usual well-known manner. *F* is the buffer plug which receives the thrust of the press piston, and *G* is the babbitt lining of the body *B*. *H* is the outside diameter die, held in place by four screws and two dowel pins. *H'* is the outside diameter punch, also held in place by four screws and two dowels. *I* is the die for cutting out the center hole, and *J* is the punch for this hole. *H'* and *I* also serve as forming dies in bringing the metal to the proper shape. *K* and *L* are shedders, supported by four push-pins, those of the former resting upon springs whose tension is controlled by short threaded plugs, as shown, and those for the latter abutting against the piston *M*, which is in turn pressed down by the large spring *N*, the tension of which is controlled by the plug *O*. The block *P* is used merely to hold the punch *J* firmly in place.

The operation of the die is as follows: The press ram being at top stroke, the copper strip is fed in across the top of *H*, and as the ram descends, the blank is cut from the strip by the punch *H'* and drawn to a cup shape between the inside edge of *H'* and the outside edge of *I*. Simultaneously, the center hole is punched by *J* and *I*. As will be seen by referring to the illustrations, *J* is made a trifle short so that the drawing operation will have begun before this hole is punched. This prevents any distortion of the piece by the punch *J*. Some little trouble was experienced at the start on account of the air in the hollow plunger *D* forming a cushion when it was compressed by the rising of the piston *M*, thus preventing the proper working of the die. This was finally obviated by making a small groove at the side of the piston where it worked in the plug *O*, and drilling a vent hole through *O* as shown. This allowed free communication to the atmosphere, and from then on the die gave complete satisfaction. The variation in size among the cups, or capsules, as they are called, is never more than 0.001 of an inch either in diameter or in length. B. W. F.

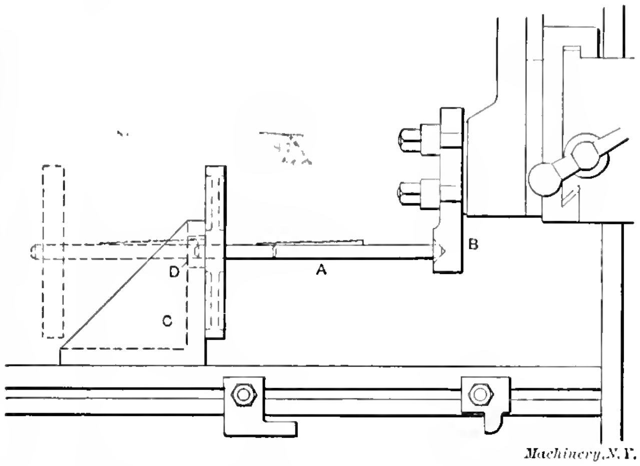
MACHINING CHANGE GEARS.

A subject which is of importance to all lathe builders, whether they be manufacturers who turn out two or three machines a day, or the smaller concerns who may finish the same quantity in a week, is the machining of the change gears. In England this is more important than in America, because the man who first supplied England with screw-cutting lathes decided that twenty-two change gears were necessary, and so twenty-two change gears have become the standard complement, while the ordinary American lathe, as far as my experience goes, has only about fifteen or sixteen. I have not been able to put all the following ideas into practice, but where circumstances permit I shall try all those that are most suitable. I should also like to know from some of the firms who have a lot of this kind of work, how they do it, and the time taken, as this is not so much a record of actual work as a few suggestions as to how the work might be done.

The first item is the castings; start with good workable castings. It will pay to give a bit extra for decent castings. Pickling will improve their workability, and annealing is still better, though perhaps too expensive. The machining of the blanks is the most expensive point of the whole job, with the possible exception of the cost of the castings, therefore it seems that this is the place where we ought to make the biggest saving. One method is first to bore and ream the hole, then drive onto an arbor, and turn down the faces of the rim and boss, using a tool at each side. After this has been done, the blanks are mounted on an arbor, five or six at a time, and the outside diameter turned. I don't care much for this method of turning the sides, because I think there is a tendency for the blank to slip on the arbor when the cut is on, so that the size and speed of the cut will have to be adapted to the gripping power of the arbor, and though two tools are in operation and balancing each other as far as the spring sideways is concerned, there will require to be twice as much power transmitted through the arbor. The method I should adopt for this work would be as follows: There would be a turret mounted in place of the tail-stock, carrying four tools, that is, a chucking drill, a single point boring tool, a roughing reamer, and a finishing reamer. This turret would be fed forward by hand by means of a large pilot wheel, and would revolve automatically on the back stroke. The reason why I should have a hand feed is because the operations would be so quickly performed (especially if the tools were high speed steel) that an automatic feed which would have to be engaged every time would not appreciably diminish the time, though a full automatic turret would no doubt be beneficial. To turn the sides, there would be a long tool-holder mounted on the carriage cross slide, and hinged thereto, so that it could be lifted up to clear the turret when the turret was in operation. Two tools would be used, one for the rim and one for the boss; they would be set in the same plane, so that the boss would be the same length through it as the width of face of the teeth when machined. The reason for this will be explained later. It will be seen now that there are two tools in operation at once, just as

in the other method, and the gear, being gripped in the chuck and thus supported at four points of the rim, is in a better position for being machined than when mounted on a comparatively small arbor. After one side has been machined, the gear is turned around and without any particular care in setting true, other than getting it flat against the faces of the jaws, the other side is machined in a similar manner. The outside diameters are turned as in the first method.

I might say for the benefit of American readers that in England an 8-inch center (16-inch swing) lathe would be supplied with twenty-two change gears, having from twenty to



The Way in which the Gears are key-seated on the Planer.

one hundred and twenty teeth, with an extra 40-, 50-, or 60-tooth gear. They would be 8 diametral pitch and 1¼ inch bore, so that it will be seen that turning up the 120-tooth gear, which is 15¼ inches diameter, on a 1¼-inch arbor is not by any means a rigid job. Another method of machining the blanks, which I think would make about the best time of any, is by grinding. A powerful grinder would soon grind the comparatively narrow faces of a change gear, and leave a better finish than could be obtained by turning and polishing. I should think the Landis Tool Company ought to be able to give us some interesting information on this subject.

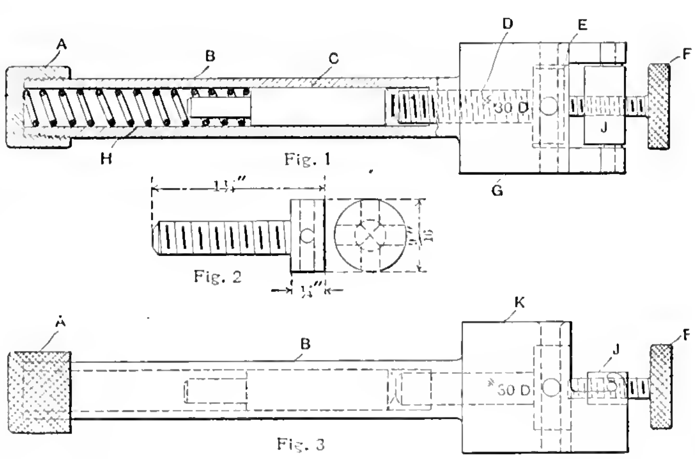
The next question is the cutting of the gears, and I can speak definitely on this point. It is possible to cut 8-pitch teeth in cast iron at a feed of ten inches per minute, and by this I don't mean for five minutes, but day after day, week in and week out. I have done this myself. The machine used was a Brown & Sharpe No. 6; the speed, fifty revolutions per minute; the cutter, a Cammell Laird 0172 high speed steel, 4 inches diameter, and the feed 0.2 inch per revolution. The blanks are cut six at once, and it is for this reason that the rim and boss are made level, the blanks thus staying each other. The indexing motion is geared up, not to cut consecutive teeth, as usual, but to pass two or more teeth, according to the number being cut. For a 120-tooth gear, we arrange to cut every seventh space because 2, 3, 4, 5, and 6, being factors of 120, would simply divide the gear into 60, 40, 30, 24, and 20 respectively; whereas, when we cut every seventh tooth, the cutting goes on until the gear is finished, the blank going around seven times. It is really wonderful how this simple proceeding dissipates the heat generated by the cutter, both cutter and blanks being comparatively cool after a two hours' run, the time usually worked with one sharpening of the cutter.

To finish the gears, they require to be key-seated, and for this a planer can be used, which, with very little outlay, will make as good time as the best key-seater. The first thing to be considered is the cutter bar or broach, which consists of a piece of tool steel *A* about twenty-four inches long, and a sliding fit in the bore of the gears. This bar is grooved to a depth of about three-eighths of its diameter, starting in at one end and finishing about three inches from the other end. Into this groove are fixed, by screws from the under side, two or three pieces of tool steel which have teeth cut therein, the teeth tapering from nothing at the front end to the depth of the key-seat at the other end, the last few teeth being all the same height so that they will keep the size longer. The first tooth is about two inches from the front end of the bar. The width of the teeth is of course equal to the width of the key-seat to be cut. To the planer tool-post is fastened a suitable cup-shaped thrust piece *B*, and an angle plate *C* is securely bolted to the platen. In the angle plate is a hole which receives bushing *D* bored the same size as the cutter bar or broach. In operation, the planer platen should not run above 15 feet a minute on the cut, the stroke being adjusted so that it is from 6 to 12 inches more than the length of the cutter bar. The front end of the cutter bar is then placed in the angle plate bushing, and run through two or three times, the bar being revolved the width of the key-seat at every stroke, so that there is no fear of the teeth having to cut into the bushing when operating on the gears. After this has been done, the stroke is altered so that when the table reverses at the end of the cutting stroke there is room for the gear between the thrust piece and the angle plate. It isn't necessary to stop the machine every time a gear has been key-seated. As soon as the end of the bar comes through the angle plate, another gear is put on, as indicated by the dotted line, and when the table reverses, the gear that has been key-seated is removed, and the bar with the gear which has been previously placed in position is withdrawn and put on the other side of the angle plate to be again pushed through. It is necessary always to keep the teeth of the cutter-bar approximately in the same position as the slot in the bushing. With this arrangement it is an easy job to key-seat one hundred and twenty gears an hour, the biggest job being the carrying of the gears to and from the machine.

RACQUET.

DRILL JIG.

Figs. 1 and 3 represent a drill jig for drilling ⅛-inch holes in the adjustment screw shown in Fig. 2. This screw is made from cold rolled stock, and the holes do not need to be very accurate, as they are only used to turn the screw by putting a pin in the holes. Referring to Fig. 1, handle *B* and the body of the jig *G* is made from a piece of square machine steel and case-hardened. The piece of work to be drilled as shown



Figs. 1, 2 and 3, showing the Jig and a Sample of the Work.

in Fig. 2, is placed into the jig and held there with the thumb and the left hand, pushing back plunger *C* against spring *H*, while cross-head *J* with screw *F* is taken in the right hand. The cross-head is placed in position as shown in Fig. 3, hooks on the jig body being provided for the pin through the cross-head, and screw *F* is then tightened. Then the screw shown in Fig. 2 is ready to be drilled. It is only necessary to drill from two sides of the jig. The size of the drill is marked on these two sides.

A very important feature is that after the piece of work is drilled, and the cross-head *J* is removed, spring *H* pushes out the piece of work, and all that is necessary to do is to insert another screw, and drill in same manner as before. Cap *A* is merely to keep spring *H* and plunger *C* from coming out.

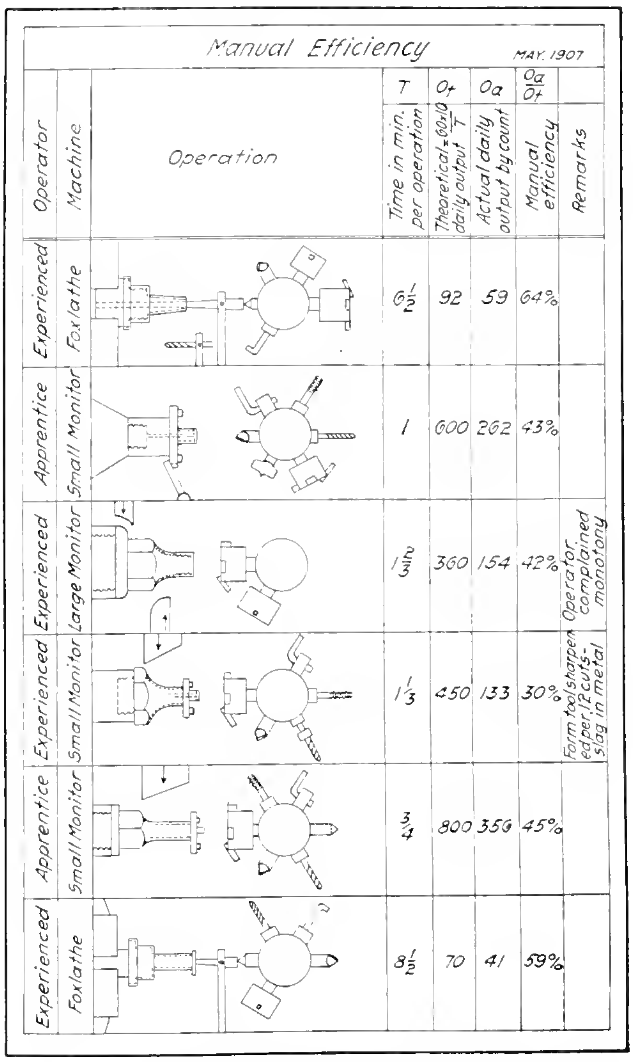
This jig was first tried with a small cam lever, instead of using the cross-head *J* and screw *F*, but owing to the variation in width of the heads of the screw (Fig. 2), it made it impossible to stop the cam lever in same position every time, which caused the lever to project past surface *K*, which of

couse, interfered in laying the jig on the table of the drill press. It may not seem practicable to make a jig and not bush the holes, but as we did not have a great many screws to drill and as the work was not very particular, it was cheaper and good enough for the job to leave out the bushings. The jig has proved very satisfactory, and has been in use at different times for more than three years, and it is still in good condition. B. M. WELLER.

Franklin, Pa.

EFFICIENCY CARD.

The accompanying cut shows a page from a data book used in one of the machine tool building shops. This card is intended for recording the time used for performing certain operations, and for recording the efficiency, expressed in per cent, of the men. In the two first columns are given the class of operator and the machine on which the operation was performed. The middle column, headed "operation," under which are shown crude sketches of the tools used, is intended to give an idea of the class of tools and the way of setting up used in the individual case for which the record was taken.



Manual Efficiency MAY. 1907

Operator	Machine	Operation	T Time in min. per operation	O_t Theoretical $= \frac{60 \times 10}{T}$ daily output	O_a Actual daily output by count	$\frac{O_a}{O_t}$ Manual efficiency	Remarks
Experienced	Fox lathe		$6\frac{1}{2}$	92	59	64%	
Apprentice	Small Monitor		1	600	262	43%	
Experienced	Large Monitor		$1\frac{2}{3}$	360	154	42%	Operator complained monotony
Experienced	Small Monitor		$1\frac{1}{3}$	450	133	30%	Form tool sharpened per 12 cuts - slag in metal
Apprentice	Small Monitor		$\frac{3}{4}$	800	356	45%	
Experienced	Fox lathe		$8\frac{1}{2}$	70	41	59%	

Sample Page from Data Book in which is recorded the Time for Performing Work, and the Efficiency of the Men

Each man is permitted to set up his work and his tools in an individual manner, using, of course, such special tools as he receives on request from the tool-room. The time given in the column T is the time in minutes used for completing one piece, the operator, unknown to himself, having been timed through one complete cycle of operation. For the sake of comparison, the number of pieces made during the day was counted after the men had left the shop. The column O_t gives the theoretical daily output, that is, the output which would result if all the pieces could be made at the same rate as the one timed in the first column. The column O_a gives the actual daily output ascertained by counting, as stated heretofore. The next column gives the efficiency in per cent, being arrived at by comparing the theoretical daily output with the actual daily output. The last column is reserved for remarks. Probably others have on hand records of a similar character, showing the comparative efficiency of workmen, subjected to a more rigid system than ours. The results of such investigations would probably be interesting to the readers of MACHINERY. H. D. Y.

PIRATING.

In a recent issue of MACHINERY an editorial appeared on "Pirating Special Machine Tools" which calls to mind another form of piracy which is possibly more common. This is the taking of ideas from other concerns in designing a machine for the market. How many times do we hear the words, "Why, that new machine of the Jones Machine Co. was designed by Smith who used to be with Jones' competitors. You can see the other fellow's ear-marks on Jones' new machine." This is probably the least objectionable form, for a man who designs a machine for one firm will probably follow more or less the same lines in designing for another concern a machine of similar nature. The next step in these forms of pirating is for one designer to take his ideas deliberately from a competing concern.

Here is the story which was told me by the draftsman who did the "designing." A concern manufacturing pumps decided to bring out a new type, and gave the draftsman general instructions as to what special features the design should include, leaving the details to be worked out by him. The draftsman happened to recall having seen a pamphlet of a competing pump manufacturer showing a pump somewhat on the lines proposed. He hunted up the pamphlet, which, by the way, announced that the pump shown was a strictly new departure. The draftsman, not letting it be known that he had the circular, followed out the design to a large extent. Things progressed, and the first pump was made according to the design and about ready to be tested, when, one day, into the drafting-room walked the manager. "There's a leak in this factory somewhere," said he to the draftsman. "Here the ———, ——— & Co. have gotten out a pump exactly on the line of our new pump. Somebody in this shop must have given it away to them." He had come across the circular the draftsman had used. A. A. ANDREWS.

THE GAGING OF HEATS FOR HARDENING.

In a recent issue of a technical magazine, I read an article on a very important subject: The heat treatment of carbon steels. This is a subject that is uppermost in the minds of a great many mechanics at the present time, and each one has his own ideas as to how it should be done to get the best results. They read everything published bearing on the subject, and use their own judgment as to the best methods of obtaining the right heat for hardening.

It takes an experienced man to gage the heat for hardening with the eye, at all times, and under all conditions, without heating some tools just a little hotter than they should be to get the best results, and that means sometimes spoiling an expensive tool, or, hardening the tool in such a way that it will not stand up to the work expected of it. Again, some of the tools on test will be found soft, and that means reheating, which is unnecessary when it is done right the first time, and in the case of taps, and such tools, that cannot be ground or lapped without a lot of trouble and expense, it means sometimes a loss of that particular tool.

There are various reasons why heats are not always gaged correctly. In the first place, the man has no gage to go by, and again, the light conditions, prevailing at the time, may interfere. This can be overcome by having shades at the windows, that can be adjusted. Sometimes the eye gets "off-color" and needs rest for a few minutes. The use of the "magnetic influence" in gaging the heats for hardening is practically new; in fact, a great many experienced mechanics, versed in the handling of carbon steels, have never heard of it, but the fact remains just the same. We all know that the proper heat for hardening steel to get the best and most lasting results, is the lowest heat that the steel will harden at. How are we to find this out? By the use of the magnetic needle,

no matter what the make, or brand of steel. Following these lines, the writer has experimented for two years, and, at the present time, can harden a tool or piece of carbon steel at the first heat, without knowing the brand or temper of steel, and with such results that tools hardened by this method outlast similar tools hardened in the old way, sometimes as high as 4 to 1. In every case, the tool lasts much longer, showing very plainly that this method is the best, or at least worth testing.

The gaging of heats by the magnetic needle, is done in such a way that you can test every piece, or you can test every second, or third or fifth piece, or only the first piece, and then, noting the color very carefully, harden several pieces and make no mistake. If the color seems to be off a little, test

Testing a Milling Cutter, when Hardening, by Swinging it Back and Forth past a Magnetic Needle.

again; this can be done right along, provided the steel is of the same "carbon temper," but in all cases where the carbon temper changes, the test must be made again. Some months ago I had a pair of rolls to harden, about 27 inches long by 6½ inches diameter. After sizing them up, I made inquiries as to what they were made of; one said they were crucible machinery steel; another, that they were tool steel, and the superintendent said that he did not know—it was up to me to harden them. Well, I did harden them, and without any experimenting or second heating. I heated them in a Brown & Sharpe furnace, and tested them with the magnet and with plenty of water, and did a good job. I had experimented with the magnet before, so I knew what to do. At another time I had to harden 1,000 horseshoe magnets for telephones, one-half of which were imported steel, the other half, domestic. I hardened them without any trouble, and the telephone company was pleased with the work. I found out afterward that the company had tried to harden them and could not get a uniform hardness. In this case I tested one in about every forty.

In starting my experiments, I bought a small pocket compass with a jeweled pivot and needle stop, about 2 inch diameter, and costing a dollar and a half. I got a wooden stool to rest it on close to furnace, as shown in the illustration. The stool and compass should be set in such a position that the natural swing of the work back and forth when testing, will be in a plane parallel with the needle; in other words, the piece being hardened should be swung north and south. By passing the tool being hardened (in this case a milling cutter) forward and backward close to the compass, the magnetism of the tool will cause the needle to be deflected one way, then the other, and the tool will still continue to deflect the needle until the right degree of heat has been obtained, that is, the proper heat for dipping in the bath. In other words, the right heat is when the tool loses its magnetism. It does not follow, that if the needle remains stationary, the first time you test, that the heat is right, because, after the tool has reached a certain degree of heat the magnetism leaves the steel, so there is no influence on the needle, showing plainly that the steel is too hot. The different carbon tempers and different grades of steel, require different degrees of heat, and the magnetism leaves the steel at a certain degree of heat to correspond to the different points of carbon in the steel, and in every case this is the proper heat for dipping. After testing until the right degree of heat is obtained, I put the tool back in the furnace for about twenty seconds, just to even up the heat. I then dip the tool in a water bath to set the hardness, then from the water bath to a lard oil bath until cold. In the case of the rolls previously spoken of, I had to rig up a tackle to the roof, and in place of a rivet in the tongs, I made a hook with thread and two nuts, one hook on each side of tongs, to hook into the tackle, so as to handle the work quickly.

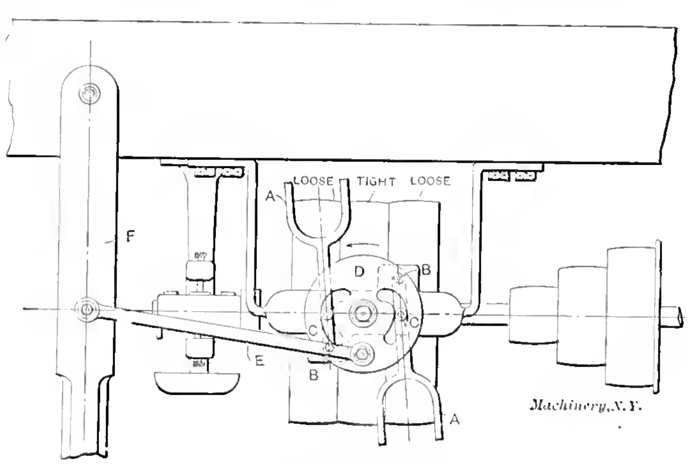
This method applies only to tools that can be heated all over, as it is obvious that heating a tool, say a tap, on the end to be hardened, would have a disturbing effect on the needle simply because only part of the tap would be hot, leaving magnetism in the shank; I am referring now to taps with long shanks. In using the magnetic needle, if it points due north and south, a large body of metal would deflect the needle, to a certain extent, from its natural position, but no matter what the position of the needle, the moment a tool is held close to it, it answers to the magnetism of the tool, and will move until the right degree of heat is reached; when this point is reached, the needle become inactive.

I make it a point to keep my furnace at 1,300 degrees F. all the time, or as near as possible to this degree of heat, and with this heat I find it is not necessary to test every piece. I have never given much thought to improving this method, but undoubtedly, there is a large field for somebody to experiment in. GEO. T. COLES.

Decatur, Ill.

A BELT SHIFTER.

The belt shifter which is shown in the cut is so simple in design and operation that little explanation is needed. The belts are guided by the forked levers *A*, which are pivoted at *B*. The rollers *C* are fixed to the forked levers, and work in the slots as shown. When the disk *D* is rotated—say in the direction of the arrow—by the levers *E* and *F*, the left roller is forced toward the center of the plate *D*, thus moving the forked lever to the right and shifting the belt on the tight pulley. The belt on the right side is not moved during this



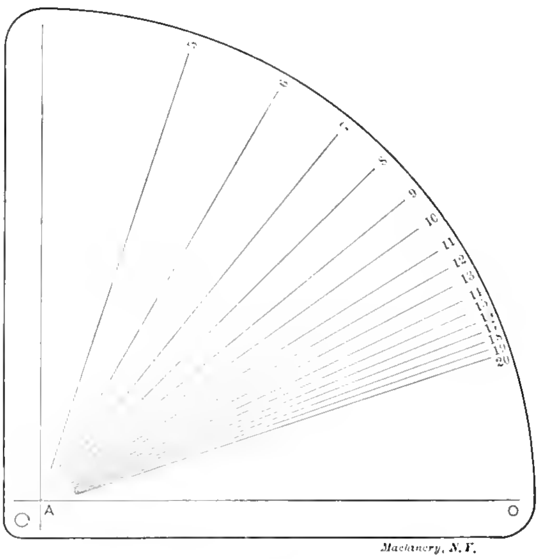
A Belt Shifter of Simple Design.

operation, as the right roller moves in a part of the slot which is concentric with the plate *D*. If the disk *D* had been rotated in a direction opposite to that indicated by the arrow, the movements would, of course, have been reversed, the right belt being shifted, and the left one remaining stationary. This shifting device has, in many cases, given better satisfaction than the friction clutch, as it does not get out of order as easily, and it is not so likely to run warm. CHARLES ROEYS.

Antwerp, Belgium.

TOOL FOR SPACING BOLT HOLES.

In drawing flanges, cylinder heads, etc., where a number of holes are shown on a given pitch circle, it is usually desirable to have them located correctly on the drawing, for the sake of appearance at least, even if not really important otherwise, and for this purpose the tool shown in the accompanying cut was designed. It is a very convenient instrument, made from transparent sheet celluloid, about 1/64 inch thick. The method of procedure when using this tool is to draw the pitch circle, and then place the instrument over it, with the point *A* on the center. One point of the dividers is placed on the line *A O*, at the point where it intersects the pitch circle, and the other point of the dividers is set at the inter-



Tool for Spacing Bolt Holes.

section of the pitch circle and the radial line marked with a number corresponding to the required number of holes in the whole pitch circle. This gives the correct spacing for the number of holes required. If reasonable care is used in the construction of this tool, it will be found to give very close results. The design, of course, can be varied to suit special requirements. The one shown in the cut was made by laying off the correct angles on the circle having 18 inches radius, and scratching the radial lines with a needle point on the celluloid, after which drawing ink was rubbed into the scratches so as to make them show plainly. F. W. C.

BALL-BEARING CONE CENTERS.

The subject of cone centers is one that has received much attention and thought from designers and mechanics for many years, and the story of the many unsuccessful attempts to design a ball bearing cone center would prove interesting reading if such an article could be written. In presenting

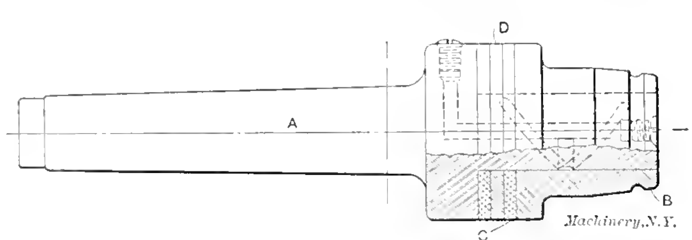


Fig 1 Cone Center of Ordinary Design.

this article, I wish to call attention to the gradual design or evolution of a most satisfactory center of this description, where a failure was turned into a complete success.

Fig. 1 shows the ordinary and most widely used cone center, also the simplest one, and the one most easily made, consisting as it does of the center proper *A*, the cone *B*, the two fiber washers *C*, and the hardened steel washer *D*. While this center will give "good enough" service in many cases, for durability and accuracy, the design is bad. The center bearing of cone *B* wears, and the cone very soon runs out of true, and this error is produced many times in the finished work. The worst feature of this design is that there is no way to prevent the small particles of steel, dirt, etc., from getting into the wearing surfaces and causing trouble. The washers *C* also wear very fast, and although many different forms and materials have been tried, the fact remains that they soon wear out, drop off, and get lost, or are mislaid. This last fact gives us the first essential of a successful cone center.

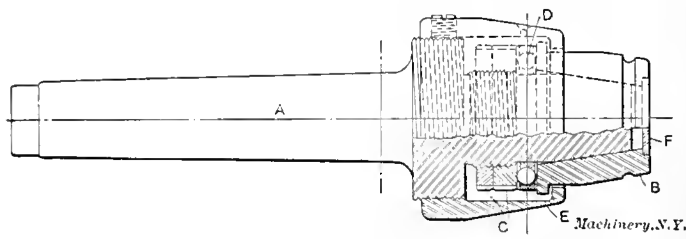

Fig. 2. Ball-bearing Cone Center which proved Unsatisfactory.

It should be self contained, and made in such a manner that the component parts are held in such a way as to prevent their being lost. The design shown in Fig. 2 was not expected to entirely overcome the wear on the cone bearing. The ball bearing *D*, was introduced and adjusting nuts *C* to provide adjustment for the cone *B* as fast as the cone bearing on spindle *A* should wear. This center also proved a failure owing to the variation in the diameter of the balls, the change in the alignment of the adjusting nuts, and the fine adjustments necessary to keep the cone true, all of which led to a combination that was too expensive to maintain, and caused the final abandonment of the design. In this design it will be noticed that the retaining guard *E*, and dirt guard *F* have been added. The final and successful center is clearly shown in Fig. 3, in which *A* is the shank having two grooves or ball races at *D* to receive 24 and 48, 1/4-inch balls, respectively. The cone *B* is hardened and ground inside and out, and has a flange a little smaller in diameter than the shoulder on *A*, allowing retaining guard *E* to slip over the cone. This guard is held in position on the shoulder of *A* by the set-screw, as shown, and prevents too much freedom of movement of the cone *B*. In order to provide for the grinding operations, and provide a dust guard, a recess is cut in the

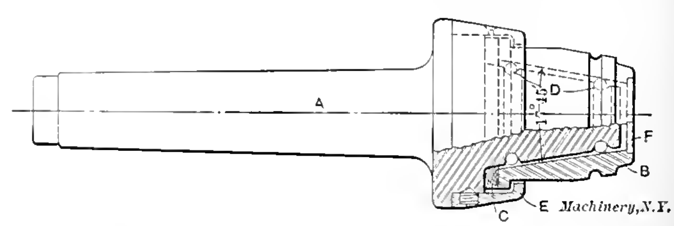

Fig. 3. Ball-bearing Cone Center of Improved Design.

small end of *B*, and, after the center is assembled and adjusted, the cone *B* is removed and a disk *F* forced into place, leaving the end flush, thus preventing any dirt or chips getting into the ball races. A felt washer *C* acts as a filter between the shank *A* and the cone *B*, and, while allowing the water to fill the cone, prevents all foreign matter getting near the balls, and at the same time allows the balls to revolve in a water bath, keeping them cool. After 500 valves had been ground, the cone and shank showed no perceptible wear, and after the first 1,000 had been turned out, the center was declared to be "just getting into good shape." One of the important points in this design is that the bearing point of the work is in direct line with the ball bearing, thus preventing the leverage which would result if the point of contact were at the extreme outside point of the cone.

There are many points to be considered in the production of this center. I have in mind a tool-maker (?) who, after the cone had been carefully ground and the center assembled for inspection, before disk *F* had been put into place, instead of removing cone *B*, carefully placed disk *F* in position and then applied pressure against the disk, cone, and balls. Naturally upon trial the center developed a bad case of "wobbles," and this tool-maker then declared that, "that cone was the worst job of grinding that he had ever seen."

Easton, Pa. F. R. PEIRCE.

SHOP RECEIPTS AND FORMULAS.

A DEPARTMENT FOR USEFUL MIXTURES.

This page is intended to be used only for the publication of such shop receipts as the contributors know from experience to be practicable. Receipts are solicited on the condition that the contributors personally know that they are reliable. The fact that a receipt is old and supposedly well-known does not bar it, provided it has not already appeared here.

398. LUBRICANT FOR ALUMINUM CUTTING.

The following mixture makes the best lubricant for turning, or any other machining operation on aluminum, that I have ever tried: Mix 1 part good lard oil with 4 parts of kerosene oil. It beats anything yet published in this department.

A. A. STEVENSON.

399. TO MAKE LIQUID GLUE.

Take one quart soft water and 2 pounds of pale glue; dissolve in a covered vessel by the heat of a water bath, cool, and add gradually 7 ounces of nitric acid (specific gravity 1.335). This glue is very strong and will not gelatinize.

C. S.

400. LUBRICANT FOR FITTING ALUMINUM THREADS.

When screwing an aluminum article on to an iron or steel part, much trouble is often experienced by the breaking and tearing of the threads of the softer metal. This can be prevented by lubricating the screw well with a mixture of oil and graphite.

SREGOR.

401. MATT DIP FOR BRASS.

To make a matt dip for brass, mix 1 part sulphuric acid in 1 to 2 parts of nitric acid and 1 part sulphate of zinc. Let the mixture stand 24 hours, and use hot. More or less nitric acid gives a fine or coarse effect, as may be preferred.

Bridgeport, Conn. J. L. LUCAS.

402. TO PREVENT SCREWS FROM GETTING RUSTY.

To prevent screws from getting rusty and sticking tight, instead of using ordinary oil only, add some graphite. After years you will be able to unscrew them with ease, and find them as bright as new, even if they were exposed to very damp air.

J. M. MENEGUS.

Los Angeles, Cal.

403. TO DISSOLVE GLASS.

A hole may be cut or etched through glass readily by using hydrofluoric acid. The acid should be applied in the same way as etching acid, using wax to surround the portion of the glass which is to be penetrated. Hydrofluoric acid is sold in wax bottles, as it cannot be kept in glass. It may be handled with a hard rubber dropper similar in construction to the ordinary glass medicine droppers.

S. W. GREEN.

404. TO ANNEAL HIGH-SPEED AND AIR-HARDENING STEELS.

To anneal "Novo" or "Blue Chip" high-speed steel or any of the air-hardening steels, pack the steel in a piece of gas pipe with powdered charcoal, and seal the ends with clay or caps screwed on. Heat to a cherry red, giving time for the contents of the pipe to reach this temperature, and then set in a dry, sheltered place to cool. The steel will be found annealed so that can be readily drilled, turned, planed or worked as required.

A. A. STEVENSON.

405. TO MAKE A WATER-TIGHT JOINT.

Take ordinary white lead, and mix enough powdered red lead with it to make a paste the consistency of putty. Spread this mixture on the joint, and when it hardens, the joint will bo perfectly water-tight. We used this mixture on flanges on a standpipe, after we had tried all kinds of rubber gaskets without success. The mixture hardened and made a tight joint, never leaking afterward.

J. D. PAGE.

Youngstown, Ohio.

406. TO TEST WHITE LEAD.

This simple test to determine the purity of white lead may be found useful where much painting is being done. It is as follows: Select a piece of charcoal of firm structure, and hollow out a cavity in one side about 1/2 inch in diameter and of the same depth. Put a sample of white lead in the hollow about the size of a pea, and subject it for a few moments to a blow-pipe flame. If the sample is pure, it will quickly reduce to metallic lead. Adulterated white lead will generally contain a residue that cannot be reduced.

M. E. CANEK.

407. ALUMINUM SOLDER.

The following is a receipt for aluminum solder which we are using with success in the Elwell-Parker Electric Co.'s shop, Cleveland, Ohio. It is the result of experiments made by several of our foremen: Pig tin, 12 ounces; sheet zinc, 3 ounces; mercury, 1 ounce. Melt the zinc first and then add the tin. When the tin is melted remove from the fire and add the mercury while still in the molten state. Be careful to stir the mixture thoroughly before pouring into the mold. Use stearic acid for a flux.

L. MILLER.

Cleveland, Ohio.

408. PARTIAL CASE-HARDENING.

The entire surface of the work, or that part which is to be hardened, should be coated with a moderately heavy coat of Japan enamel, and then a medium heavy coat of copper should be applied to the remaining portion of the work. In applying the copper, care should be taken not to disturb the Japan. After the copper is applied, the piece is ready to be carbonized. It should be packed, and heated to a bright red, and held at this heat long enough for the requirements of the work. Then the box or case, containing the pieces to be case-hardened, are taken out of the fire and the work is permitted to cool in the box. When cool, the work is taken out and reheated in the open fire, and dipped in oil or water. The copper prevents the absorption of the carbon, while the Japan enamel burns off and allows the carbon to take effect.

E. S. WHEELER.

409. HARDENING CAST IRON.

The following process can be used for hardening cast iron whether rough or after machining. The casting is first heated to a cherry-red heat; it is then dipped in a bath which consists of a practically anhydrous acid of high heat-conducting power, preferably sulphuric acid of a specific gravity of from 1.8 to 1.9, to which is added a suitable quantity of one or more of the heavy metals or their compounds—such, for example, as arsenic or the like. The preferable ingredients of the bath are sulphuric acid of a specific gravity of approximately 1.84 and red arsenic in the proportions of 3/4 pound of red arsenic crystals to 1 gallon of sulphuric acid. The castings may be either suddenly dipped in the aforementioned mixture, and then taken out and cooled in water, or they may be left in the bath until cool. In preparing the bath, when sulphuric acid and red arsenic are used, better results are obtained when the crystals are added to the sulphuric acid and the bath is allowed to stand for about a week before using.

O. G.

410. A TEMPERING SOLUTION.

A tempering solution used for high heats may be composed of two parts Chili saltpeter and one part nitrate of soda. This tempering solution is used only at high temperatures, as it becomes solid at about 500 degrees F. It is used in place of tempering oils, as they often thicken after short use, and will flash or ignite at about 600 degrees F., and often at a lower temperature. It should be used in connection with a tempering furnace, the heat being gaged by a thermometer. The thermometer should be removed when the day's work is over. At night, two iron plugs, with a fairly liberal taper per foot, and long enough to reach from the inside bottom of the tank containing the bath, to about four inches above the top of the solution, should be placed vertically with the small end of the taper down, and some little distance apart. These should be permitted to stay in the solution when it solidifies. On the following morning, these iron plugs should be unscrewed and removed. The holes left in the solidified solution by these plugs afford an escape for gases that form in reheating the bath.

E. S. WHEELER.

HOW AND WHY.

A DEPARTMENT INTENDED TO CONTAIN CORRECT ANSWERS TO PRACTICAL QUESTIONS OF GENERAL INTEREST.

Give all details and name and address. The latter are for our own convenience and will not be published.

WIDTHS OF TOOLS FOR CUTTING SQUARE THREADS.

C. H. H.—Please give, in your "How and Why" columns, the dimensions for tools used for cutting square threads. As is well known, in order to procure clearance between threads in the screw and the nut, when provided with square threads, the threads in the screw and the nut must be cut somewhat different from what would be the actual theoretical standard width for square threads. What I wish to know is the width of the point of the tool for cutting screws and nuts having square thread.

A.—When cutting square threads it is customary to make the screws exactly according to the theoretical standard of the square thread. The width of the point of the tool for cutting *screws* with square threads is therefore exactly one-half of the pitch, but the width of the point of the tool for cutting taps, which afterwards are used for tapping nuts, is slightly less than one-half the pitch, so that the groove in the tap becomes narrower, and the land or cutting point wider than the theoretical square thread, thereby cutting a groove in the nut which will be slightly wider than the thread in the screw, so as to provide for clearance. An inside threading tool for threading nuts evidently must be of the same width as the land on the tap would be, or in other words, slightly wider than one-half the pitch. This provides, then, the required clearance. The accompanying table gives the width

TABLE OF WIDTHS OF TOOLS FOR CUTTING SQUARE THREADS.

Number of Threads per inch.	Width of Point of Tool for Taps.	Width of Point of Tool for Screws.	For Inside Thread Tools for Nuts.
1	0.4965	0.5000	0.5035

24	0.0203	0.0208	0.0213

of the point of the tool for all ordinary pitches from one to twenty-four threads per inch. The second column gives the width of the point for cutting taps to be used for producing square thread nuts. The third column gives the width of the point of the tool for cutting screws which, as we have said, equals one-half the pitch, and the fourth column gives the width of the point for inside threading tools for nuts. While the table has been carried to as fine pitches as those having twenty-four threads per inch, square threaded screws having so fine a pitch are very seldom used. Some manufacturers of square threading tools, however, make square threading tools for pitches as fine as these, and for this reason they have been included.

TRUCK EQUALIZER.

H. E. R.—How should fiber stress and thickness be determined for a truck equalizer such as shown in Fig. 1? The total load on the truck is 43,000 pounds, supported by two springs, each spring hung between two equalizers.

A.—This equalizer is a beam supported at the ends and loaded symmetrically at two points between the supports, and should be so considered in figuring the fiber stress for a given load, except as the calculations are modified by the curved shape. The maximum bending moment and fiber stress will occur at the points where the springs are attached, and at all sections between these two points.

Fig. 2 shows the method of finding the bending moment at section $x\ y$ through the point of spring suspension, or at any other point $x_1\ y_1$ between the spring and the support. The sections must be taken at right angles to the neutral axis,

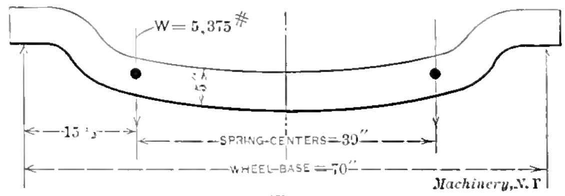

Fig.

and the distance l is measured from the neutral point of the section perpendicularly to the line of reaction. The bending moment at all points between B and the corresponding point on the opposite side of the center line is the same as at B

Between B and the point of support when the sections are at a different angle from the reaction, as in Fig. 2, there is a direct tensile stress to be added to the maximum tensile stress due to bending. The greater the angle, the greater this stress. It is found as given by the formulas in Fig. 2. Between point B and the corresponding one the other side of the center line, the angularity of the section makes no difference, and does not enter into the calculation at all. In this calculation we will consider that the hole for the spring sup-

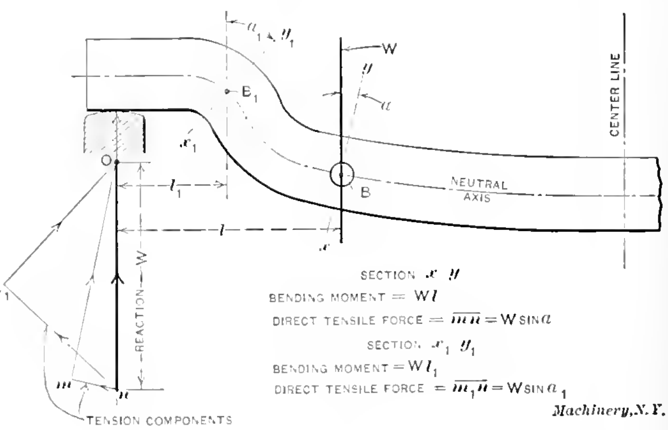

Fig. 2.

porting pin is located on the neutral axis. The section will be the strongest if this is the case, and there seems to be no good reason why it should not be so located.

In the formulas and calculations these reference letters will be used, in addition to those given in Figs. 2, 3 and 4.

A = area of section.
W = load = reaction.
M = bending moment.
Z = section modulus.
s_b = fiber stress due to bending.
s_t = stress due to direct tension.
s = total tensile stress.

The maximum tensile stress at any section between B and the point of support is found by the following formulas:

$$s_b = \frac{M}{Z} \tag{1}$$

$$s_t = \frac{W \sin a}{A} \tag{2}$$

$$s = s_b + s_t \tag{3}$$

To find M, see Fig. 2; to find Z, see Figs. 3 and 4.

The section at $x\ y$, which is the weakest, sustains the maximum fiber stress. Assuming that $b = 1\frac{1}{2}$ inch and $d = 1\ 1/8$ inch (Fig. 4), the maximum stress is found by the following calculations:

$M = 5{,}375 \times 15.5 = 83{,}312.5$ inch-pounds See Fig. 2.

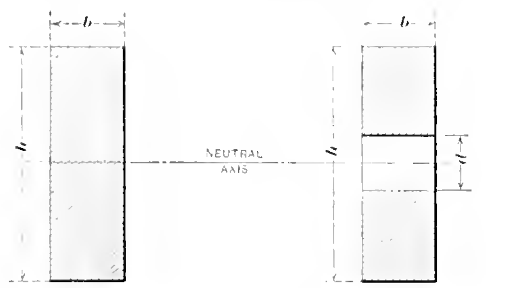
$$Z = \frac{1.5}{6 \times 5}(5^3 - 1.125^3) = \frac{123.577}{20} = 6.1788 \quad \text{See Fig. 4.}$$

$$s_b = \frac{83,312.5}{6.1788} = 13,500 \text{ pounds per square inch—about.} \quad \text{See (1)}$$

The section seems to have an inclination of about 12 degrees, of which the sine is about 0.208.

$$s_t = \frac{5,375 \times 0.208}{3.875 \times 1.5} = 192 \text{ pounds per square inch—about.} \quad \text{See (2)}$$

$$s = 13,500 + 192 = 13,692 \text{ pounds per square inch.} \quad (4)$$



$Z = \frac{bh^2}{6}$ $\qquad Z = \frac{b}{6h}(h^3 - d^3)$

Figs. 3 and 4.

If we take any other section to the left of B, such as $x_1 y_1$, we will find the maximum fiber stress considerably less than at $x y$. This section has an inclination of about 43 degrees.

$$M = 5,375 \times 7.5 = 40,312.5 \text{ inch-pounds.}$$

$$Z = \frac{1.5 \times 5^2}{6} = \frac{25}{4} = 6.25. \quad \text{See Fig 3.}$$

$$s_b = \frac{40,312.5}{6.25} = 6,450 \text{ pounds per square inch.}$$

$$s_t = \frac{5,375 \times 0.682}{5 \times 1.5} = 490 \text{ pounds per square inch.}$$

$$s = 6,450 + 490 = 6,940 \text{ pounds per square inch.} \quad (5)$$

In these calculations, we have assumed a thickness b of $1\frac{1}{2}$ inches. This gives, see (4), a maximum fiber stress of 13,692 pounds. This is a reasonable value for wrought iron. The thickness is greater than usual, and it would be better, perhaps, to make the bar somewhat wider and so reduce its thickness.

* * *

CALCULATING THE SIDE OF AN INSCRIBED POLYGON.

FRED WALSLEBEN.

In the February issue of MACHINERY a method is suggested for determining the sides of regular inscribed polygons when the number of sides increases in geometrical proportion in the ratio 2. The method suggested must seem rather vague to those not acquainted with its proof. It is only applicable to polygons whose radius is unity, and its application involves a confusing alternation of minus and plus signs. A more satisfactory way is as follows:

Given the side a and the radius R of a regular inscribed polygon, to find the side D of a regular inscribed polygon of double the number of sides and the same radius:

$$D = \sqrt{R\left(2R - \sqrt{4R^2 - a^2}\right)}$$

This formula is general. Its derivation and proof can be found in any treatise on plane geometry.

* * *

A report from Consul-General Richard Guenther, of Frankfort, Germany, states that in 1907 the production of denatured alcohol in that country was 27,720,000 gallons, an increase of about 2,900,000 gallons over the previous year. The price for alcohol was high, having been considerably advanced at different times, but in the report, the actual price per gallon is not stated. It is stated that the alcohol production in Germany is controlled by a trust or combination, which fixes both the amount of production and the price. German alcohol is made principally from potatoes.

SOME EXAMPLES OF ELECTRIC WELDING.

Although the electric welding process passed out of the experimental into the practical stage some years ago, to most mechanics electric welding is still a rather vague subject. Electric welding, however, plays an important part nowadays in the manufacture of a great many articles, and several companies have been formed which devote their entire attention to the manufacture of articles in which electric welding is an integral part of the manufacturing process. Without the process of electric welding, many of these products would have to be manufactured in an entirely different way, and in many cases at a greatly increased cost.

It may be well to state at the outset that there are at least four distinct processes of electric welding in use at the present time. These processes are commonly named the Zerener, the La Grange-Hoho, the Benardos, and the Thomson processes. In the process first mentioned above, the Zerener process, perhaps more commonly known as the electric blow-pipe method, an electric arc is drawn between two carbon electrodes. This arc is then caused to impinge upon the metal surfaces to be welded, by means of an electro-magnet.

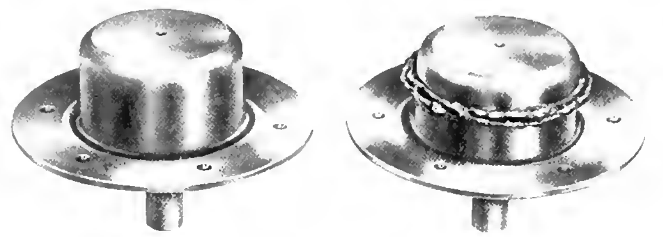


Fig 1. Automobile Hub Completed by Electric Welding.

The second process mentioned, the La Grange-Hoho, commonly known as the "water-pail forge," is distinctly different from all the other processes in principle, as well as in its practical application. A wooden tank is filled with a suitable fluid, and in this the positive electrode of the electric circuit is placed. The negative electrode is connected to the metal to be forged or welded, which is then immersed in the fluid in the tank. The metal is permitted to remain in the fluid until it has reached a welding temperature. The object to be welded is then removed, and the actual forging or welding process is carried out in the usual manner under a hammer. Strictly speaking, this is not an electric welding process, but merely an electric heating process to bring the metal to a welding heat.

Fig 2. Electric Weld on Automobile Pinion Casing

The characteristic principle of the Benardos process is, that an electric arc is drawn directly between the metal to be welded, which itself forms one electrode for the electric circuit, and the carbon electrode, which forms the other terminal for the circuit. In this process the pieces of metal to be welded are melted on their faces, together with a small rod of iron which acts as a kind of solder, and flows in between the two surfaces to be joined together by the welding process.

Finally, in the fourth, or the Thomson process, often known as the incandescent process, the metals to be welded are brought into intimate contact, being usually held closely together by metal clamps actuated by springs so as to permit

a permanent pressure on the parts even when the metal at the welding surfaces commences to melt. By this contact, the parts to be welded complete an electric circuit, and the resistance at the points of contact between the metals produces a welding temperature in a very few seconds, at the same time as the two metals are, by the spring-actuated clamps, forced together automatically, and welded. A distinct feature of this electric welding process is that the interior is raised to a welding temperature before the surface reaches that heat. When heated in the forge for welding, the opposite conditions take place. In the process of electric welding, if the exterior surfaces weld, the operator is sure that the interior is also welded, since it must, by necessity, be of a somewhat higher heat. With ordinary forge welding the surfaces may present a perfect weld and still cover an imperfect joint inside. The accompanying photographs show a number of applications of electric welding, as carried out in the shops of the Standard Welding Co., Cleveland, Ohio, by the use of the Thomson process, which will illustrate its possibilities.

Fig. 3. Stem of Carbon Steel Welded to a Soft Steel Disk.

A few years ago it was thought that electric welding would be practical only for very small objects, on account of the high amperage required, but since that time the process has been developed so that it is now possible to electrically weld parts of considerable size. The process is particularly suited for the manufacture of automobile and bicycle parts, carriage hardware, and mechanics' tools of various descriptions. While the process is employed to a considerable extent among manufacturers, it is probable that in the shops of the company mentioned above there is a greater variety of work welded by the electric process than in any other.

When, as mentioned above, the two parts to be welded have been placed against each other, in the electric circuit, which heats the metal at the juncture to a molten state, the separate parts will be united into one piece in such a manner that the joint is practically imperceptible, but at first a burr or upset is produced around the welded surface, composed of the expelled oxidized and otherwise inferior metal. This oxidation, examples of which are shown in all of the accompanying cuts, is, of course, removed, and then a perfect joint is the result. In the cut, Fig. 1, an automobile hub is shown, on which an electric welding process has been performed. The dome or cover and the spindle of the hub are drop forged as an integral part, the flange being produced under a power press. The parts are then roughly machined, so as to be fairly uniform in the dimensions where the joint is to take place, and are then subjected to the electric welding process. At the right, in the cut, the hub is shown with the burr or upset resulting from the welding process still left in place, while at the left is shown the finished hub after this burr has been removed. The turning and grinding operations complete the work, producing practically a solid hub.

The cut, Fig. 2, illustrates an automobile pinion casing. The parts for making up this casing are of stamped steel. The burr incidental to the welding process is shown, in order to indicate where the joint is located. While the welding process is being carried out, the parts are held in alignment so that after being roughed and finished, and after having been cupped at the ends, the ball races will be in correct alignment.

In the cut, Fig. 3, is illustrated a soft steel disk, welded to a stem or spindle, containing from 0.12 to 0.60 per cent carbon. The detail shown is used largely in the manufacture of cream separator bowls, but, of course, similar applications are found in a great many other machines. It is possible to join soft steel disks to stems or spindles of even higher carbon content than that mentioned.

In Fig. 4 is shown a double lever or arm welded to the steering knuckle on an automobile. This illustration presents a case where it would not be possible, without greatly increased expense, to produce the part without electric welding.

The illustrations shown are, of course, only general examples of what can be accomplished by means of the electric welding process, but they are suggestive to the mechanical mind which may be unfamiliar with the wide field of application for electric welding, indicating as well, that the future of electric welding is one of great possibilities. For a more complete description of the shops, methods and products of the Standard Welding Co., see MACHINERY, April, 1903.

One very important question in regard to electric welding, and for that matter any other process for joining metallic parts, is whether the joint is sound. Experiments and tests, as well as use of electrically welded joints, have unquestionably demonstrated its reliability. In the case of electric welding, the great variety of parts so joined has shown, beyond doubt, that the joint is practically as sound as the solid sections in the parts so joined. Very commonly the parts which are welded by the electric process are subjected to abuse and rough handling, or to heavy stresses. Especially is this so in automobile work. The results obtained have been so satisfactory as to place the art among the most useful of the applications of electricity.

In this connection, it may be well to mention that the Thomson process, while originally an American invention, has also received considerable attention in England. A writer in the *London Times* some time ago, called attention to the fact that the system has caused a complete revolution in existing methods of manufacture in many industries, and that electric welding had created some entirely new manufactures. As to the reliability of these joints, this writer also mentioned that tests had been carried on regarding the comparative strength of electric and ordinary forged welds, and that these tests

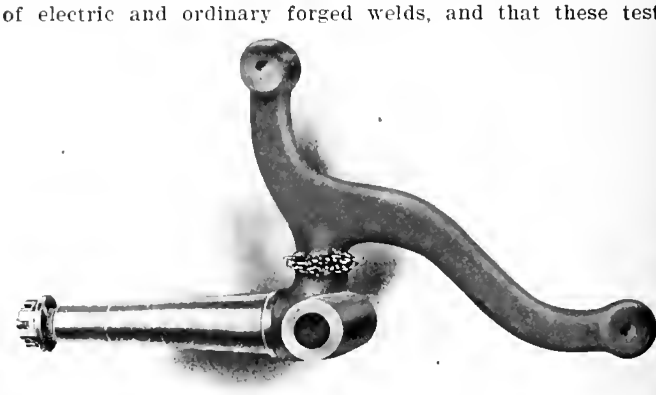

Fig. 4. Welding Operation on Automobile Steering Knuckle and Lever.

show that while the ordinary forge weld of iron bars shows an average strength of 89.3 per cent, as compared with the strength of the solid, electrically welded joints show a strength of 91.9 per cent.

In giving a summary of the advantages which can, with propriety, be claimed for the electric welding process, the following may be stated as being the most important: Finished or nearly finished work may be welded and repaired without damage; the welding operation can be closely watched as it proceeds, and faulty welds prevented; the process is carried out with great rapidity, occupying only a few seconds, and in small work it is performed almost instantaneously; and, finally, impurities are expelled from the joint, and a perfectly homogeneous weld is obtained. The cost for the generation of heat, generally speaking, is probably the same for forge and electric welding, but with the electric process the cost of labor is greatly reduced.

THE SETTING UP AND OPERATION OF THE POTTER & JOHNSTON AUTOMATIC CHUCKING MACHINE.—I.

The invasion by the automatic turret machine of the field so long held by the lathe, in its work of machining castings, has been one of the important developments of the past decade in the machine tool business. Beginning with the original automatic screw machine, which first came into use a quarter of a century ago, the automatically operated turret machine has steadily found wider and wider fields of usefulness, being applied first to small turned parts made from bar stock, later to small castings, and more recently to the machining of castings and forgings of considerable size.

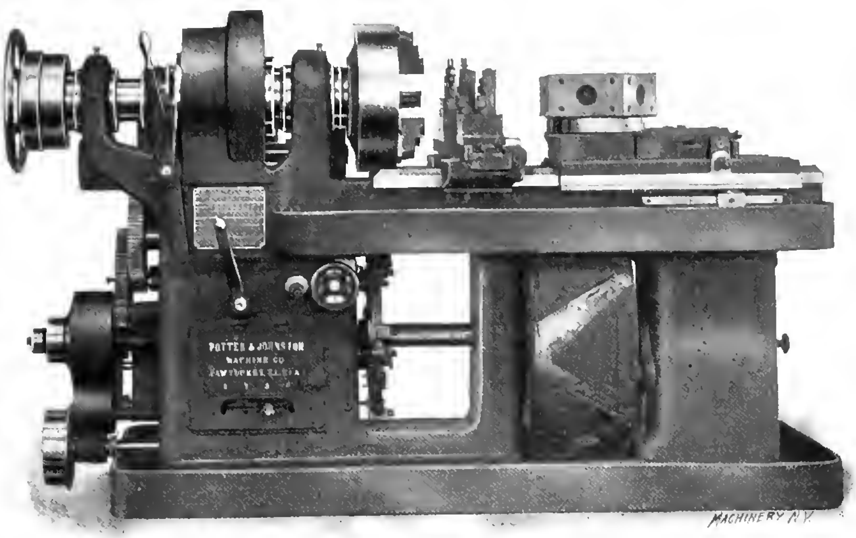

Fig. 1. Potter & Johnston Automatic Chucking and Turning Machine, with Two-speed Geared Spindle Drive.

The automatic chucking machine shown in Fig. 1, built by Potter & Johnston, Pawtucket, R. I., is the logical result of this extension of the automatic screw machine idea to the handling of large work. There are so many of them in use, that it was believed that a description of the operation of this machine, particularly as relates to setting it up for simple work, would be valuable and interesting to our readers. This article was prepared with this in view, the information and illustrative matter it contains being gathered during a special visit to the shops of the builders, who freely provided every facility that could be asked for.

Description of the Machine.

A clear understanding of the action of the machine is essential for the operator, if he expects to set it up and work it intelligently. We will describe its construction as simply and in as few words as possible.

In Fig. 1 is shown a machine of the type from which the observations were taken. Various styles of machines are made by the builders, there being two sizes and several arrangements of the driving mechanism. Some of the machines have spindles driven directly from pulleys on the spindle. Some have one spindle speed only; some have two speeds of fixed ratio for any given piece of work; while others (as in this case, which is the form most suited for heavy chucking work in iron or steel) have two speeds available for the same piece of work, which speeds may be selected without reference to each other, from a wide range.

The principle of operation of the machine is simple. Mechanism has to be provided to stop, start and change the spindle feed; to operate the cross slide; and to feed the turret slide forward, return it quickly, rotate the turret to a new position, and feed it forward quickly for taking a new cut. The cross slide and turret slide movements are effected by cams mounted on the large drum seen beneath the turret in Fig. 1, while the various feed and speed changes are effected by dogs and pins carried on a disk keyed to the same shaft on which the cam drum is mounted. This shaft, with the cam drum and the governing disk, makes one revolution for each piece of work completed.

The periphery of the drum carries the cams for operating the turret slide, which is moved positively in both directions, without the use of springs. The cam roll is carried by an intermediate slide, lying in a groove in the upper surface of the bed. This slide has rack teeth cut on it, engaging a pinion on the squared shaft, seen projecting from the side of the turret slide. By turning this shaft with a crank, the position of the turret slide with relation to the cam may be altered, so that it may be adjusted for long or short work and long or short tools, as may be required.

The cross-slide cams, and the means for transmitting the movement obtained from them to the cross slide, are best seen in Figs. 3 and 5. These cams are mounted on the rear face of drum *W*, and act on a roll, carried at the front of yoke *A*, which extends diagonally upward toward the rear of the machine. The rear end of this yoke has rack teeth formed on it, meshing with teeth of a segmental pinion, which is fast to a stout rock shaft *B*, extending lengthwise of the machine at the rear. At the head-stock end, this rock shaft carries another segmental pinion, meshing with rack teeth formed on the cross slide. The movement imparted to the yoke by the cams, is thus transmitted through the pinions and the rock shaft to the cross slide.

The cam drum is driven by a pinion meshing with a gear (seen in Fig. 1) which is fast to its front periphery. This pinion is driven through a train of gearing from pulley *L* (see Fig. 6), which is belted to the spindle. The feeds are thus always dependent on the spindle speeds, as should always be the case in any machine of the lathe type. By means of epicyclic gearing and suitable clutches, the motion thus derived from the spindle may be made either very rapid, for returning the turret to be indexed and then advancing to the cutting position again, or very slow for the forward feed. These changes from slow to rapid movement or *vice versa* are effected by mechanism operated from a cam on a shaft whose outer end terminates in a star-wheel, shown just at the right of the small hand-wheel beneath the main head-stock bearing in Fig. 1. Whenever the motion is to be changed, this star-wheel is operated by pins carried by the governing disk, seen best in Fig. 6. The first

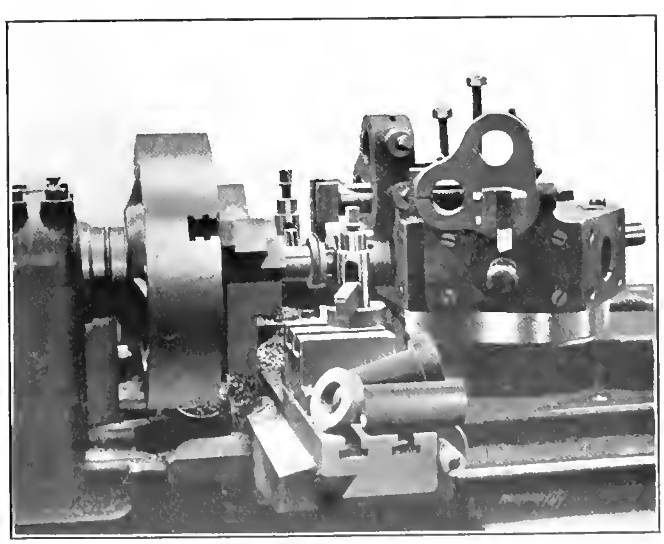

Fig. 2. Front View of Machine set up for the Finishing Operation on the Recessed Bushing and Collar shown in the Foreground and in Fig. 4.

pin *M* that strikes it advances it one-sixth of a rotation, changing the feed from fast to slow. The next pin that strikes it will change it another sixth of a rotation, from slow to fast feeding—and so on. Hand wheel *E* is geared with the cam-shaft on which the star-wheel is mounted, so that the feeds may be changed manually from slow to fast, or *vice versa*.

A unique constructional feature of disk *D* is best seen in Fig. 6. The slot in which pins *M* are located is a continuous one,

extending clear around the disk, so that the rim is entirely separate from the inner portion, which is supported by the arms. The two parts of the disk are always held together, however, by the various pins carried in the slot, which are never all unclamped simultaneously. This makes the two parts practically solid, without disturbing the continuity of the slot. Besides these feed changing pins, there is also carried in this slot, a dog which operates a lever by which the feed movement is stopped, when the work has been completed.

Four rates of feed are provided for by quick change gearing of the sliding gear type, operated by handle *K* shown projecting through the door in the cabinet leg beneath the head-stock. When this handle is set in the central position, the feed is disengaged. The ability to change the feed quickly tends toward running the machine at its highest efficiency. The operator is more likely to speed the machine up, if he sees that the tools are all working too easily, than he would be if he had to stop the machine to alter the setting of change gears of the ordinary type.

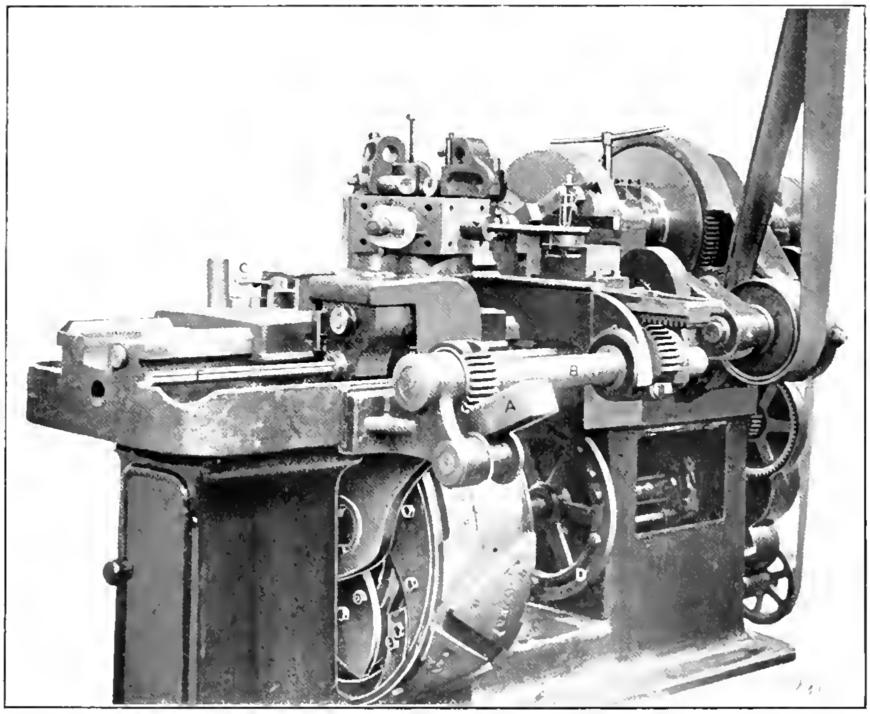

Fig. 3. Rear View of Machine set up for Work as in Fig 2; shows the Cross-slide Mechanism, Driving Gearing, etc.

On the periphery of the governing disk are also clamped dogs or cams *N*, which operate a horizontal swinging lever *P*, connected by a link with vertical lever *J*, which controls the two spindle speeds with which the machine is provided, either one of which may thus be thrown into action at any time. The spindle driving connections are best seen in Fig. 3. As may be seen, a single speed pulley is used. The shaft on which it is mounted is connected to two sets of change gearing, enclosed in suitable guards, one on each side of the driving pulley, and each connected with its own loose driving gear on the spindle. Either of these driving gears may be connected with the spindle by clutch lever *J*, operated by the dogs *N* on the disk *D*. These driving gears are connected with the driving pulley in different ratios, and with the change gears used, ten different speeds may be obtained from each, 20 speeds being available in all, of which the two most suitable are available for any given piece. Lever *H* connects or disconnects the driving pulley with the shaft on which it is mounted, thus stopping and starting the machine.

Vertical lever *H* in the cabinet base, stops and starts the automatic feed. The shaft with the squared end, projecting from the base just at the left of hand-wheel *E*, is used with the crank to operate the drums by hand.

The rotation of the turret, which takes place at the rear of its travel of course, is effected by power. In Fig. 3 will be seen a shaft *F* extending from the head-stock through the gear casing at the rear of the turret slide. This shaft is driven from the constant speed drive pulley of the machine, and operates the turret revolving mechanism at constant speed. A dog shown in Fig. 1 at the side of the bed, is set to trip the turret revolving mechanism at the proper point in the travel to avoid interference between the tools and the work. The turret is provided with an automatic clamping device. The mechanism first withdraws the locking pin and unclamps the turret, revolves it, then throws in the locking pin and clamps the turret again. The horizontal lever at the right of the turret in Fig. 1 may be used to release the locking pin for turning the turret by hand, the clamping mechanism having been released by lever *C*, Fig. 3.

The Work and the Operations to be Performed.

The piece we have selected for illustrating the setting up and operation of the machine is shown in Fig. 4. It is a very simple piece, and will thus best serve for illustrating the principles involved. Although it is simple, it is of special interest in one or two particulars. For instance, the operation we are to perform is a second operation. In the first operation, the hole was drilled, bored and reamed, the small end of the bushing was faced, and the outside diameter finished. The enlarged diameter at the end was used for holding the work in the chuck, so, of course, it was left rough. This brings the part to the condition shown at the right in Fig. 4, where it is ready for our second operation. In this second operation we have to cut off the enlarged end, whose original purpose was that of furnishing a chucking piece to hold the work by. In order, however, not to waste any stock, this piece which we cut off is made to serve as a collar on another part of the machine for which the bushing is intended. For this purpose, we turn its outside diameter, and face the outside end of it before cutting it off. Besides this, we have to recess the bushing, as shown, and face its outer end.

In order to have the second operation dead true with the first one, we place a set of soft false jaws in the chuck (see Figs. 2 and 3) and clamp them down on a short piece of stock, slightly smaller in diameter than the diameter to be held. Then the jaws are carefully bored out to exactly the diameter of the work to be held. We can now be sure that the work will be held truly, within reasonable limits, provided the chuck is always tightened up in the same way as when it was tightened for boring.

The first thing to do is to decide on the order of operations. These are performed in the following order: On the first turret face we will turn the outside diameter of the collar, and face the outer end. On the second turret face we will finish turn the outside diameter of the collar, and finish the outer face. The third face of the turret will not be used, this portion of the cycle being taken up in cutting off the collar with the cut-off tool on the rear cross slide. For the fourth operation we will recess the bushing, as shown in Fig. 4, and for the fifth operation we will face the end of the bushing, to remove the rough surface left by the cutting-off tool.

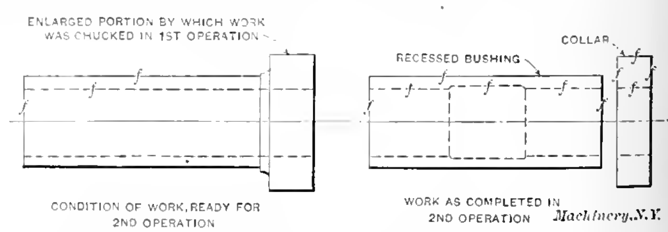

Fig. 4. The Work to be Operated on; this Second Operation recesses the Bushing, and finishes the Chucking Portion for Use on the Collar.

The tools used are shown in place in Figs. 2 and 3. For the first operation, standard turning tools are used, consisting of brackets bolted to the face of the turrets, with upward projections, provided with three holes each for carrying turn-

ing tool holders. As will be shown later, this arrangement provides for turning a number of diameters at different lengths simultaneously; but for our purpose a single turning tool for each holder will be used, located, as shown, in the lowest of the possible positions. A special device is used for recessing, as will be described later, while the facing of the end of the bushing is effected by tools so simple as to be self explanatory.

Setting the Tools.

We have first to determine the change gears to be used to get suitable spindle speeds to agree with the diameter of

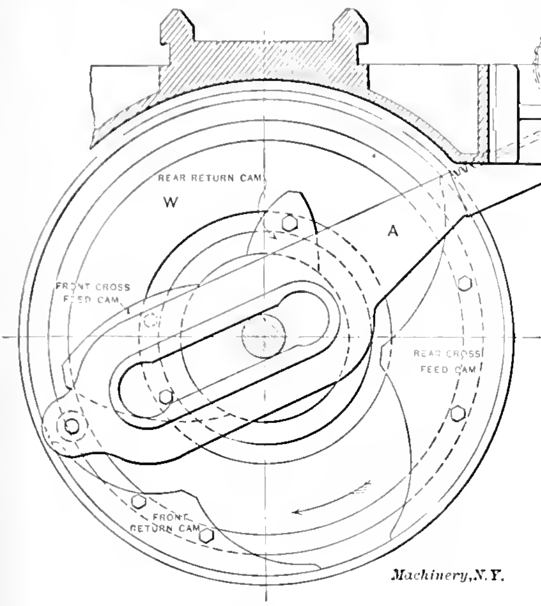

Fig. 5. Diagram of Cross-slide Cams and Mechanism.

the work. Referring to the speed and feed plate on the head-stock of the machine (see Fig. 7) we are permitted to use one speed from the list given for the fast train and one from the list for the slow train, so long as the same gears are not used in each case. The diameter of the collar for our piece of work in Fig. 4 is 2½ inches, while the diameter of the body is 2 inches. We should use a surface speed of about 40 feet per minute. A little calculation shows that the 66 revolutions per minute given by the fast train, gives 43 feet

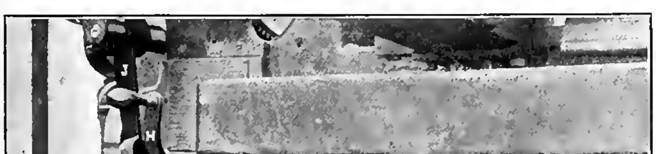

Fig. 6. The Controlling Mechanism for Feeds and Speeds.

per minute on 2½ inches diameter; and the 78 revolutions per minute obtained from the slow train of gearing, gives about 41 feet per minute on 2 inches diameter. The spindle gearing indicated for these speeds is therefore placed in position on the proper studs at the back of the machine.

Next, we have to determine on which faces of the turret to place the different tools. Each turret face is numbered to agree with the corresponding feed cam on the drum. The brass plate at the head-stock end of the machine gives the various feeds obtainable per revolution of the spindle. As will be seen, the different cams give different feeds. Cam No. 1 has a coarse feed suitable for roughing; cam No. 2 a finer feed, adapted to finishing cuts; and so on. Since our first operation consists in rough turning, it seems reasonable to give this operation to cam No. 1. Cam No. 2 will then have a finer feed for the finish turning; No. 3 is devoted to cutting off the collar; No. 4, which is ordinarily used for reaming, would, in our case, be devoted to recessing. Since this recess is for clearance only, and may be done with a coarse feed, this cam is entirely suitable.

The final operation, which is a facing one, could be done on any cam, so No. 5 will do. It will be understood, of course, that for facing operations, the feeds given do not apply. As the roll is going over the point of the feed cam at the extreme of the movement, the feed of the turret slide is gradually slowed down to zero. Since the facing takes place in the last eighth or sixteenth-inch of this movement, it is done at a feed which is gradually tapered off to zero. This is, of course, just as it should be, and we need pay no attention to tabulated feeds in facing operations.

The next adjustment to make on the machine, is that of setting the turret slide in proper position. In making this setting, the turret is set in relation to the work so that the tools will require but a small amount of over-hang, the cam-shaft having been revolved by hand until the cam-roll is on the extreme top of the forward feeding cam, so that the turret slide is at the extreme of its forward motion. When

this adjustment has been made by the means provided, set the turret index tripping dog so as to revolve the turret at the proper point.

We have, then, a standard turning tool holder on face No. 1. In the lowest hole of this is placed a turning tool stem with a cutter in place. With cam No. 1 in action, we revolve the cam by hand until the roll is on the point of the cam and the turret at the forward extreme of its motion. At this point we set the turning tool stem, so that when the cutter is in place it will have completely passed over the surface to be turned. Clamping the stem in this position we turn the feed cam backwards, returning the turret slide toward the rear again, and clamping the cutter in the stem at about the proper diameter for the desired roughing cut. By manipulating the crank on shaft A, the turret slide is fed forward and back while this cutter is adjusted for diameter, until it is properly set. We then turn this diameter, feeding the cam drum by hand.

A facing tool, shown in action in Fig. 2, is placed at this station of the turret, being held in the turret hole. This consists, as may be seen, of a pilot bar clamped in the turret hole, carrying a circular body holding a facing blade. Feeding by hand, as before, this is adjusted lengthwise to rough face the work for the dimension desired. In a similar way, the finish turning and facing tools in the second face are set, the cam-shaft being revolved by hand to bring this second face and second cam into operation. The finishing facing tool is not shown in place in Fig. 3.

NEW MACHINERY AND TOOLS.

A MONTHLY RECORD OF APPLIANCES FOR THE MACHINE SHOP.

HEALD INTERNAL GRINDING MACHINE.

One of the many important developments of the automobile industry has been the new importance given to the operation of internal grinding. This operation has been proved to be a most practicable one for finishing holes accurately to size, in all sorts of work which at one time was thought to be best finished by the reamer. The reaming operation is a costly one, owing to the large expense involved in keeping the tools to size, requiring the purchase of new reamers if the solid type was used; if the adjustable variety is employed, there is always a slight variation in size due to the change in diameter

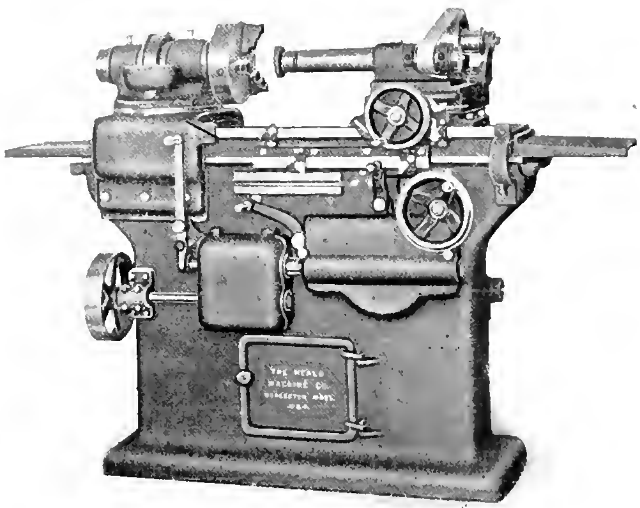

Fig. 1. The Heald Internal Grinding Machine.

that takes place before the necessary readjusting and regrinding is undertaken. Besides this, there is much work that is difficult to hold for reaming without distortion, because of thin walls which give under the pressure of the of the chuck jaws by which the work is held. The comparatively light clamping necessary for the grinding operation, and the light contact between the wheel and the work, permit the obtaining of holes much more nearly true and accurate to dimensions than is possible in any other way.

A good internal grinding machine will finish holes day after day, rapidly and true to size within 0.00025 inch (or closer if desired) directly from a rough bored cut, and without any expense for reamers for the various diameters, and without expense for keeping such reamers sharp. Besides this, it will finish to size, rapidly, holes in hardened steel parts, which cannot be reamed under any circumstances, and at a fraction of the time required for lapping them out.

Internal grinding has not always been done with all the rapidity and economy which the operation is capable of showing. This is owing to the fact that practically all internal grinding has been done on machines in which the wheel was supported by a structure in the nature of an attachment of the machine, instead of being an integral part of it. This usual construction (by which the wheel is supported on an over-hanging arm reaching forward from the wheel stand at the back of the machine) was so light and flexible as to encourage the vibrations which are one of the most serious troubles met with in grinding. The vibration of a spindle thus poorly supported breaks down the texture of the wheel, and makes it impossible for it to cut either rapidly or smoothly. Rigidity is the fundamental requirement in a successful internal grinding machine. The Heald Machine Co. of Worcester, Mass., believes that it has fulfilled this requirement in the internal grinding machiue which we herewith describe and illustrate.

As may be seen, this tool is not an external cylindrical grinder modified for internal grinding, but is radically designed for the operation it is to perform. The bed is of simple and rigid form, provided with ways on its upper surface, on which slides a table carrying the wheel spindle. The work spindle head-stock is mounted on a frame which straddles the work table, and is fastened to the base on either side. A more direct and rigid construction it would be difficult to imagine.

The saddle or bridge on which the head-stock is mounted is of heavy design, as may be seen in Fig. 3. The head-stock *B* may be swiveled on it to any angle for grinding tapered holes, graduations being provided which read in degrees and in tapers per foot. Hardened bushing *C* is driven into *A*, and fitted carefully to *B*, furnishing a pivot about which the adjustment is made. The spindle is made of a special grade of high carbon steel, ground and lapped, and, as may be seen, is of generous diameter. It runs in tapered phosphor bronze bushings, adjustable for wear, and provided for suitable means for excluding dust and grit.

This spindle is driven by a belt from a 5-speed quick change gear box, which forms a part of the counter-shaft; by this mechanism correct work speeds for holes of different diameters are easily obtained, the changes being made much more quickly and easily than is possible with the cone pulleys ordinarily used. This encourages the operator to change the speed to suit the diameter of the work being ground, instead of (as is more often the case) using the same speed day after day on work of different kinds. It also permits him to instantly speed up the work during the finishing cut, to get the mirror-like finish possible with increased peripheral speed.

The cutter spindle is mounted on a cross slide for adjusting the wheel for the desired diameter. This cross slide, in turn, may be adjusted lengthwise of the table to bring the wheel in proper position for the length of work being ground. The cross slide carries a double idler pulley, of which the small diameter is driven from the counter-shaft, while the large diameter is belted to the driving pulley on the wheel spindle.

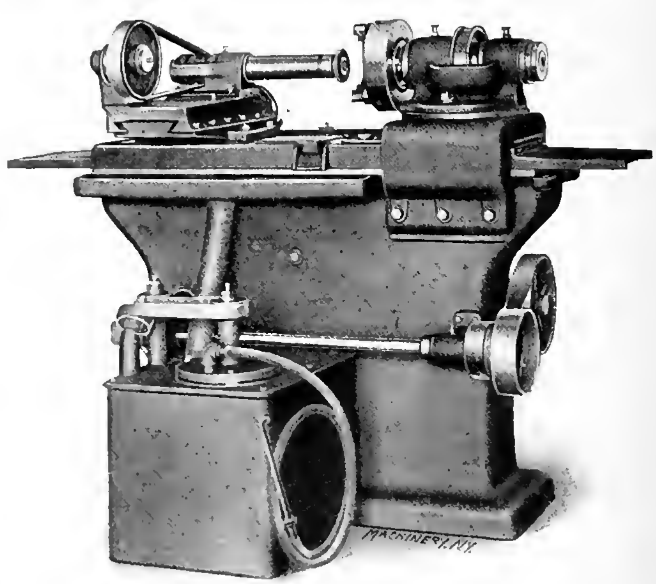

Fig. 2. Rear View of Machine showing Drive of Wheel Spindle and Provision for Wet Grinding.

The construction of the wheel spindle is shown in Fig. 4. The head *D* is held by a gibbed bearing to the cross slide. It supports the wheel spindle at three points—by two ball bearings on either side of spindle pulley *E*, and by a bronze bushing *F*, next to the wheel. This bronze bushing, which is tapered on its outside diameter, is adjusted in or out for wear by nut *G*; screws *H*, with tapered points, are used for expanding it to tightly fill the bore of the hole in which it is placed, thus giving a solid bearing without vibration, and fitting closely both the spindle and the head casting. The two ball bearings *J*, on either side of the driving pulley *E*, are suitably protected from dust and grit. The outer bearing is supported in such a way that an endless belt may be used,

connecting pulley E with the idler pulley. The stand on which the idler pulley is mounted is adjustable to maintain the tension on this belt.

Various sizes of heads D are provided for holes of different diameters. The regular line of heads is made in seven sizes, of which the smallest is suitable for a minimum hole of 7/8 inch diameter, while the minimum diameter for the largest size is 3 inches. These will grind holes varying in depth from

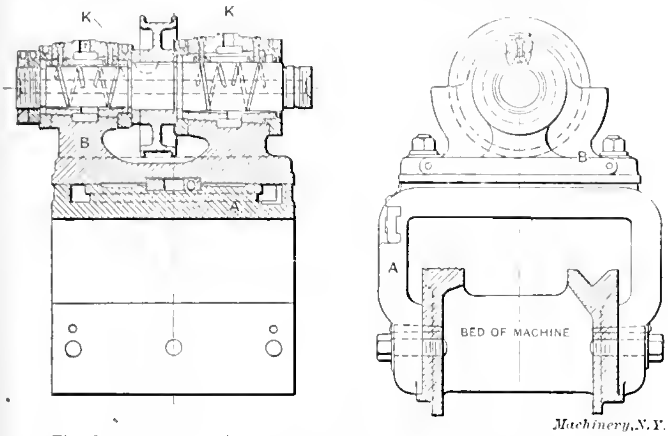

Fig. 3. Work Spindle Head and Method of Supporting it on Bed.

a maximum of 4 inches long for the smallest, up to 11 inches long for the largest. The heads are self-contained and interchangeable, so that different sizes can be instantly substituted when changing from the grinding of large holes to small holes or *vice versa.* In shops equipped with several machines, the same head may be used on different ones, so that the expense of purchasing extra spindles is avoided. The diameter of the driving pulley on the different wheel spindles of these heads is made proportional to the diameter of the grinding wheels used, so that the correct speed for any given wheel is obtained automatically, without requiring any attention on the part of the operator.

The cross feed of the wheel, as may be seen in Fig. 1, is arranged to be operated either by hand or automatically, at either one or both ends of the table travel. Provision is made also for automatically throwing out this feed when the work has been brought down to size. The rate of feed may be varied from 0.00025 inches to 0.003 inch at each reversal of the table.

On the front of the base is mounted the automatic reversing gear box, and at the left the three-speed quick change gear box for giving the table three different rates of travel for each work speed. The feed is driven from the same shaft on the overhead works which drives the work table, so that the feed and work speed are always proportional—the proper arrange-

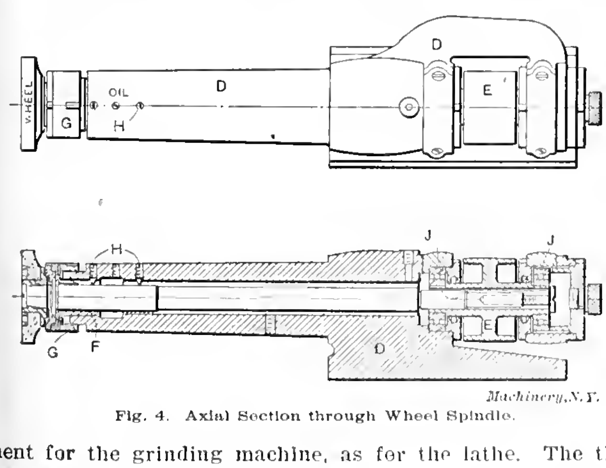

Fig. 4. Axial Section through Wheel Spindle.

ment for the grinding machine, as for the lathe. The three different feeds provided and the easy means of changing them, encourage the operator to use the fast travel for roughing out the stock, and the slower rates for truing and finishing the holes. They are controlled by the vertical handle at the left end of the gear box. All changes of feeds and speeds are made from the front of the machine without stopping either the table, work, or wheel.

The provision made for the use of the water in this machine is carefully worked out, the table being provided with water channels leading to a water pan on the back. This tank is made unusually large, with an ample settling chamber, so that only clear water passes to the pump chamber and back to the wheel again. The pump is of the centrifugal type, so constructed that all the bearings are above the water, no packing or attention being required.

The builders consider that they have obtained in this machine the following essentials for rapid and accurate work: First, a massive and rigid design which will resist vibration, and give the wheel the ability to cut freely and smoothly. Second, suitable range of speeds of rotation for the work, covering the different sizes of holes, and materials to be ground, with means for changing these speeds instantly and easily. Third, a suitable range of table feeds for each of the spindle speeds, covering the requirements for roughing and finishing in different materials; these feed changes are also easily obtained. The design of the machine is, it must be admitted, a very attractive one.

BROWN & SHARPE GEAR-CUTTER GRINDING MACHINE.

We have previously called attention in MACHINERY to the necessity for grinding the faces of gear-cutter teeth radially, if the correct form of the cutter is to be preserved. With the common "rough and ready" method of grinding, in which the cutter is laid on a rest in front of a dish wheel, and ground by hand on the faces of its teeth, these faces may or

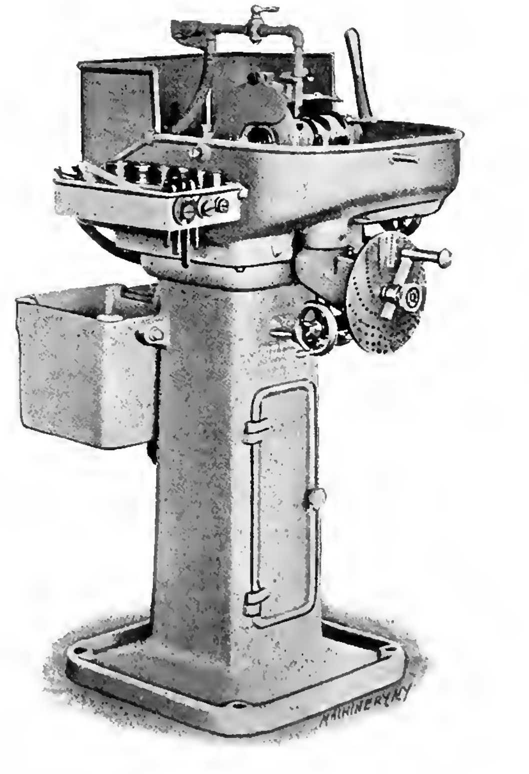

Fig. 1. Brown & Sharpe Wet Grinder for Formed Gear-cutters.

may not be radial. Usually they are far from it, and the tooth space produced is consequently too flaring if the cutter teeth are ground too far back at the tops, or the tooth spaces are as badly off in the other direction if the teeth of the cutter are "hooked." To provide means for grinding the cutter exactly radial, and doing it quickly, cheaply and conveniently, the Brown & Sharpe Mfg. Co., Providence, R. I., is building the grinding machine which we herewith describe and illustrate. As well as providing for grinding the cutter radially, it also spaces the grinding of the faces accurately, so that the teeth are always of the same height, thus allowing each one to do its share of the work, and permitting the maximum output from the cutter.

Fig. 1 shows the front view of the machine as a whole, and gives a very good idea of the design, which, it will be seen, gives great rigidity and freedom from vibration, in combination with a very moderate weight. Fig. 2 shows the right-hand side, and illustrates the compactness and convenient ar-

rangement of the operating mechanism. This mechanism is best understood by referring to the line drawings, Figs. 3, 4 and 5.

The cutter to be ground is dropped onto the hollow work spindle *A*, the open side clamping washer *B* being slipped from beneath the head of clamping bolt *C* for that purpose. A spring bearing against a shoulder in *A* keeps the clamping bolt forced upward, except when it is drawn down onto the

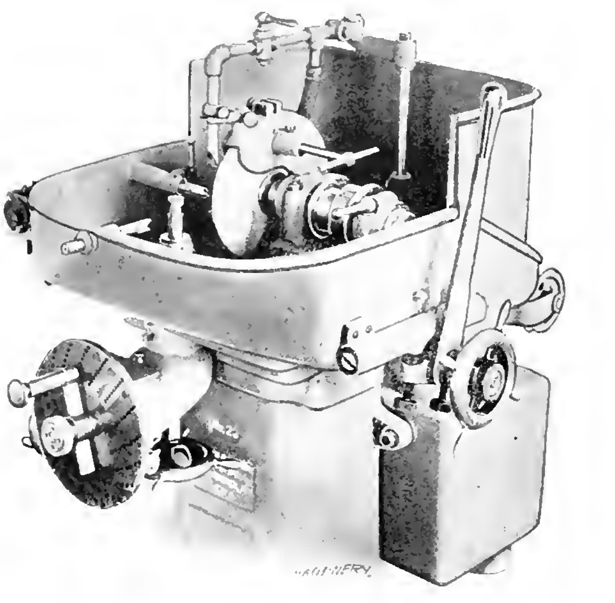

Fig. 2. Details of the Wheel Feed and Work-holding Arrangements.

work by revolving the work clamping hand-wheel *D*. Various bushings are provided for the work spindle, to suit various diameters of holes in the cutters; and various washers are provided to bring the center of the cutter in the horizontal plane of the axis of the wheel. The centering of the cutter is tested by the work centering gage *E*, which is pushed in until the V-groove in its end rests on the point of the cutter tooth. The centering need be only approximate.

Index crank-shaft *F* is connected with the work spindle by bevel gears, as shown, and carries an index crank and pin similar to that used on the index centers of the milling machines. The index crank can be moved from one row of holes to another in the usual fashion, being tightened by the clamp nut shown on the end of the crank-shaft. Index plate *G* is provided with 9 rows of holes, for obtaining any number of settings up to 18. It is keyed to the hub of a worm-wheel, and is operated by a worm connected with the work spindle adjusting wheel *H*. Wheel *H* is used to rotate the work into posi-

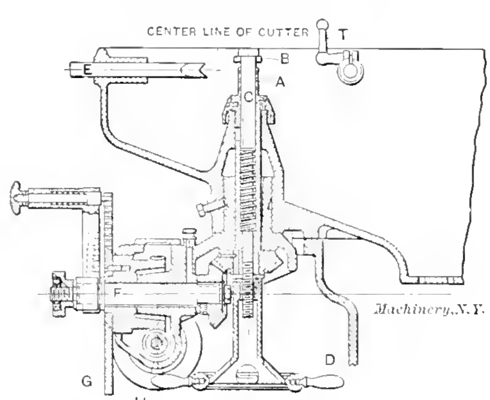

Fig. 3. The Work Spindle and its Clamping and Indexing Mechanism.

tion for the wheel to grind the faces of the teeth, and to feed the wheel for successively deeper cuts, as the teeth are ground. The feeding is not continuous, taking place only at the end of each complete revolution of the work.

The emery wheel, which is of the dished variety, is mounted, as may be seen in Fig. 4, on a spindle driven by a two-step cone pulley. The wheel spindle head-stock is adjustable in the direction of the center line of the spindle, as will be explained later, for centering the wheel so that it will grind the faces of the teeth radially. The base on which the headstock is mounted slides in and out, toward and away from the work, being actuated by a rack, and a segmental gear *M*, keyed to a rock-shaft on which is mounted hand lever *N*. This hand lever is not directly connected with the rock-shaft, but has clutch teeth formed on its hub, which engage similar teeth in the hub of the wheel slide adjusting hand-wheel *O*, which is keyed to the shaft. The clutch teeth are kept in contact by the spring shown. By pulling the hand-wheel out, turning it in relation to the lever, and re-engaging it, the lever may be brought into any desired relation with the position of the wheel slide, to make the operation of the machine convenient. As is best seen in Fig. 2, the hub of the hand lever is provided with lugs carrying adjustable stop-screws *P* (Fig. 4) which are set to limit the movement of the slide when in operation, so that the wheel grinds to the proper depth in the cutter, and is allowed to come far enough out of the cutter to permit it to be indexed for the next tooth. Spring plunger *Q* keeps the wheel slide normally in its backward position.

Provision is made for thoroughly flooding the work with water while it is being ground. A centrifugal pump of simple construction is provided with all its bearings above the water line. Convenient piping, settling tanks and reservoir are included with the machine, so that water is kept off the floor and from all those parts of the machine where it does not belong. The water is strained and returned to the reservoir ready to be used over again. A number of other conveniences are provided. In the side of the water pan is cast a boss with a clamp handle *T* for holding a diamond tool in truing the wheel. This diamond tool is adjusted to the proper position while the wheel is fed back and forth across it by lever *N*, as when grinding cutters.

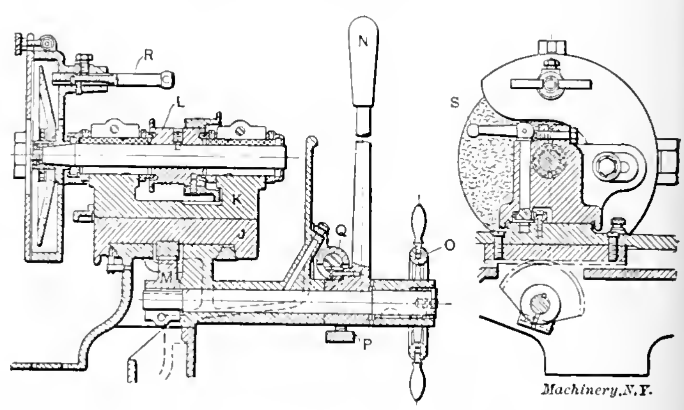

Fig. 4, Side View, and Fig. 5, Cross-section of Wheel Head-stock, Slide, etc., showing the Movements and Adjustments.

Two-step cone pulley *L* is only used for speeding up the wheel, when it is worn to so small a diameter that the peripheral speed is below the normal rate. When this takes place, the belt is shifted to the smaller pulley. To make sure that the belt will not be shifted before the wheel has been worn down sufficiently, the device shown at *R* is used. This consists of a stud with a cross handle, which prevents shifting the belt to the small step. It can be pushed in out of the way only when the wheel, as shown in Fig. 4, has been worn down small enough to allow it to clear. When it has been worn down this amount, the time has arrived for shifting the belt. This prevents the possibility of running the wheel at a dangerous rate. The wheel is provided with a guard, as shown, to prevent accidental breakage of the wheel or injury to the operator.

The centering of the wheel is simply effected by the method indicated in Fig. 6. The center gage is laid against the trued side of the wheel, and the slide is adjusted (by means of lever *S* in Fig. 5) in or out until the surface of the gage just touches the body diameter of the work clamp bolt. When the gage just touches this point as it rests on the face of the wheel, the wheel is exactly centered with the work spindle.

The stand is of box form, rigidly braced internally to resist vibration, and its interior is fitted up as a closet to hold small tools. A finished pad is provided at the back of the stand for attaching a motor when desired. The water pan is a separate casting securely bolted to this stand, amply large

enough to take care of all water used. The back is cut away and a removable sheet iron guard, heavily japanned, is provided to facilitate cleaning.

This machine will grind cutters up to 8 inches in diameter, 1½ inch pitch and 2¼ inches thick, using an 8-inch emery wheel with 1¼-inch hole. The work spindle and the bushings provided are arranged to fit holes ⅞, 1 1-16, 1¼, 1½, and 1¾ inch in diameter, respectively. The counter-shaft is provided

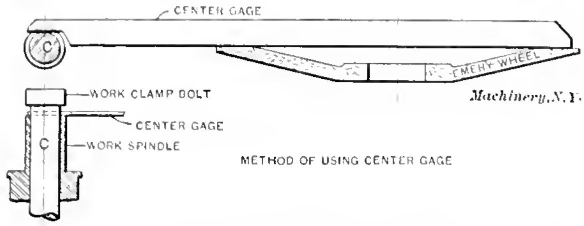

Fig. 6. Use of the Centering Gage in aligning Face of the Wheel with the Center Line of the Work.

with tight and loose pulleys 6 inches in diameter for 2-inch belt, and should run at 600 revolutions per minute. The net weight of the grinder is 760 pounds. It occupies a floor space 33 inches wide, parallel to the wheel spindle, and 39 inches long, perpendicular to the spindle.

REVOLVING OILSTONE SCRAPER SHARPENER.

The revolving oilstone grinding machine, made by Mummert, Wolf & Dixon, of Hanover, Pa., which we have previously described (see New Machinery and Tools in the June, 1907, issue of MACHINERY), has been adapted by the builders to the sharpening of scraping tools.

Figs. 1 and 2 show it so arranged. It is claimed by the builders that scrapers sharpened on this machine are much superior to those sharpened by the usual hand method on a bench oilstone. It is said that the scraper will not only be sharpened quicker and better, but in such a way that it will cut better and longer without resharpening, and in such a way as to enable an inexperienced man to get the greatest efficiency out of the tool.

In the first place, the device may be used for concaving the faces of the scraper in much the same way that a razor is concaved, to prevent the cutting edges from displaying their tendency to become so obtuse that the tool will not work unless held at a considerable angle with the surface being scraped. By concaving the scraper in the way shown in Fig. 3, a much freer cutting edge is obtained.

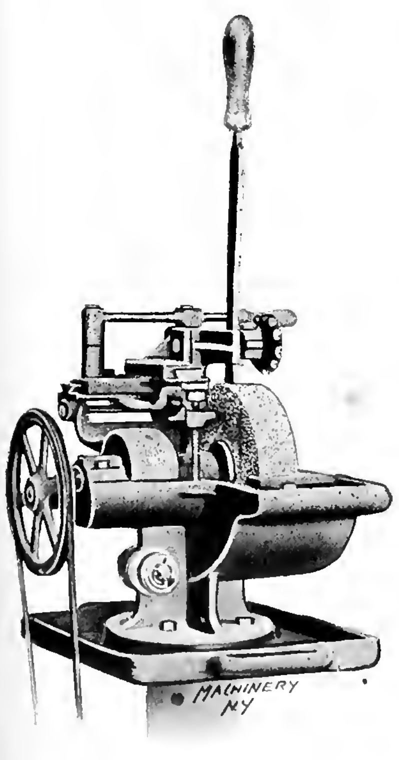

Fig. 1. Revolving Oilstone sharpening a Machine Scraper.

For grinding the edge, as shown in Fig. 1, the scraper is held in a vise supported by suitable slides. By the use of the hand lever, the scraper is moved back and forth as well as laterally across the face of the stone. By these two motions the tool is ground all over the cutting edge, and the stone is kept straight as well. For gripping the scraper quickly and accurately in the vise, a small reference surface is provided which is always in line with the face of the wheel, and parallel with the lines of the motion of the two slides. To use this, the scraper is first pushed over this reference surface; the scraper is set to it, and then gripped by turning the small hand-wheel shown, after which the vise is pushed laterally forward until the scraper comes over the stone. The feed is regulated by the adjusting screw shown at the front of the machine.

This revolving oilstone may be used for other purposes besides sharpening scrapers—such as touching up and putting a keen, smooth edge on thread cutting or other tools on which a fine edge is required. In doing work like this, the scraper holding attachment is thrown back out of the way, as shown in Fig. 2. The wheel is run in a bath of kerosene, which prevents heating the tool and keeps the surface of the wheel keen and sharp, without allowing it to glaze. In the design shown, the wheel is driven by a motor, connected by a belt with the driving pulley, which transmits the power to the wheel through two-to-one gearing. The motor, which is of ¼ horse-power capacity, is furnished for either direct or alternating current.

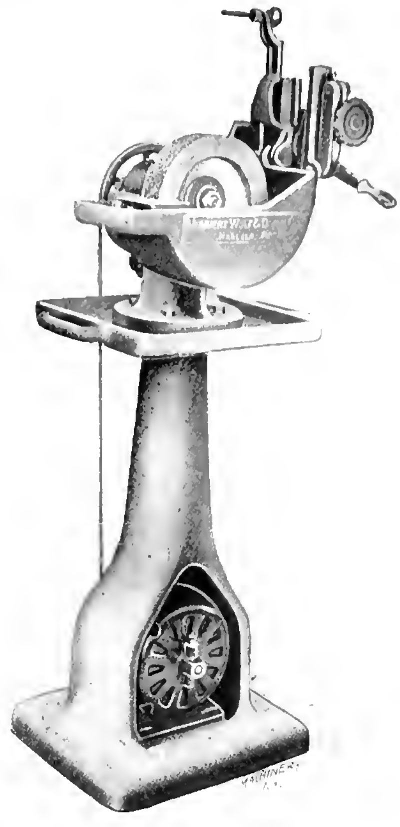

Fig. 2. Scraper Holding Device thrown Back, leaving Wheel Free for General Use.

When electrically driven, the tool is especially adapted to the work of grinding scrapers, as it is provided with two

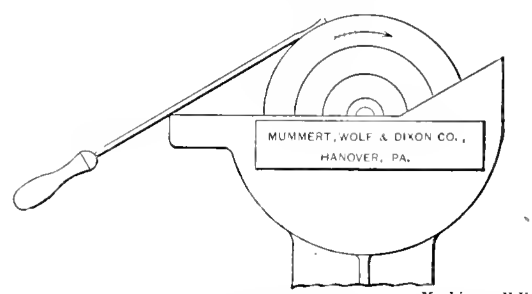

Fig. 3. Recommended Method of Concaving Scrapers to give Free Cutting Action.

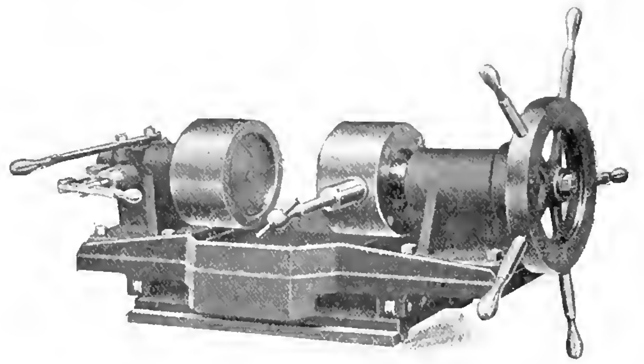
handles by which it may be easily carried by two persons and placed close to the work on which the scraping men are engaged. When desired, it will be furnished with a countershaft and belt drive, instead of a motor as shown.

MURCHEY REVOLVING CHUCK FOR DRILLING AND TAPPING.

The accompanying half-tone illustrates an improved revolving chuck, designed for holding steam, gas, or water fittings, and valves, and adapted for use on a vertical drill press or tapping machine. This chuck is made by the Murchey Machine & Tool Co., 1th and Porter Sts., Detroit, Mich. The following description will make clear the points of improvement claimed for this chuck over former designs:

The work is held between the two cylindrical clamping heads shown at the center of the machine, the final clamping action being accomplished by means of the pilot wheel to the right. When the work is removed, this pilot wheel is first given a slight turn, enough to release the pressure on the work and on the indexing pin attached to the lower lever shown at the left-hand end in the cut. The indexing pin, which serves the purpose of taking the end thrust as well as preventing the clamping heads from rotating while the work

is operated upon, is now withdrawn, and finally, the left-hand clamping head is moved back by the upper lever at the left end, which quickly opens the chuck and permits the work to be removed. This improvement considerably lessens the time required for removing and inserting work as compared with the old style chucks having right-hand and left-hand screws.



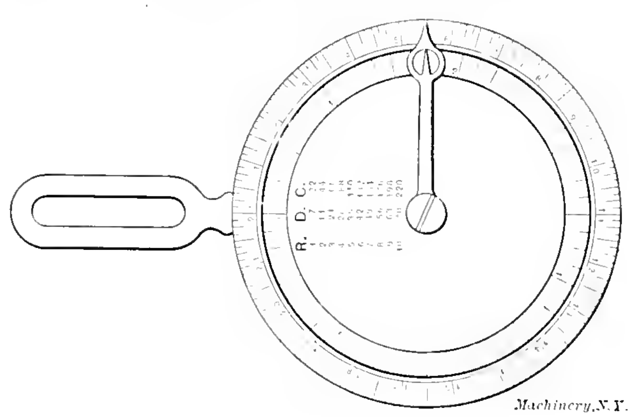
Murchey Revolving Chuck for Drilling and Tapping Valves, Pipe Fittings, etc.

The several faces of the fitting are drilled and tapped at one setting of the work, the indexing mechanism permitting the work to be turned to any required angle.

The rollers shown at both ends of the device under the bed plate of the chuck, between it and the base, are intended to permit the work to adjust itself easily to the position of the drill, and also permit the operator to pull the chuck easily from under the drill press spindle for removing the work.

JONES DIAL MEASURING WHEEL.

The illustration shows a dial measuring wheel designed for the use of boilermakers, blacksmiths, and plate metal workers. Diameters and circumferences are simultaneously obtained by setting the indicator at zero and running the wheel around the circumference of the piece to be measured. The pointer is made double, and indicates diameters on the inner



Jones Dial Measuring Wheel.

circle and circumferences on the outer one. The wheel is made of brass with raised and polished figures, letters, and graduations. The handle is mounted on the back, thus leaving the face of the wheel free of obstruction. The wheel is 7 inches diameter and 22 inches circumference (nearly). It is made and sold by J. M. Jones, 1560 Cambridge St., Cambridge, Mass.

STURTEVANT STEAM-TURBINE-DRIVEN FOUNDRY BLOWERS.

The Sturtevant steam turbine, which we illustrated and described in the New Machinery and Tools Department of the November, 1907, issue of MACHINERY, has been arranged by its builder, the B. F. Sturtevant Co., of Hyde Park, Mass., in combination with its line of foundry blowers, in a series of self-contained units. These turbine-blower units are especially suitable combinations for foundry use, since the driving of the foundry blowers by either steam engine or motor presents numerous difficulties of operation, all of which are overcome in the steam turbine.

With a blower driven by a reciprocating engine, the connection between the two must, of necessity, be by belt or some other speed increasing mechanism, since the high pressure required for foundry service demands a high rate of speed for the blower. Usually a counter-shaft is employed to give the necessary increase. Another difficulty is the chance of having the engine disabled by water coming over from the boiler in the long pipes which must be used. This danger may, of course, be minimized by the use of separators, but it is always in existence. There is, besides this, the liability to wear and break down, due to the somewhat complicated mechanism of the valve gear, piston, cross-head, etc.

The electric motor is generally used in preference to the engine, where there is a supply of electricity, the motor being usually connected with the blower by belting. Due to the

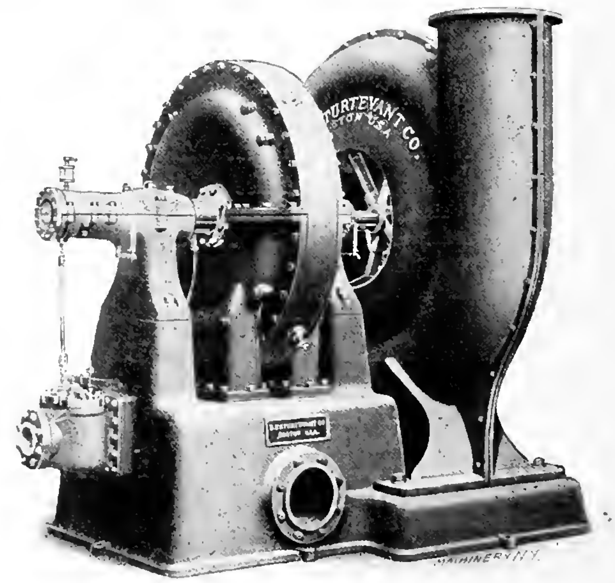


Fig. 1. Sturtevant Steam Turbine and Foundry Blower Set.

varying volume and pressure of air required, it is difficult to fit an electric motor for the conditions under which the blower will have to operate, since it is often impossible to determine these in the beginning. Besides this, the motor will deteriorate rapidly in the heat and dust of the foundry atmosphere, and usually has to be placed in a room of its own, or be removed to a considerable distance from the cupola.

In a steam turbine, such as is shown in Fig. 1, the difficulties of both the reciprocating engine and the motor are believed to have been obviated. It can be continuously operated, without attention, requiring only a weekly filling of the oil cups. The entire absence of mechanism makes the cost of

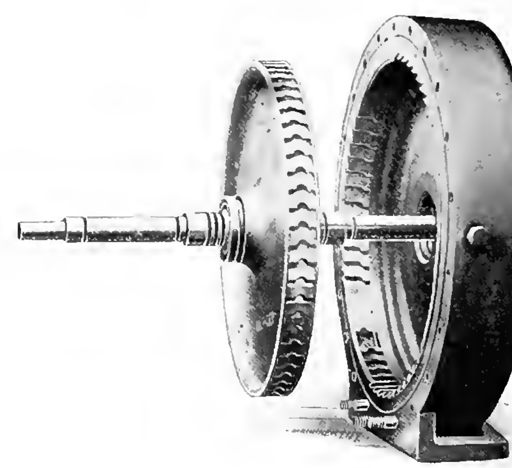

Fig. 2. The Runner of the Turbine withdrawn from the Casing to show the Solid Buckets.

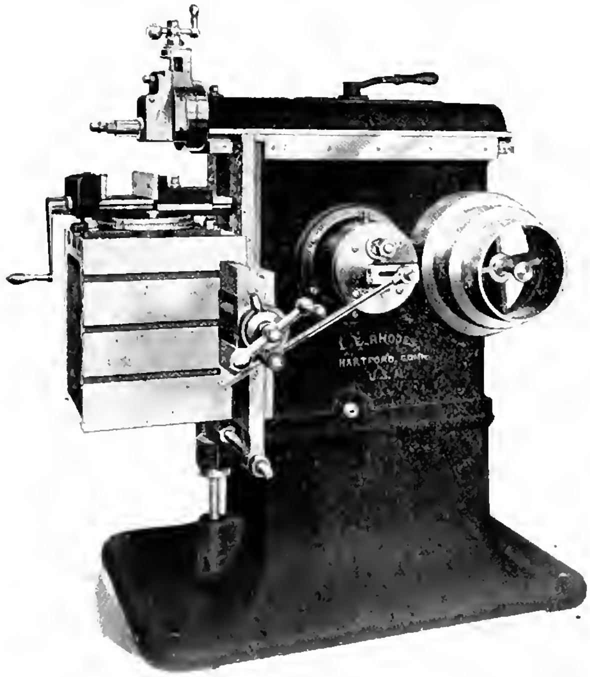
renewals and repairs so small as to scarcely have to be reckoned with. There are no valves to set or eccentrics to adjust. Although the reciprocating engine is as economical, the steam consumption is not the true measure of ultimate economy. When other items, such as repairs, deterioration, etc., are considered, the builders believe that the turbine will prove ultimately more economical than the reciprocating engine.

The wheel, removed from the casing, is shown in Fig. 2. The buckets are cut from the solid forging, not being separate pieces as in many turbines now on the market. A single solid wheel is used, in which the steam is used over again a number of times, so as to reduce the peripheral velocity of the wheel, and at the same time abstract all available energy from the steam before it escapes into the exhaust. For a more detailed description of the action of the steam in this turbine, see the article in MACHINERY previously referred to.

RHODES 12-INCH BACK-GEARED CRANK SHAPER.

The back-geared crank shaper shown herewith is built by L. E. Rhodes, of Hartford, Conn. Its special feature, aside from its small size and convenient arrangement, which fit it for tool-room work, is the fact that it is provided with back-gearing for varying the ratio of the connecting gearing between the cone pulleys and the crank. This is an unusual provision for so small a machine. Six changes of speed are furnished in all, with the three steps provided on the driving cone. The back-gear change is made by pushing the knob shown in the cone pulley either in or out, as may be required. This shifts a double driving pinion on the driving shaft, so that either its large or small diameter engages with gears on the intermediate shaft, by which it is connected to the crank gear.

The machine is provided with a suitable vise, as shown, having tool steel faced jaws 9 inches long and 2 inches deep, opening 6 inches. The finest table feed is 0.005 inch. The table is fastened to the cross rail by a wedge-shaped gib, thus insuring a bearing surface through its whole length.



A Small Back-geared Crank Shaper

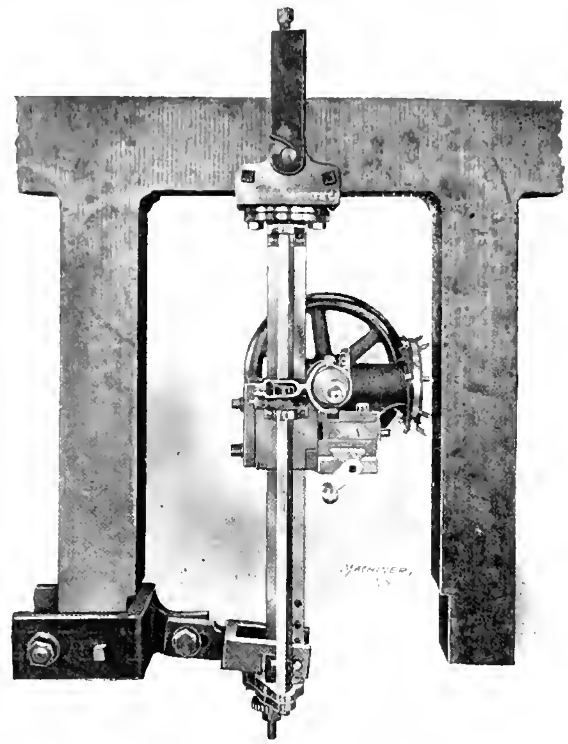
The stroke of the ram is 13 inches, the vertical adjustment of the table 12 inches, and the traverse of the table 18 inches. The working surface of the table is 11 x 13 inches. The machine is driven by a 2½-inch belt. The weight of the machine, complete, is 1,650 pounds.

UNDERWOOD PORTABLE FACING MACHINE FOR LOCOMOTIVE FRAME PEDESTALS.

H. B. Underwood & Co., 1024 Hamilton Street, Philadelphia, Pa., have recently added another tool to their list of portable devices for general railroad and machine shop use. This new tool, as may be seen in the accompanying half-tone, is designed for facing the inner surfaces of the pedestal legs on locomotive engine frames.

The milling head by which the facing is done is carried by a square bar, which is the main supporting member of the mechanism. This bar is provided at the top with a steel swivel connection to the clamping block by which it is fastened to the frame. This steel swivel allows the cutting tool to be swung around for cutting the other side of the opening, and also allows the square bar to be set at an angle for facing on a taper. The clamping block may be easily changed to enable it to enter narrow spaces. At the lower end of the square bar the universal adjustable clamp holds it securely to the frame.

The milling head is fed along the square bar by a bronze half nut, which may be engaged with, or disengaged from the feed-screw. This screw is revolved by a ratchet and dog at the lower end of the device, operated, through the squared shaft shown, by an eccentric on the milling head. The feed is thus automatic, and may be varied to suit the requirements. The milling spindle has adjustments in two directions—to and from the leg, and across the face. Fine or rapid adjustments may be made without difficulty, suitable cranks being provided for obtaining these movements.



A Portable Machine for Facing the Pedestal Jaws of Locomotive Frames.

The milling spindle is threaded to receive the milling cutters, which have blades of square high-speed steel, set in a solid head; they are removable for grinding or adjustment. The power is applied by a telescopic shaft with universal joints, operating through gearing on the spindle, and allowing the source of the power to be in any convenient, out of the way place, making belts, etc., unnecessary. The maker's two-cylinder air or steam motor is a very suitable prime mover for a portable tool of this kind.

In using this machine, a large quantity of metal can be removed in a given time, by taking a succession of light cuts and feeding very rapidly.

GOULD & EBERHARDT RACK-CUTTING MACHINE.

We illustrate in Figs. 1 and 2 a new design of rack-cutter built by Messrs. Gould & Eberhardt, of Newark, N. J. This machine has been improved in a number of particulars over the designs formerly built adapting it to faster and heavier cutting and greater accuracy. It is designed with a view of obtaining to the fullest extent the benefits to be derived from the use of high-speed steel cutters, and at the same time give a product of the highest degree of accuracy required in commercial work.

One important change has been made in the design of the bed of the machine. This was formerly of rectangular form, supported by box legs. The new construction is solid in one piece, resting directly on the floor, thus taking directly all

strains from the action of the cutters on the work. That part of the bed which supports the cutter slide column is also cast solid with the main bed casting, still further adding to the rigidity of the entire machine. Another improvement consists in arranging the thrust bearings of the feed-screw so

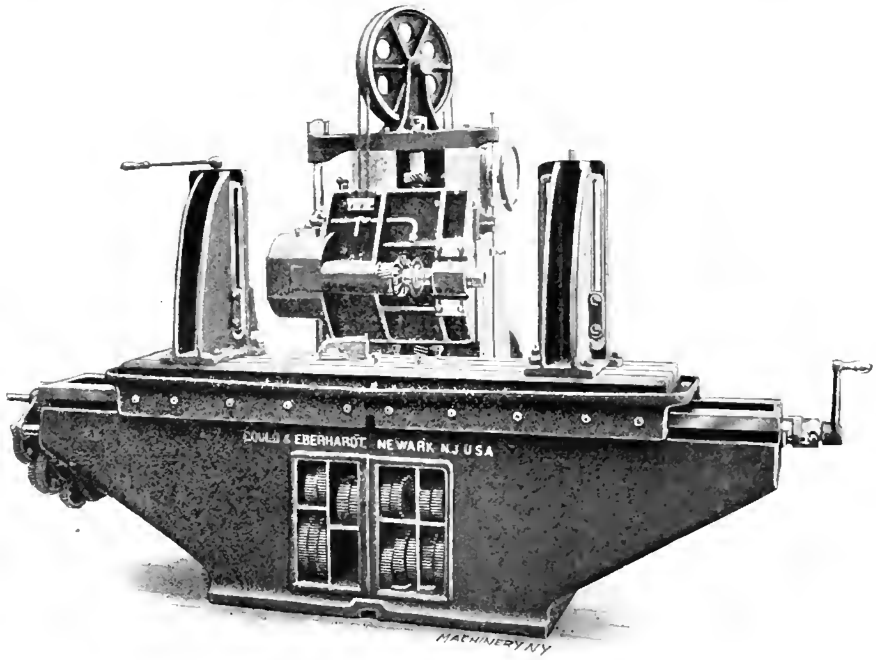


Fig. 1. A New Design of the Gould & Eberhardt Rack-cutting Machine.

that the cutter slide is pulled down, as it feeds through the work, on the draw-cut principle. This, in connection with the style of bed furnished, insures not only increased feeds, but greater accuracy as well.

The cutter slide is counterbalanced, and is so arranged that it cannot possibly feed downward unless the proper indexing for the work and all previous necessary movements have been completed. The cutter spindle is located approximately in the center of the slide, which has a large bearing surface, giving freedom from chatter under heavy work. The cutter spindle is driven by double spiral gears, one pair placed at the outboard end, and the other close up to the cutter, where the full driving effect can be obtained. One of these pairs is cut right- and the other left-hand, thus neutralizing by this herringbone gear effect the end thrust in the cutter spindle. The guard over the inner driving gear has been removed in Fig. 1 to show this drive.

The feeds for the cutter slide range in geometrical progression from ¾-inch to 14½-inch per minute, thus providing a range that will economically take care of all classes of work. The spindle drive, feed motion and the indexing are all derived from the single speed driving pulley at the rear. This makes the matter of changing to individual motor drive a very simple one. The feeds are obtained by quick change gear mechanism, shown next to the driving pulley in Fig. 2. The cutter speeds are varied by the change gears shown at the end of the rear extension of the bed. These cutter speeds vary from 12 to 76 revolutions per minute, in geometrical progression.

The work table is provided with chucks or vises for holding the work. These vises are so designed that they are fastened solidly, metal to metal, to the top of the table, thus avoiding the common fault of springing or warping the latter out of line. The table has a generous bearing surface, and is strongly gibbed to the ways on the main bed casting. The vertical position of the blanks and the vertical travel of the cutter slide, permit chips and oil to drop down out of the way of the cutters, leaving the work free. An opening in the bed of the machine is provided, through which the chips and lubricant are drained, being separated by suitable screens so that the oil is returned to the pump and the cutters, free from chips.

The indexing mechanism for the table is simple and absolutely positive in its action, reducing the chances of error to a minimum. One novel feature is the provision for the insertion of translating gears for changing the setting of the machine from diametral to circular pitch or *vice versa*, or to set it for cutting metric module or circular pitch—all with the same lead or dividing screw. An auxiliary end adjustment for the screw is provided which is useful in resetting work which has to be recut, or for taking a light cut on one side of the tooth. The table is geared to index in either direction, avoiding the necessity for returning the table every time a new blank is set. Adjustable stops are provided which can be set at any predetermined point, to automatically throw out the table indexing movement.

The machine shown, which has a capacity of work up to 6 feet long at one setting, was furnished to a large planer manufacturer for cutting the planer table racks. Duplicate machines from the same lot have been furnished to other manufacturers of machine tools, printing presses, etc. This tool will cut any width of face up to 10 inches, or a series of narrow-faced racks up to the same width. Any pitch as coarse as 1½ diametral in cast iron, or 2 diametral in steel may be cut, using from 1 to 12 cutters, depending on the pitch. It is possible to use a roughing and a finishing cutter at the same time on the largest pitch mentioned above. Gang cutters provided with this machine have their cutting points set spirally, so as to avoid chatter and the consequent rapid dulling of the cutting edges. A bed and table for work up to ten feet in length at a single setting will be furnished if the purchaser requires it.

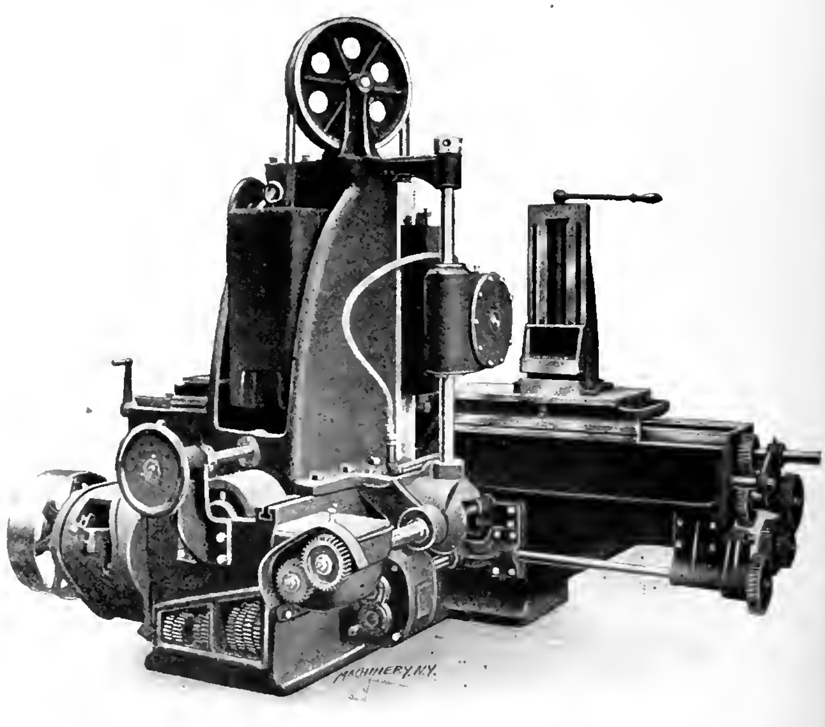

Fig. 2. Rear View of the Machine, showing Single-speed Drive, Quick-change Gear Feed, Indexing Mechanism, etc.

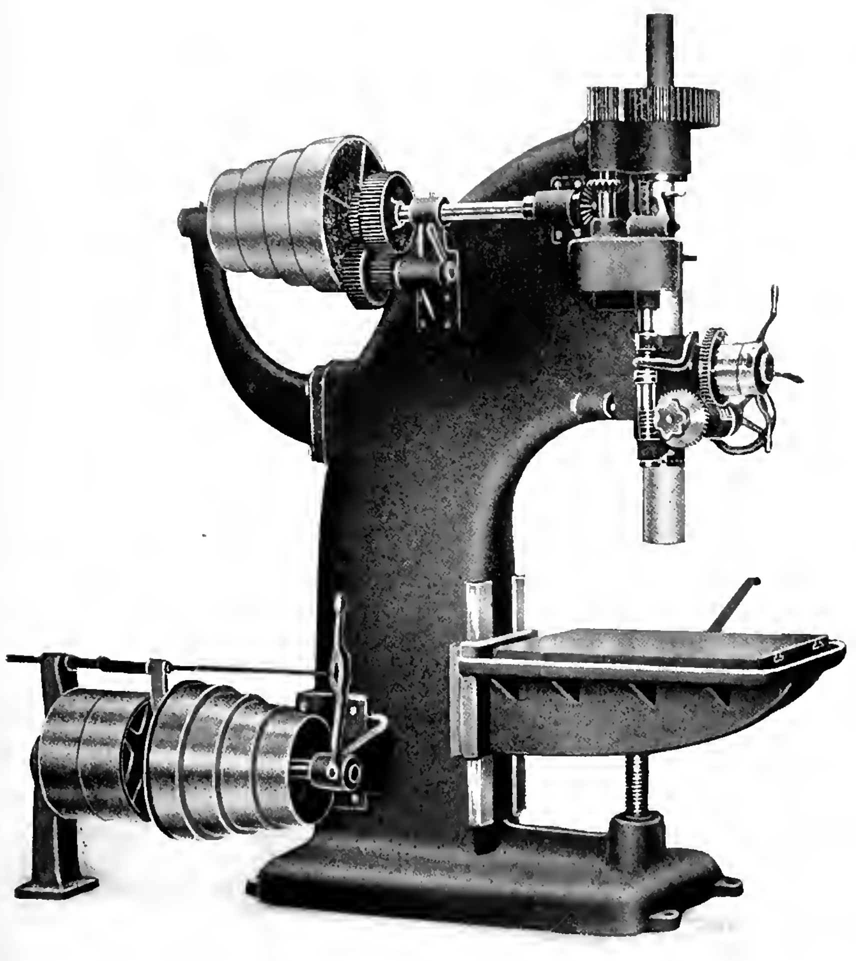
It will be seen that this machine in its structural features belongs with the other Gould & Eberhardt machine and the Reinecker machine, shown in Figs. 69 and 70 of the article on

gear-cutting machinery (on page 509 of the engineering edition of this issue) though it differs considerably in its mechanism from either of them.

FOOTE-BURT HIGH DUTY DRILL PRESS.

It used to be considered that, for drilling tools, all it was necessary to have was a revolving spindle, properly driven, and a table on which the work could be placed, having a surface approximately perpendicular to the axis of the spindle. Carefulness of workmanship, strength and rigidity of frame, and other such features as are looked out for in the design of lathes, planers, milling machines, etc., were once thought to be a waste of time and money when applied to drilling machines. Of recent years, however, this attitude has changed, since it has been found that drills, particularly of the modern high-speed type, can be worked harder, and will remove more material in a given space of time, when driven by a heavy, rigidly built machine, than when used in a tool of the older type; heavier feeds can be taken, and the cutting edge lasts longer. Recognizing this condition, the Foote-Burt Co., of Cleveland, Ohio, has brought out the drill press shown in the accompanying engraving.



A Drill Press for Heavy Duty with High-speed Drill

The spindle is of forged carbon steel, $3\frac{1}{2}$ inches in diameter in the sleeve, with a No. 6 Morse taper hole. The thrust of the cut is taken by a bearing of $\frac{3}{4}$-inch balls which is made in the shops of the builder, and is guaranteed to stand up under the hardest service continuously, without breaking the balls or crushing the collars. The spindle is driven from a four-step cone, through bevel and spur gears and a set of back gears, which, in combination with the cone pulleys, give eight changes of speed to the spindle.

Three changes of gear feed are provided, any one of which is instantly available by simply shifting a lever conveniently located at the front of the machine. The power feed, hand worm-feed, automatic stop and quick return levers are all within easy reach of the operator at all times.

The maximum distance from the end of the spindle to the body of the table is 32 inches, the distance from the center of the spindle to the face of the column is 22 or 30 inches (as may be ordered), and the spindle has 16 inches of power feed. The revolutions per minute vary from 23 to 170. Either a plain or a compound table movement may be furnished. The 44-inch swing size weighs 6,000 pounds, and the 60-inch swing 6,800 pounds. The machine is powerful enough to drive a $3\frac{1}{2}$-inch high speed drill up to its full capacity.

HILBERT TRIPLE-GEARED UPRIGHT DRILLING MACHINE.

As may be seen from the accompanying engravings, the designer of this drill press (which is built by the Hilbert Machine Co., Cincinnati, Ohio) has broken entirely away from the traditions of the standard drill press builder. Everything, from the shape of the frame to the method of driving, has been worked out on original lines. The designer's reasons for these changes will appear in the following description.

The frame consists of a round column of generous dimensions, provided with a large bottom flange, bolted to a heavily ribbed T-slotted base. This column is supported by a second column or back brace, which connects the base and the top housing, making these four members solid.

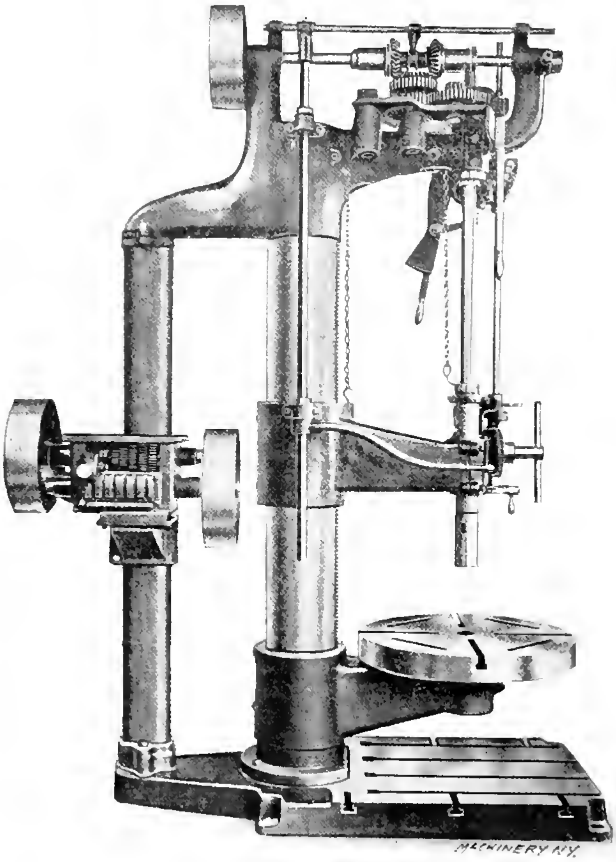
The work table is fixed in height, avoiding the raising and lowering mechanism usually provided. Instead of this, the arm carrying the lower spindle bearing is adjusted up and down on the column. This has a long bearing, and surrounds the column, sliding down on the latter to the top of the table arm, when the nose of the spindle will nearly touch the base. These two arms for supporting the table and the spindle are of box shape, and of nearly the same pattern. Each is clamped securely to the column by means of two strong screws, insuring the rigidity of the structure of which they are a part. This arrangement is believed by the builders to be superior to the usual method of fastening the lower spindle bearing to the frame work by screws and flat bearings, so far as concerns the matter of obtaining the necessary rigidity for heavy duty work.

The machine is connected to the countershaft by a belt to the single speed pulley, shown attached to the speed variator on the rear column. This single pulley allows the machine to be set in any direction under the line shafting, either at right angles with it or parallel to it. The speed variator is of the most simple type, and is operated with one lever only, giving six speeds arranged in geometrical progression. From here, the power is carried by belt to the shaft on top of the machine. This belt serves as a safety device in the otherwise positive power transmission system, preventing the breakage of the drilling or boring tools. The six speeds given by the variator are multiplied by three, by the operation of the handle shown in front, depending from the upper spindle bearing. This lever is conveniently located for the operator, and its position can be changed instantly.

The spindle is driven by either one of two gears, a large one with a coarse pitch for the slowest speeds and a small one with finer pitch for the higher speeds. None of these gears run idle. When the back gear is thrown in, the gears of the medium and high speeds are thrown out, and *vice versa*. Having this change of speed directly on the spindle, allows all the shafts of the machine to rotate slowly when the spindle speed is high, as contrasted with the great rate of rotation necessary for the horizontal shaft in the usual type of upright drill, with its bevel gear drive ratio of one to two or one to three. In such cases the shafts have to rotate two or three times faster than the spindle.

Another feature of this machine is the design and location

of the tapping mechanism provided. Instead of being applied directly to the spindle drive, as usual, where the torque is at the highest point, it is located on the high speed driving shaft. It consists of two miter gears, provided with friction clutches which are adjustable for wear. The clutches are so designed that they tighten in proportion to the load placed on them. Either of these friction clutches may be connected



An Upright Drill of Original Design, made by the Hilbert Machine Co.

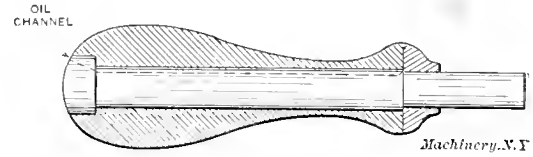
with its miter gear by means of the horizontal handle shown, pivoted to the lower spindle bearing head, and operating the vertical squared shaft, which transmits the movement to the clutch. This lever is directly in front of the operator, and is used by him for stopping, starting and reversing the machine, as well as for tapping. Owing to the use of the friction clutch, the reversing of the spindle may be done at any speed. These clutches have proved to be reliable in actual use, having been in operation for over six years without requiring any adjustment for wear.

The power feed is the positive gear type, having four changes. It is very powerful and constructed in a mechanical manner. It is quickly and easily changed by the handle shown in the engraving, hanging from the upper bearing of the spindle on the further side of the machine. Hand feed and quick return movements are provided for the spindle, as well as an automatic trip, adjustable to work at any point throughout the travel of the spindle.

The machine shown is the standard type furnished by the builders, and is of 36-inch capacity. As shown, it is regularly provided with the tapping attachment. It is built in a workmanlike manner; all the important gears are of steel and all the important bearings are of phosphor-bronze.

CINCINNATI QUICK-ACTION BALL CRANK.

The Cincinnati Ball Crank Co., of Cincinnati, O., has been for some years manufacturing solid crank handles for machine tool builders, for general use on cranks, hand-wheels, etc. It has recently added to this line of solid handles, a "quick action" design of the type shown in the accompanying line engraving. As may be seen, it consists of a central pin which is riveted or otherwise fastened to the crank or balance wheel, and carries a washer, and a loose handle or spool, which is grasped by the hand of the operator. Since this handle revolves freely, the workman is able to use it much more quickly and easily than would be the case if it were solid. It will be found especially adapted to heavy tools, being useful, for instance, for such applications as to the carriage movement of a large lathe. The rotation of the



Machine Crank or Wheel Handle with Revolving Grip.

handle makes it possible to operate such machines with the ease and rapidity of tools of much smaller size. As is shown, an oil channel is provided, by means of which the handle can be lubricated.

CYLINDER GRINDING ATTACHMENT FOR THOMPSON GRINDING MACHINE.

The accompanying Figs. 1 and 2 show a method of holding automobile cylinders and similar work for internal grinding operations, which is much superior to any possible method of clamping it to a face-plate or holding it in a chuck. Fig. 1 shows the device mounted on the table of a grinding machine built by the maker of the attachment, the Thompson Grinder Co., of Springfield, O. Fig. 2 shows the device in action, with the work in place.

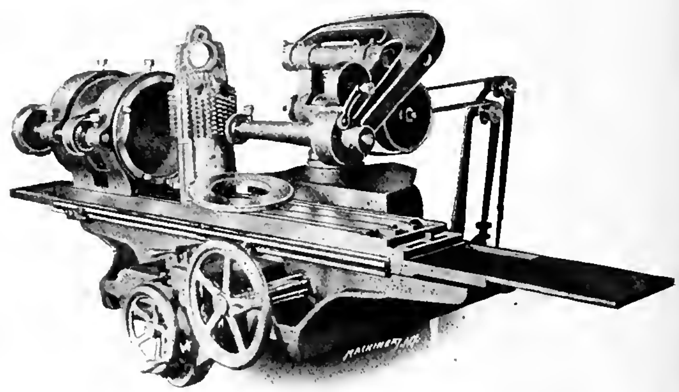


Fig. 1. Hollow Spindle Head-stock for Grinding Automobile Cylinders in Thompson Grinding Machine.

As will be seen in the engravings, the front end of the work is held in a face-plate, bored to the same size as the recess of the crank-case, thereby holding it without any possible chance of springing it in clamping. This face-plate, in turn, is bolted to the face of the hollow spindle, which runs in generous bearings, with suitable provision for adjust-

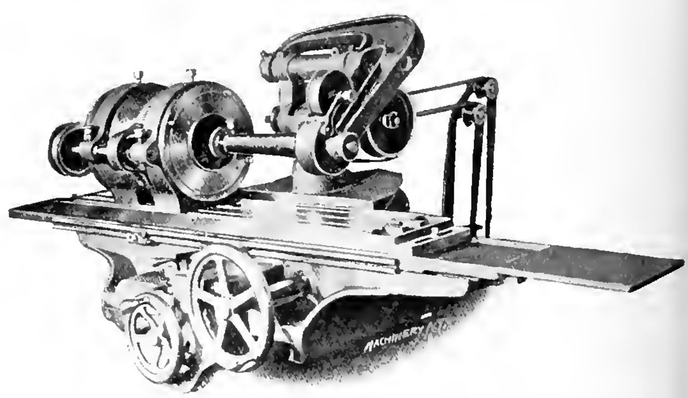

Fig. 2. Cylinders in Place in Hollow Spindle Attachment and Grinding in Progress.

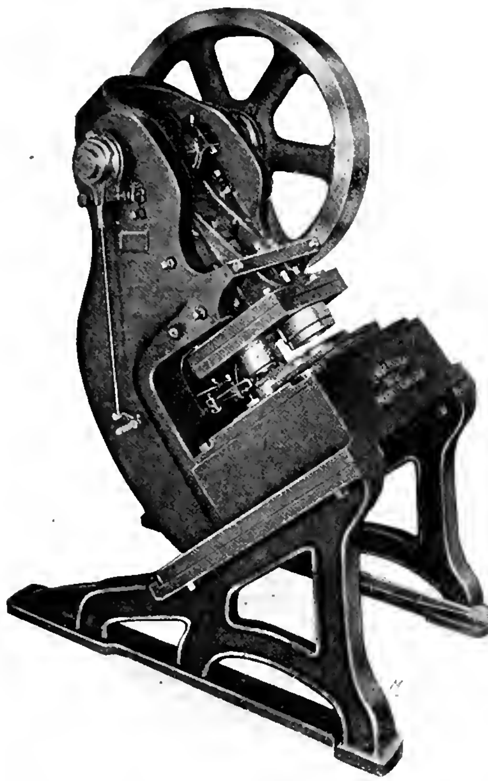
ment for wear. It is driven by gearing from a fast-running shaft. The diameter of the hole in the hollow spindle is 10 inches. At the rear end of the attachment, appropriate means are provided for supporting the closed end of the work.

The cylinder shown on the table of Fig. 1 is of the air-cooled type, and is $5\frac{1}{2}$ inches bore by 11 inches deep. In this machine the internal grinding spindle is of tool steel, hardened and ground, and running in adjustable bearings, by which all lost motion is taken up, except that necessary

for the lubricating oil. It is driven by an endless cotton belt, held at the proper tension by the idler seen in the engraving, thereby securing long life to the belt and bearings. As the machine is regularly provided with pumps, pipes, etc., for wet grinding, provision has also been made for using water with this attachment when desired.

INCLINED BLISS PRESS WITH DOUBLE DIE ATTACHMENT.

The press shown in the accompanying engraving is built by the E. W. Bliss Company, 5 Adams Street, Brooklyn. It is fitted with tools for blanking, drawing and wiring shallow cups or similar shaped work. Double dies are used. The first one is a regular combination die, which cuts, draws and forms the blank. The press being in an inclined position, the work thus blanked slides by gravity down the chute, where it is caught and supported by a finger gage, which holds it in position beneath the second member of the die, which wires the edges on the next downward stroke of the ram. On this same stroke, of course, another blank is being cut and formed



Bliss Press arranged for Performing Two Successive Operations at Each Stroke.

in the first die. On the return of the ram to its upper position, the wired blank is released by the finger feed, and drops into a receptacle placed to receive it, after which the finger quickly returns to center the next blank, which has meantime dropped down from the first die. The feed is operated by the cam shown at the end of the crank-shaft. The ram has a stroke of two inches, and is operated by a crank-shaft made from hammered, high carbon steel. It is fitted with a cross-bar knock-out. The press, arranged as shown, weighs 5,350 pounds.

WILMARTH & MORMAN SURFACE GRINDER.

The builders of the tool shown in Figs. 1 to 4 call their machine a "surface grinder," but that title scarcely gives a proper idea of the range of operations which may be performed on the machine. If desired by the purchaser, it may be furnished for surface grinding pure and simple, but provision is made for using a cutter and reamer grinding attachment, or a drill grinding attachment when desired, so that, when completely fitted out, the machine will cover practically the whole range of tool-room work so far as concerns the sharpening of drills, cutters, reamers, dies, etc. The surface grinding table may be arranged to be operated entirely by hand, or may be supplied with automatic feed as desired. If supplied with automatic feed, this may be for the longitudinal movement only, or both longitudinal and cross movements may be automatic.

The spindle is of crucible steel, ground and lapped to size, and supported close up to the wheel, so as to do away with vibration due to springing and overhang. The spindle cone pulley is carefully turned both inside and out to secure per-

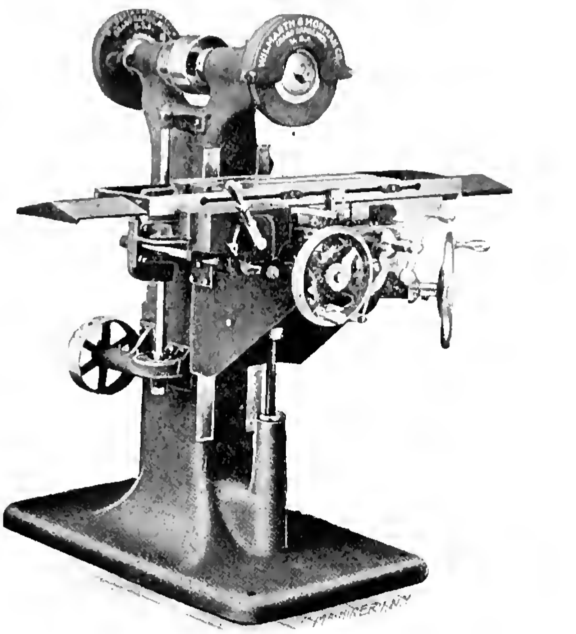


Fig. 1. Front View of the Wilmarth & Morman No. 2 Surface Grinder.

fect balance. The bearings are of phosphor bronze, with liberal dimensions, being 8 inches and 5 inches, respectively, in length, and tapering from 2 inches to 1½ inch in diameter. The bearings in each box may be adjusted independently. The matter of lubrication has been carefully looked out for. The oil chambers are very large, and supply the bearings with oil through felt wicks, by capillary attraction. Surplus oil that may be run out to the front of the bearings is returned to the oil chambers by small channels. The bearings are carefully protected from dust and grit.

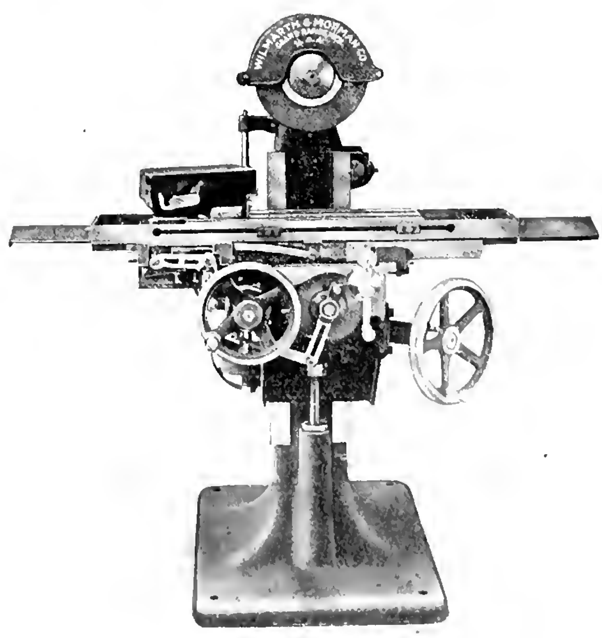

Fig. 2. Surface Grinder with Automatic Feed Box removed to show Mechanism.

The table of this machine is 8 inches wide and 50 inches long, and has a working surface of 8 inches by 20 inches. This 20 inches of length is carried by 36 inches length of saddle, so that the work is always well supported. A gib is attached to the rear of the table which effectually prevents any tipping, even when an excessive load is placed on the overhang end of the table at the extreme limit of its travel

The machine is designed for a 10-inch diameter wheel for ordinary surfacing work, and with a wheel of this size, has a capacity for work up to 11½ inches high. The spindle driving cone has two steps, giving the proper speeds for both 7-inch and 10-inch wheels. The 7-inch wheel is used for cutter and reamer grinding, and may be used for surfacing as well, where circumstances make its use advisable.

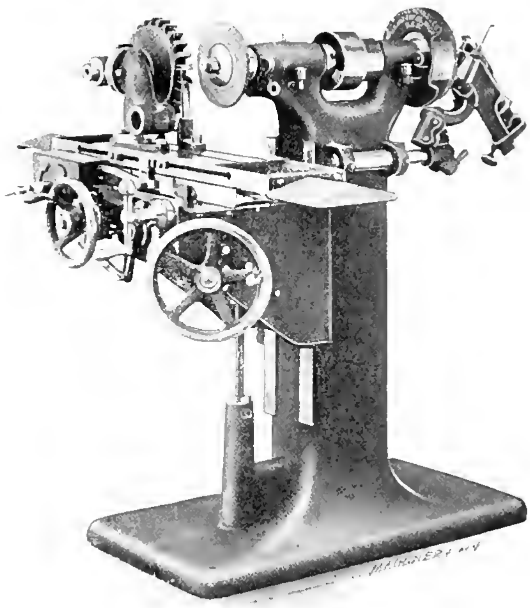

Fig. 3. Cutter Grinding Attachment in Use on Table of Surface Grinder. Note Drill Grinding Attachment on Rear of Column.

Where the machine is furnished for plain hand feed, the longitudinal movement is effected by means of the hand-wheel at the left of the front of the knee, and operates through a plain rack and pinion movement. The cross movement is by ball crank and screw, and may be read on a dial to a thousandth of an inch. The vertical adjustment is effected by a vertical screw running on a ball thrust bearing and working in a bronze nut. This adjustment may be easily read to half a thousandth of an inch.

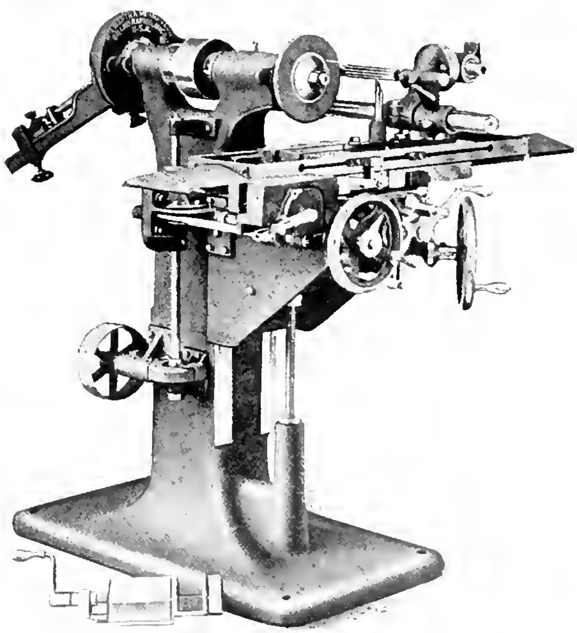

Fig. 4. Centers for Reamer Grinding in Use on Table of Surface Grinder.

When automatic feeds are used, as in the machine shown, the reversing mechanism is contained in a casing on the front left end of the saddle, shown removed in Fig. 2. The reversing lever may be placed in the center so as to hold the clutches in neutral position when desired, thus leaving the machine free for plain hand feeding. When the transverse feed is used, it is arranged to be applied or released by a friction clutch, operated by the knurled knob in the center of the table traverse hand-wheel. This feed may be arranged to act in either direction at the will of the operator, and may be varied in amount to suit the work in hand. All gears are carefully guarded, to protect them from dust, and from injuring the operator. The ways of the various slides are also protected from grit.

The cutter grinding attachment shown in use in Fig. 3, is universal in its application, and has a capacity for handling all kinds of milling cutters, including face and side mills up to 30 inches in diameter. It can be mounted on the table of the surface grinder by simply clamping it in place with two bolts, and can be manipulated as conveniently and quickly as regular cutter grinders made especially for the purpose. In Fig. 4 this cutter grinding attachment is shown in use in conjunction with centers, mounted on a bar and supporting a taper reamer for grinding. The adjustments of the attachment permit the grinding of reamers at any angle. Counterbores, end mills, etc., may be sharpened in the same way.

The "New Yankee" drill grinder shown attached to the rear of the column is a well-known tool. Its use on the same base does not interfere in any way with the use of the surface grinder, as one operator may be using the front side of the machine while another comes up and sharpens his drills, without either being in the slightest degree in the other's way.

NEW TYPES OF DRILLS AND CHUCKS MADE BY WHITMAN & BARNES.

The Whitman & Barnes Mfg. Co., of Akron, Ohio, and Chicago, Ill., has developed a line of drills to cover the requirements of the heaviest service that is asked of these tools in metal working. The first design, shown with the chuck for holding it, is illustrated in Fig. 1. As may be seen, this drill, known as the "Economy," is a modified flat drill. It is so made as to be capable of standing extremely heavy feeds in the very hardest and toughest materials, such as high carbon steels, hard cast iron, armor plate, steel rails, and steel castings. It is not especially adapted to work where unusual accuracy of diameter is required, nor should it be used for very deep drilling, it being best adapted for holes from 1 to 3 inches deep. The drills are made of the very best grade of high speed steel, are ground to size, and are tempered so that practically the whole length can be used. The chuck for holding them, as may be seen in Fig. 1, is so arranged that only as much of the drill as is necessary needs to project beyond the chuck. The back end of the drill fits a plug held in place by a cross bar secured by a retaining sleeve. In the body of the chuck are bored a series of holes in which the cross bar fits. By releasing the cross bar, the plug and drill may be moved out the required distance, the adjustment being fixed by slipping the retaining sleeve over the cross bar again. The use of this chuck reduces the torsional strain on the drill very

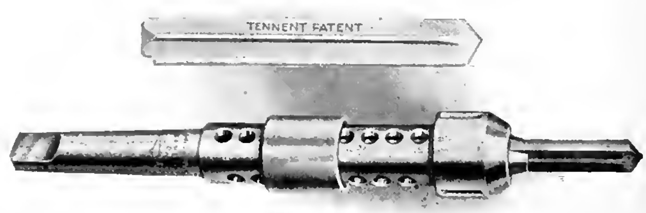

Fig. 1. The "Economy" Flat Drill and the Chuck for Holding it.

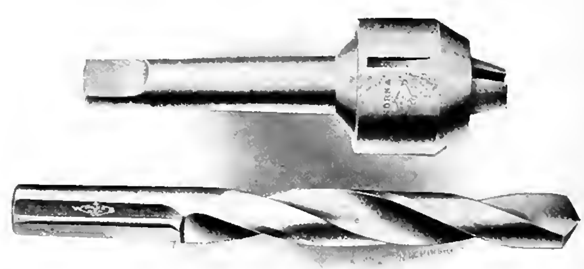

Fig. 2. The "Norka" High Speed Twist Drill and Chuck.

greatly, and increases its efficiency, so it may be run at a higher rate of speed without injury or breakage.

The "Norka" high speed twist drill and the chuck used for holding it are shown in Fig. 2. These drills are made from high speed steel, twisted while hot, so that the grain of the steel is not disturbed at all. This gives them great strength, ability to stand hard and rough service, and adaptability to all kinds of drilling in any class of material in which drilling is possible. They are ground to size, and proper clearance is formed on the flutes. In making the drill, the end of the blank is left flat and straight. This forms the shank, which fits into the chuck, so that there is no possibility of the tangs twisting off, or of the drills turning in the socket. This flat end of the drill is beaded to fit grooves in the jaws of the chuck, so that the drill is held firmly and centered. In the chuck used, the drill is centered by a steel plug, and is securely locked in the jaws with the clamping nut shown. The chuck may be used with taper shank drills by removing the jaws and steel plug, when the drill will fit into the chuck as in an ordinary sleeve or socket.

FRICTION-DRIVEN SENSITIVE DRILL PRESS OF NOVEL DESIGN.

The Washburn Shops of the Polytechnic Institute of Worcester are well known as being the only school or college shops actively engaged in the building of machine tools for the trade. Their drill grinders have been well known for many years. They have recently added to their line a new product, which we illustrate herewith; it is a friction-driven sensitive drill press, presenting novelties of design and construction which make it of unusual interest to the mechanic and designer.

As may be seen in Fig. 1, which shows the single spindle type, the tool has the convenient arrangement in which the head is vertically adjustable through a considerable range, and in which a circular table, vertically adjustable, is provided in addition to the usual swinging rectangular table. This combination is most useful, in that it makes provision for doing all sorts and conditions of work.

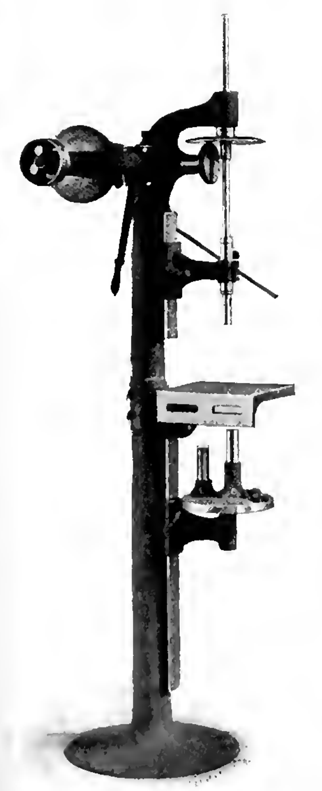

Fig. 1. Friction-driven Sensitive Drill Press, built by the Washburn Shops of the Worcester Polytechnic Institute.

In addition to the adjustments mentioned, the rectangular work table may be swiveled about a horizontal axis to present the work at any desired angle with the drill spindle. It is provided also with a short vertical face, with cored slots, by means of which the work may be clamped to it when it is more convenient to present it to the drill in this way. The round, vertically adjustable table may be removed, and either a V-center or a cone center used in its place. These are convenient for drilling cross holes in round work, or for center drilling round shafts.

The chief novelty of the arrangement, however, lies in the design of the friction drive provided. As may be seen, the machine is driven by a horizontal shaft at the back, carrying a friction disk which bears on the periphery of a fiber roll on a second horizontal shaft at right angles to it. The front end of this shaft carries a second similar fiber roll, bearing on the face of the disk on the vertical spindle of the machine. By means of the handle shown in Fig. 1 at the side of the column, this shaft and its two rolls can be moved toward the rear or toward the front, thus changing their positions on the faces of the disks, and decreasing or increasing the spindle speed in a total ratio of about 4 to 1, for an end-wise movement of only about 2 inches.

The most original feature of this arrangement is the provision made for supplying just enough pressure to the friction drive to transmit the required amount of power. As is best

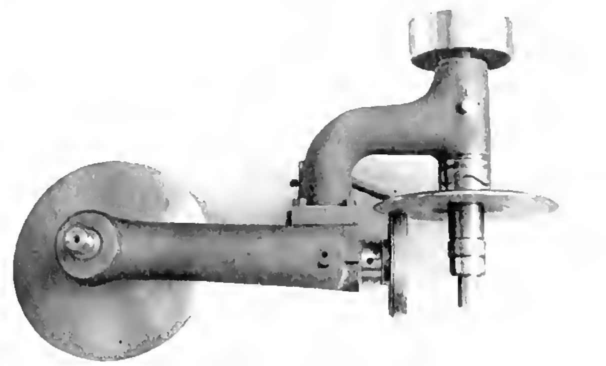

Fig. 2. Top View of Machine, showing Friction Drive.

seen by comparing Fig. 1 and Fig. 2, both of the friction disks are loose on their shafts, being driven from them by cam faces on their hubs, corresponding with and bearing on cam faces on collars fast to the shafts. When no resistance is offered by the drill, very little power is required to rotate the spindle. Under these circumstances the disks are only lightly in contact with the rollers. As soon, however, as the drill reaches the work, the contact between the friction disks and their rolls is not enough to drive the spindle. Under these circumstances the friction disks slip on the shafts, but this slippage involves the climbing of the cam surfaces of the disks and their collars on each other in such a way as to force the friction parts into closer contact. Every bit of slip, therefore, involves an increased pressure on the friction rolls, so that this pressure is always great enough to drive the spindle, but is never any more than is needed.

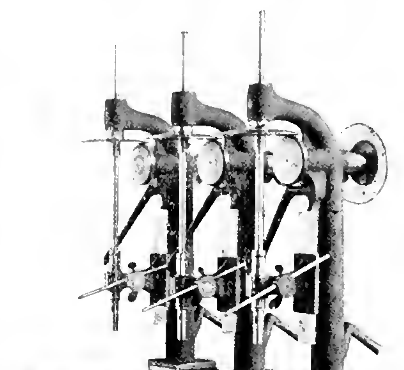

Fig. 3. Multiple Spindle Form of the Machine, with the Columns Adjustable for Center Distance.

This arrangement makes unnecessary the use of cones and quarter-turn belts, and permits an instantaneous change of speed. The thrust of the friction members is taken up by ball bearings, and the journals of the two horizontal shafts are ring-oiled from ample oil reservoirs. No counter-shaft is required. To stop the spindle, the speed lever is thrown to its extreme position. While in this position, the driven roll is out of contact with the driving disk, which is recessed for this purpose to clear the roll.

The elimination of this counter-shaft is especially advantageous in the multiple spindle type of machine, shown in Fig. 3. Note the ease with which the variations of spindle speeds may be obtained without the trouble of shifting belts. This design also presents a much neater appearance than is possible in designs which depend on a quarter-turn belt to transmit the power. Each head of the multiple spindle type is a unit in itself, and the heads may be slipped along the bed to any position required, to drill to within a minimum center distance, between adjacent drills, of 10 inches. Any head may be taken from the base, or extra heads may be

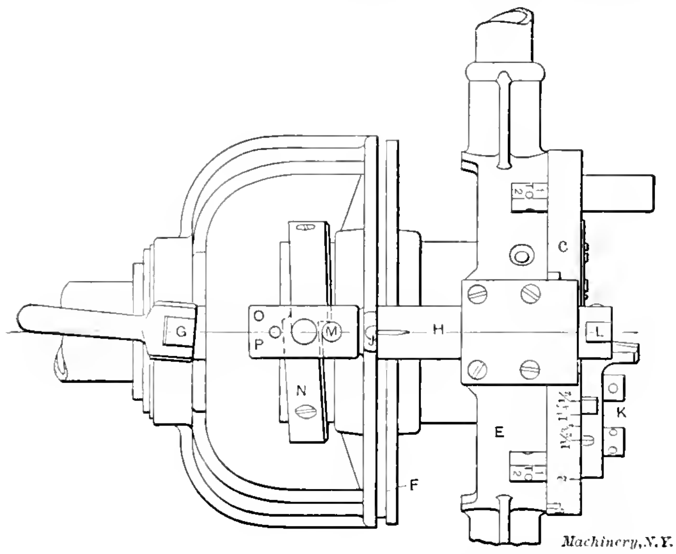
added, as the work requires. The head is fastened to the base by a T-bolt set at an angle, and is brought down and forward into position by the lever and nut shown at the rear of the machine.

The spindles of these machines have a feed of 3 inches, and a vertical adjustment of 7½ inches. The diameter of the spindle in the sleeve is ⅞ inch. The single spindle machine weighs about 250 pounds, the two-spindle 450 pounds, and the three-spindle, 650.

This machine is not an experiment, having been thoroughly tested for several months by everyday use in the Washburn Shops. It is designed for sensitive drill work, and will handle both carbon and high speed steel drills up to 9/16 inch in diameter, at their proper speeds and feeds.

HART'S "BUCKEYE" DIE-STOCK.

The accompanying line-cut, Fig. 1, and the half-tones, Figs. 2 and 3, illustrate an interesting die-stock for threading pipe, manufactured by the Hart Manufacturing Co., 10 Wood St., Cleveland, Ohio. The principal feature of this die stock is that the chasers which cut the tapered thread, and which are inserted into the die body, are not as wide as the length of the thread, but the mechanism permits the chasers to recede from the work as the thread progresses along the pipe, so that a full length thread is cut on the pipe by this means. This construction permits the use of chasers with comparatively nar-



which have been cut, and the die can be removed directly by pulling it outward without turning it backward over the threads. The dies can be instantly reset to the proper position for cutting the thread on another pipe of the same size by simply turning the cam plate back to the original position, no clamping of any kind being necessary.

A third feature wherein this die differs from the ordinary die-stocks for pipe threading is in the adjustment of the dies.

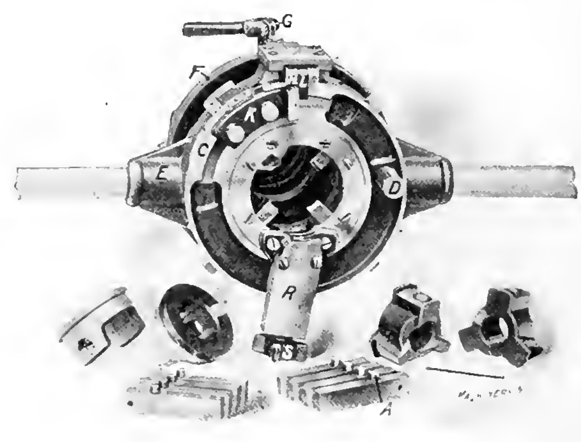


Fig. 2. Front View of the Buckeye Die-stock, showing Cam Plate, Adjusting Dog and Stop, and Cut-off Attachment.

A wide range of sizes may be cut with the same chasers by simply loosening a screw and setting a stop to the required graduation, the chasers thereby being pulled out or pushed in, by means of cam grooves, to the position required for cutting the corresponding sizes of pipe.

Instead of the leader screw ordinarily used in dies of this type, a so-called leader ring has been adopted, which, as will be presently explained, feeds the die inward over the pipe for the first revolution of the die-stock, thus causing the chasers to start the thread without any hand pressure or extra exertion. The same leader ring is employed for different pitches. Theoretically, of course, it might be claimed that the rise of the cam surface of the leader ring, which causes the feeding-in motion of the die, should be exactly the same as the pitch of the thread, so that a different leader ring would be required for each different number of threads per inch, but as this leader ring simply serves the purpose of starting the thread, the slight difference in rise between the cam surface on the leader ring and the pitch of the thread is of no practical consequence.

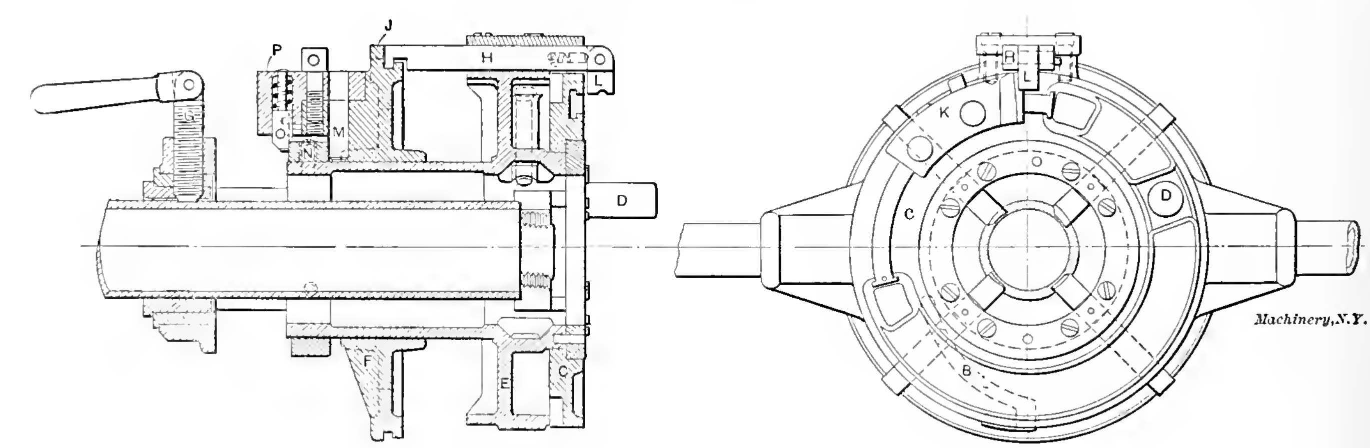

Fig. 1. Plan, Section and End View of Hart's Buckeye Pipe Die-stock.

row faces, and this, in turn, reduces the amount of power necessary for turning the die-stock, which is explained mostly by the reduction of friction between the chasers and the metal being cut, which is considerably less than the friction in the case of dies which have chasers of usual length of face, equal to the length of the taper thread required.

Another of the principal features of the die is that as soon as the full length of the tapered thread has been cut on the pipe, the chasers release automatically, and as soon as a slight turn by hand of the cam which controls the radial position of the chasers has been made, the chasers will clear the threads

A description of the design of the die will show how these various features are accomplished by the mechanism employed. In Fig. 2 is shown a full set of chasers. On the top surface of these chasers a small pin *A* will be noticed. The pin works in an eccentric groove *B* shown in the end view in Fig. 1, this groove being cut in the cam plate *C*. Thus, when this cam plate is turned, the cutting edges of the chasers evidently approach toward, or recede from, the center of the die. A handle *D* is provided for this cam plate, by means of which it can be turned by hand. It will also be seen from Fig. 1 that the die consists, in general, of a revolving part or body *E*, in

which the chasers are inserted, and a stationary part F, called the frame. The actual design of this frame is most clearly shown in Fig. 3. When wanting to thread the pipe, the body E is first placed in the correct position in relation to the frame F, by turning it so that the bar H comes exactly opposite to the indicating boss J on the frame. The body E is also pulled forward out of the frame F as far as possible. The dog K is now placed, and tightened to the cam plate C,

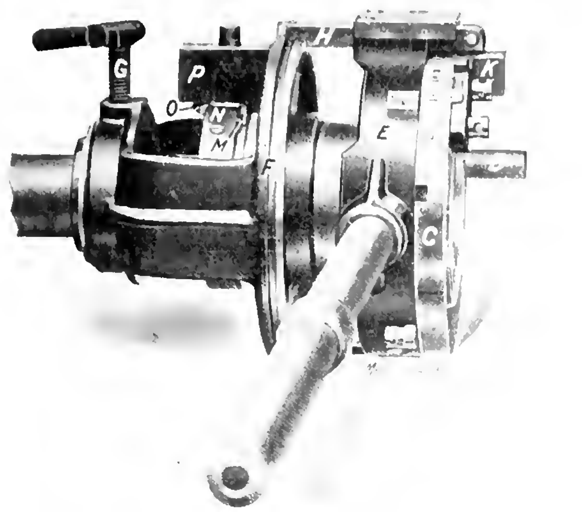

Fig. 3. Side View of Pipe Die-stock, showing Frame, Leader Ring and Graduations on Side of Cam Plate.

in such a position that the indicating mark on the dog coincides with that graduation on the cam plate which corresponds to the size of the pipe to be threaded. This is most clearly shown in Fig. 3. After having clamped the dog K as mentioned, the cam plate C is turned by means of handle D until the face of the dog K touches the side of the stop L. The chasers are now in the proper position to start cutting the size of pipe for which the dog K has been set. The die is placed on the pipe, the bar H being over the center of the pipe, and the pipe is permitted to enter into the die as far as possible, after which the binding screw G is clamped, thereby holding the frame F of the die firmly to the pipe.

The die body E, with the chasers, is now turned, as in ordinary threading. During the first turn the pin M, which is stationary, feeds the body E inward by acting against the cam surface of the leader ring N, which is held to body E by three set-screws. As soon as the die has been turned once, the chasers themselves have gripped the pipe enough to feed the die forward. As this forward motion proceeds, the body E progresses closer toward the frame F, and the bar H, which is held at one end in a groove in the frame F, is pushed forward out through the body E, the distance between the stop L and the face of the cam C, of course, then becoming greater. The face of the stop L and also of the dog K, where they bear against each other, is formed according to such a curve that the plate C will move slightly in a clock-wise direction as the stop moves outward, and by this motion the chasers are withdrawn the proper amount from the center of the die to form the correct taper of the thread. The pressure of the threading operation on the chasers is utilized for effecting the turning of the cam plate, so that the dog K always bears against the stop L. As soon as the thread is fully completed, the stop L slides completely by the dog K, thereby leaving it free to move any amount in a direction toward the right. The cam plate is then turned by the handle D a sufficient amount to the right to release the chasers completely from the thread, and the die is removed from the work by simply pulling it outward, there being no need of turning the die backward. In fact, it should not be attempted to turn the tool backward over the threads, as that might result in injury to the threads.

It will be noticed that a plunger O is located against one side of the leader ring N. This plunger simply serves the purpose of locating the leader ring N against the pin M, at the beginning of the cut. When the body E has almost completed one revolution, the plunger O mounts on an incline, on the rear edge of the leader ring N, and disengages this edge, thereby permitting the body E, with the leader ring, to progress independently of the frame F which holds the bracket in which the pins O and M are mounted. It will also be noted by examining the plan view of the die in Fig. 1 that, at the beginning of the cut, when the pin M is placed in relation to the leader ring N as shown, it is possible to turn the body E only in the right direction for the thread to be cut, the pin M bearing against a shoulder on the leader ring in the other direction, thus preventing turning the die-stock the wrong way.

When left-hand threads are cut, the plunger block P may simply be removed and the operation of threading proceeds in the same way as when cutting right-hand threads, excepting that hand pressure is required to force the chasers to grip the pipe. A left-hand leader ring N, however, is supplied with these dies if required.

Straight threads may be cut by not clamping the binding screw G, thus permitting the frame F to revolve freely on the pipe, together with the body E.

The die-stock is also equipped with a cutting-off attachment, as shown at R, Fig. 2. The cutting-off tool in this attachment is fed inward by the knob S, while the die-stock is turned around in the same way as when cutting threads. Back rests shaped in the same way as the chasers, but having blank end surfaces, support the die on the pipe during the cutting-off operation.

THE POTTER & JOHNSTON LONG TRAVEL CHUCKING MACHINE.

The use of cams in one form or another has been found to be the most practical method of controlling the movements of automatic turret machines of all kinds. There is no limit to the complexity of motion it is possible to obtain from them. The working parts may be advanced, stopped, withdrawn, and advanced again at any rate of speed and for any length of travel desired. Effecting these same movements by the use of the rack and pinion, or a screw and nut, operated by gearing and controlled by clutches, would be a matter requiring mechanism so complicated as to be impracticable.

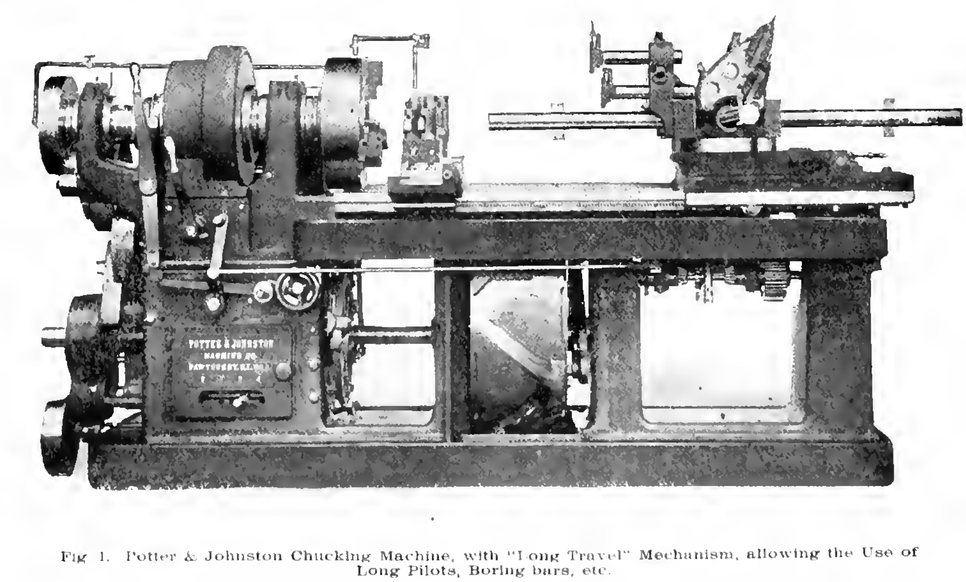

Fig. 1. Potter & Johnston Chucking Machine, with "Long Travel" Mechanism, allowing the Use of Long Pilots, Boring bars, etc.

There is one difficulty, however, with the use of cams for large machines, which is well shown in the case of the automatic chucking machine built by Potter & Johnston, Pawtucket, R. I. This difficulty is the great size of the cam required for movements on large machines. As may be seen by referring to Fig. 1 in the article describing

the operation of this machine (a few pages back in this same issue of MACHINERY), the turret cam drum is made of as large diameter as is possible, filling practically the whole space available between the turret slide and the floor. For the range of work for which the machine is intended, this gives sufficiently easy rises for the cam, and operates the mechanism very satisfactorily.

When it comes, however, to controlling the movements for operations requiring very long travel, the diameter of the

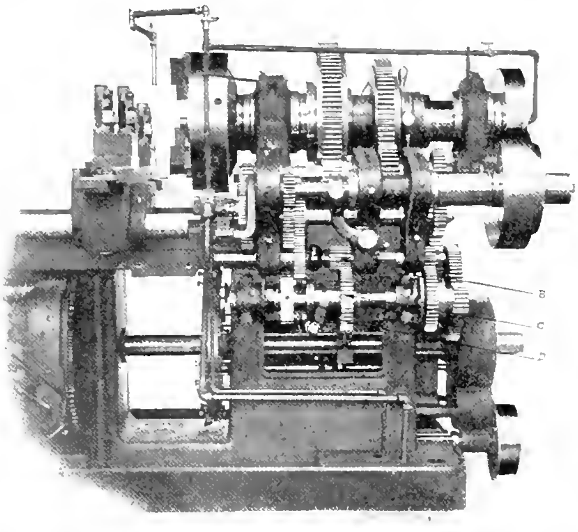

Fig. 2. Geared Connections for Effecting all the Idle Movements at Constant Speed.

drum would have to be so greatly increased to allow the use of the same easy rises for the cams, that it would be entirely impossible to incorporate it in the machine. This difficulty is especially met with in providing for the necessary movements for handling tools carrying pilot bars, which bear in a bushing in the nose of the spindle and are used to steady the tools under the pressure of the cut. These long bars require that the turret slide be moved back a long distance to enable them to clear the work for indexing. They then have to be brought up for a considerable distance again before the tools are ready to cut. This long travel it is impossible to effect by cams, as we have shown. The difficulty has, however, been overcome in another way by the builders, and they have succeeded in building a combination of rack and pinion, and cam operated mechanism which gives the flexibility of the cam mechanism, and the long travel of the rack and pinion device, without requiring the cam drum to be increased in diameter, or involving the complexity usually attendant on the use of the rack and pinion. The machine, as a whole, will not be described, the readers being referred to the article previously mentioned for a more complete treatment; only the difference between the "long travel" and the standard types of machine will be touched on.

The turret slide is under the influence of the cams for the feeding movements, and for returning the turret slide again to the point where the feeding movement commences. When it has been returned to this point, however, a clutch is automatically thrown in which starts the rotation of a pinion geared with the rack connected with the turret slide, so that the latter is rapidly drawn backward as far as may be required for clearing the work with pilot bars, such as those shown in place in Figs. 1 and 3. Here the turret slide stops, the indexing mechanism is thrown into action and the turret is revolved. When this has been accomplished the pinion is again rotated, but in the opposite direction, and by its action on the rack the turret slide is moved forward until the cam roll is again in position to be acted on by the cams for feeding.

This is repeated for each operation of the turret, the front portion of the travel of the slide being taken care of by cams, while the backward end of the movement is effected by the rack and pinion controlled by clutches and reversing movements. These two mechanisms are made so dependent on each other that they work together automatically without requiring any attention or adjustment on the part of the operator at any time, their relations being permanently fixed in the design of the machine. The long travel mechanism may, however, be thrown out of use by shifting to the proper position, a lever shown at the back of the machine in Fig. 3. The long travel mechanism is operated by the same shaft that controls the indexing. There is no limit to the length of bed which may be used with this device. It may be extended as far as necessary to clear the longest tools that the machine may ever be called on to use.

Another important change has been made in the design of this machine, as compared with the previous standard type of automatic chucking machine. In this machine the fast movement of the cam shaft has been arranged (as may be seen in Fig. 2, which shows the rear view of the tool with the guards removed) to be driven by the constant speed pulley, while the slow or fast feed movement is connected directly with the spindle, as before, so that the feed in turns per minute remains constant for a given combination of gearing, whatever the spindle speed. But by this arrangement the fast movements take place always at the highest practicable speed, whatever the spindle speeds may be. The same is true, of course, of the indexing and long travel movements, which are also connected with the constant speed pulley.

In Fig. 2, *B* is a loose double gear connected to the driving pulley, and running at constant speed, driving the gear *C*. When clutch *D* is thrown in by the action of the star-wheel which controls the feed mechanism, a fixed constant speed is transmitted to the drum operating gearing, which is thus moved rapidly, running ahead of the slow feeding motion.

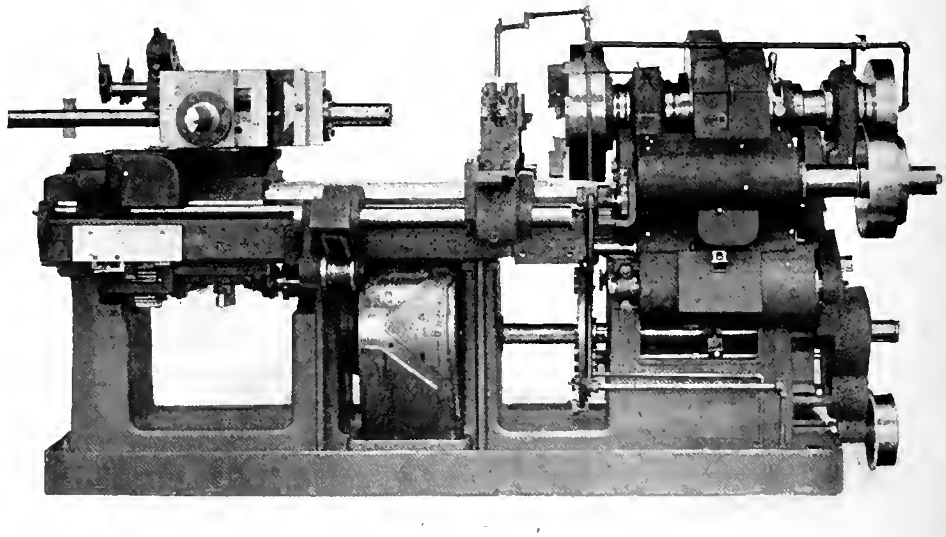

Fig. 3. Rear View of the "Long Travel" Automatic Chucking Machine.

This slow feeding motion again becomes operative as soon as clutch *D* is thrown out. As in the older style of machine, the feeding movement is driven by a belt running from the pulley at the rear end of the spindle to the feed pulley at the base of the machine.

A number of improvements have been made in the general design as well. The ways and slides have been made very wide and substantial throughout, and the turret and its supporting base have been enlarged. While the same principle has been maintained in the turret revolving mechanism of this machine, as in the standard design, a change has been made in the method of operation. When this slide reaches its extreme backward position, it stops for a few seconds while the turret revolves, so that all of the distance possible between the chuck and the end of the bar is gained.

None of the slide movements take place while the rotating is in action. The arrangement is such that with even heavy tools like those shown in Figs. 1 and 3 working on large diameters, the turret revolves very gently and comes to its position without any shock or jar.

The tool equipments shown in Figs. 1 and 3 are interesting, and may be studied in connection with the article on the setting up and operation of the machine. In Fig. 1, long boring bars with pilots entering the supporting bushing in the chuck, are used in combination with standard turning tools, bolted to the faces of the turret. In Fig. 3 one of the faces is provided with this combination of boring-bar and standard facing tool. The other two faces have boring-bars mounted on supplementary cross slides bolted to the table and actuated by the main cross slide. These are used for recessing, etc.

The advantages of this long travel mechanism will be easily understood. Without complicating at all the setting up of the machine (which is in itself a simple matter), it permits the use of tools provided with long pilot bars which, by the support they give to the cutting tools, allow heavier chips to be taken and produce work of very much greater accuracy. It will thus be seen that the arrangement is an important improvement of an already useful machine.

HAHN FLEXIBLE SHAFT.

The flexible shaft shown herewith is made by William Hahn, 220 Washington St., Chicago, Ill. In the sample illustrated, the shaft is covered with a thick braided cover and provided with end couplings of the kind generally used for dental work. It is made in larger sizes, however, for operating grinding

Hahn Flexible Shaft made of Coiled Piano Wire.

wheels, portable drills and other such tools where flexibility of drive is an important factor in the usefulness of the device. This shaft is built up of multiple coiled springs, both right-hand and left-hand, so that it may be run in either direction. These coils are formed of piano wire, and the device is thus as strong and durable as it is possible to make it.

ATTACHMENTS TO THE HAMILTON LATHES FOR TAPER TURNING AND RELIEVING.

Two new attachments of unusual interest have been recently designed by the Hamilton Machine Tool Co., of Hamilton, O., for its line of Hamilton lathes. The first one, shown in Fig. 1, is a taper turning attachment. This attachment is fastened to the carriage, and is always in position to use, the design being such that it can be added to a lathe which has been properly drilled and tapped to receive it, whenever the owner desires to purchase the device. As may be seen, the carriage has fastened to it a bracket, provided with a slide, which is connected by a rod with a clamping bracket, which latter may be fastened to the bed at any desired point. This slide carries a swiveling guide bar, which is adjusted to the degree of taper wanted by the adjusting screw shown, suitable graduations being furnished to facilitate the setting. This swivel slide bar carries, on dove-tailed ways, a sliding shoe, which is pivoted to a connecting bar, in which is journaled the rear end of the cross feed screw. The attachment is never disengaged. To change from straight

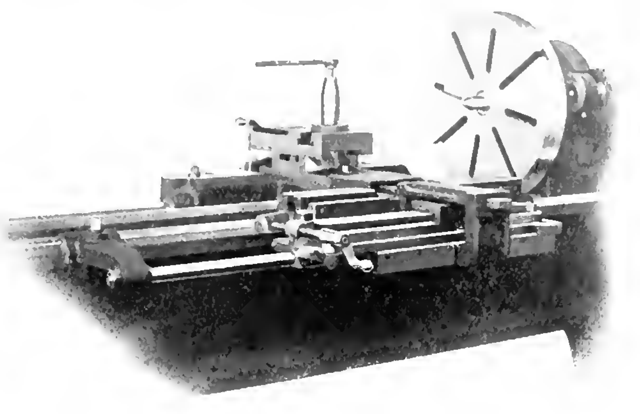

Fig. 1. Taper Attachment for Hamilton Lathes.

to taper work it is only necessary to tighten the bolt in the clamping bracket and set the guide bar to the desired taper, as shown by the graduated scale. To disconnect the taper attachment, the bolt in the clamping bracket is loosened. The tool-post wrench fits all the bolts used for adjusting the taper attachment.

The relieving attachment shown in Fig. 2 is used for backing off the teeth of milling cutters, taps, hobs, and similar tools. It is remarkably flexible in its applications, it being possible to use the attachments with the screw-cutting mechanism and the taper attachment, the relieving action taking place at any angle. This last feature, which is patented, is accomplished by having the reciprocating action necessary for the backing off, act through the center of the compound rest, so that it is effective at any angle through a full circle, not being limited by universal joints, etc., which are effective only through a limited angle. This makes the device universal in relieving formed end mills, counter-bores, etc., where the tool has to work at right angles to the cross slide movement.

The construction is quite simple, the cam being mounted on the carriage or compound rest, while the driving gearing,

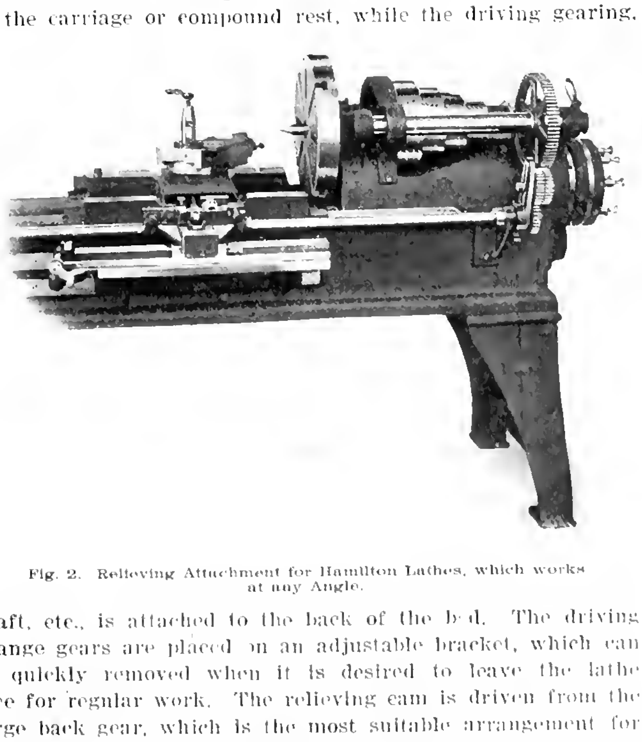

Fig. 2. Relieving Attachment for Hamilton Lathes, which works at any Angle.

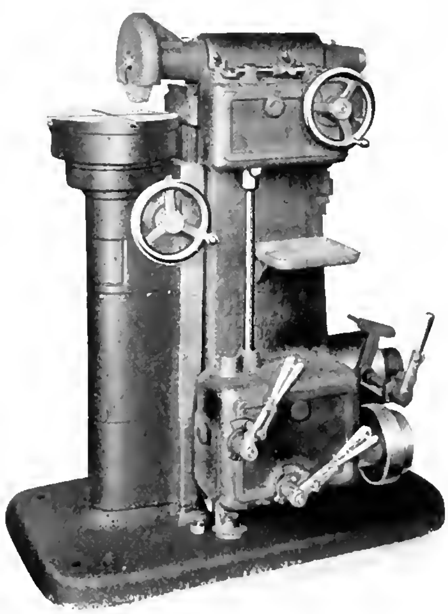
shaft, etc., is attached to the back of the bed. The driving change gears are placed on an adjustable bracket, which can be quickly removed when it is desired to leave the lathe free for regular work. The relieving cam is driven from the large back gear, which is the most suitable arrangement for such work, as it is thus possible to speed the relieving cam up at the proper rate in relation to the work, without strain-

ing any part of the mechanism. The back gears are, of course, naturally used in giving the slow movement required for relieving operations.

This attachment is furnished by the builders only for their 16-inch lathe, this being the size best adapted to general tool-room use. Change gears are provided for relieving cutters having from 2 to 24 teeth. Cams are regularly furnished, giving clearance of 1/32, 1/16 and 3/32 inch, respectively. Two styles of the device are furnished, in one of which provision is made only for the usual relieving movement at right angles to the axis of the lathe. The universal relieving attachment is the same as the plain, with the addition of the necessary parts to provide for relieving at any angle at which the compound rest may be set. These attachments must be ordered at the same time as the lathe they are used on, as a special carriage and tool rest has to be used.

IMPROVED SAXON RING GRINDER.

The accompanying half-tone illustrates a new ring grinder, which has been brought out by the Saxon Machine Co., Holyoke, Mass. The design of this grinder is very simple, and it



Improved Ring Grinding Machine made by the Saxon Machine Co.

can be operated easily by inexperienced help. Care has been taken to place all handles and dogs for adjusting the grinder, on the side nearest to the operator. The machine is driven directly from the main line, a special counter-shaft not being necessary. An important feature in the machine is its weight and stiffness, special attention having been paid to the matter of rigidity, when designing this machine.

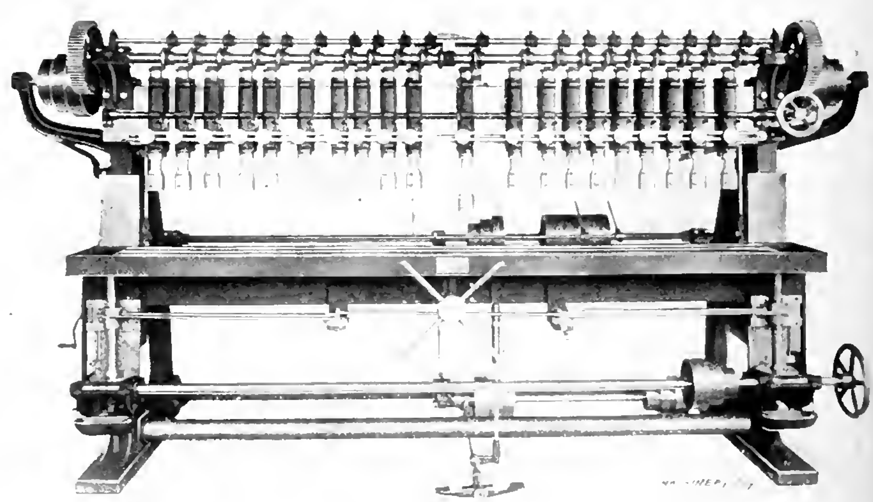
The work-holding chuck is attached to a vertical spindle, driven from the lower gear box. This gear box gives 8 different speeds for work of varying diameters. A magnetic chuck is regularly fitted to each machine, as this affords the quickest way of fastening the work for grinding and eliminates the liability of springing the work, which is always present in greater or less degree when the work is clamped by mechanical means. The magnetic chucks are furnished in three different sizes, having 8⅝, 10⅝, and 12⅜ inches diameter. A direct current of either 110 or 220 volts may be employed for supplying electricity to the chuck, and connection can be made directly to a lamp socket. In cases where direct current is not available, the makers of the grinder furnish a small generator which can be placed in any convenient place around the shop, and wires brought to the grinder. The amount of current required by the chuck when in operation is no more than that required by an ordinary incandescent lamp A plain chuck is furnished for brass, copper, hard rubber and other materials, which cannot be held by magnetism, or for use in cases when the magnetic chuck is not wanted. This plain chuck is furnished with three or four jaws as required.

The wheel-carrying head may be adjusted in such a manner that the work may be ground thicker or thinner at the center than at the circumference. The necessity for such adjustment, as is well known, is present when it is required to grind slitting saws and plain cutters, having no teeth on the sides, but intended for cutting slots or grooves in the work. This head is provided with three speeds. The feed is automatic, but can be operated by hand when necessary. The spindle carrying the grinding wheel is provided with adjustable bushing bearings, thoroughly protected by caps from dust. The use of bearings of this kind permits the best means for taking up the wear. The height of the center of the spindle from the floor line is 46 inches. The greatest distance from the center of the wheel to the chuck is 12 inches, and the size of the grinding wheel is 8 inches diameter by ¾ inch width of face. The speed of the driving shaft is 450 R. P. M. The floor space required for the machine is 26 x 45 inches, and the net weight about 1,300 pounds.

ANDREW IMPROVED MULTIPLE DRILLING MACHINE.

In the November, 1907, issue of MACHINERY, a multiple drilling machine intended for heavy duty, built by M. L. Andrew & Co., 2852-2854 Spring Grove Avenue, Cincinnati, Ohio, was described and illustrated. The accompanying half-tone shows an important improvement introduced on these machines for the purpose of rapid and accurate adjustment of the position of the spindles along the cross rail. This adjustment is accomplished by turning the hand-wheel at the right-hand side of the machine, from which the long adjusting screw receives its motion. Each of the spindle-carrying heads is provided with independent means for connecting them with this screw, they being engaged and disengaged by suitable handles. A slotted bar runs in front of the machine, as shown, and the various heads, when adjusted, are clamped to this bar by knurled nuts. Two men are, of course, necessary to carry out the adjustment, one turning the hand-wheel and with it the adjusting screw, while the other operates the handles, engaging and disengaging each head with the screw until the proper position for each spindle has been obtained. This feature is distinctly new, and will prove a great convenience in adjusting the spindles.

As in the previous machines of this line, the feed movement is effected by raising and lowering the table. Feed screws are provided at each end of the table, engaging half nuts which can be thrown in or out of mesh at any time by



Andrew 20-spindle Multiple Drilling Machine, with Improved Method of Adjusting the Spindle.

a lever conveniently located for the operator. The table, being counterbalanced with adjustable weights, may be easily raised or lowered by operating the pilot wheel at the front. Each spindle has an independent vertical adjustment of 4 inches, to make allowance for the various thicknesses of work

and various lengths of drills. The spindle driving gears are made of high carbon steel, accurately cut so as to be nearly noiseless in operation. The main driving gears are driven by rawhide pinions, keyed to the cone pulleys. The table has sufficient feed and the drive is sufficiently powerful to drill twenty ⅞-inch holes in steel, 8 inches deep, at one time. Larger or smaller machines of this description can be furnished, according to the capacity required.

CHICAGO BORING TOOL HOLDER.

The Krieger Tool & Mfg. Co., of Grand Rapids, Wis. (main office 479 North Park St., Chicago), is making the boring tool holder shown in Figs. 1 and 2. As may be seen, this holder is adapted to a wide range of sizes of boring tool shanks, owing to the peculiar construction of the clamp, which is made

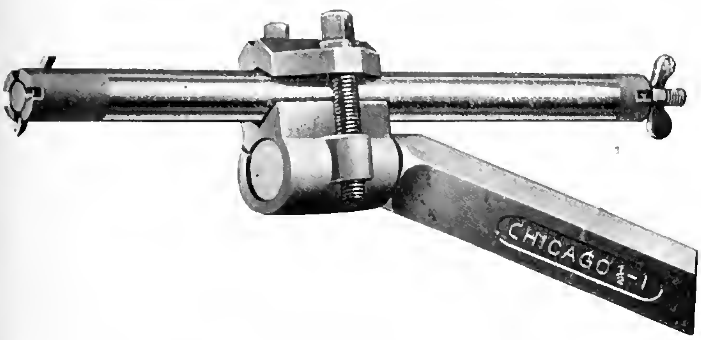


Fig. 1. Chicago Boring Tool Holder with Boring-bar in Place.

with a large V on one side for tools such as shown in Fig. 1, and a smaller V on the other, so that it will hold very small diameters when reversed, as shown in Fig. 2. The full range of diameters is for shanks from ⅛ up to ¾ inch, no blocking being required.

In Fig. 1 a boring-bar is used with an inserted tool. Boring tools of different sizes, such as shown in use in Fig. 2, will also be provided as a part of the outfit. The head can be swiveled about a pivot on the shank, so as to bring the tool

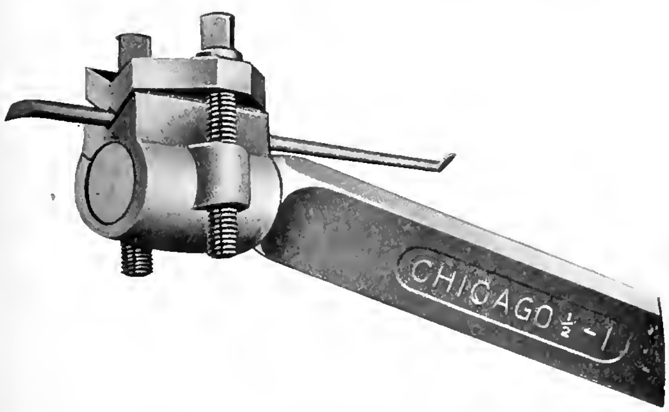

Fig. 2. Holder in Use with Forged Boring Tool of Small Diameter.

to the desired height to center with the axis of the lathe. The boring tools, and blades for the boring-bar, can be furnished in high speed steel or carbon. The steel holding parts are drop forged and case-hardened. The tool may be used for holding inside and outside test indicators, as well as for boring.

IMPROVED MELVIN ADJUSTABLE BORING HEAD.

We have previously described the boring heads made by Melvin & Hamaker, of Meadville, Pa. (see New Machinery and Tools in the November, 1907, issue of MACHINERY). The boring head shown in the cut, made by the same builders, is of larger size than the one previously shown, and includes some new improvements in design. The front collar or clamping ring is provided with graduations, which enable the operator to get the required changes without measurement. An intermediate is provided, having rubber rings, which maintain the pressure on the cutters even when the front collar is loosened. This serves two purposes: First, it prevents the cutters from falling out, or loosening so as to allow chips to accumulate between the cutters and their seats; and second, it allows the operator to make adjustments without the liability of disturbing the seating of the cutters in the grooves which hold them. The blades, as was explained in the previous description, are formed from steel having an equilateral triangular section, and are seated in grooves

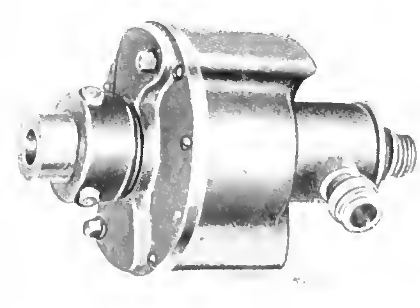
Adjustable Shell Type Boring Head, made by Melvin & Hamaker.

of corresponding shape in the body of the tool, which present them to the work at the required cutting angle. When one cutting edge is dull, the blade may be turned in its seat, presenting a new one. By doing this, six new cutting edges may be obtained in succession. When the point of the tool is rounded to give a smooth finishing cut, four cutting edges are provided for.

These shell type heads are made in all sizes, from 5 inches to 18 inches in diameter. They have an adjustment of from ⅝ to 1 inch in diameter, depending on the size, this adjustment not being provided for on sizes less than six inches.

COFFIELD WATER MOTOR.

The engraving shown herewith illustrates a water motor of the positive piston type, invented by Mr. P. T. Coffield, of Dayton, Ohio, and sold by the Patterson Tool and Supply Co. of the same city. This differs from the ordinary water motor in the fact that the direct pressure of the fluid is utilized on a steel piston, instead of employing the kinetic energy of the fluid, impinging against the floats of a rotating wheel. Numerous advantages result from this arrangement. It is stated that higher power is developed than with jet motors with the same water consumption. The device may be operated at slow speed or at high, often making reduction gearing or countershaft unnecessary. Another important feature is the fact that the exhaust of the water from the motor does not have to be so arranged as to preclude the possibility of back pressure. On the contrary, the exhaust can be piped away for any desired distance, and used for any purpose desired, the back pressure merely serving to reduce somewhat the power instead of entirely stopping the action of the device as in the case of the jet machine.



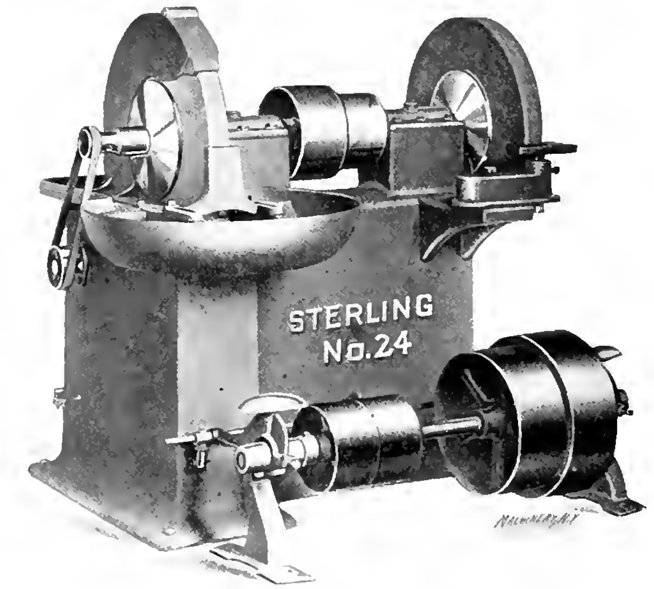
A Positive Piston-action Water Motor.

The motor is simple in construction, having only two valves and a piston. These parts are leather-packed in such a manner that leakage is reduced to a minimum. The machine shown, running at a speed of 100 revolutions per minute, developed 1/10 of a horse-power, with a consumption of water of

1 1/3 gallon per minute—at what pressure the report does not state. An efficiency of 100 per cent would require a pressure of about 110 pounds per square inch, under the conditions given.

STERLING COMBINATION WET AND DRY GRINDER.

The grinder shown in the accompanying engraving has been designed by its builder, the Sterling Emery Wheel Mfg. Co., Tiffin, Ohio, to combine the advantages of the wet tool grinder and the grinder for general purposes in one machine, thus economizing floor space. The water bowl and hood are detachable. The tool grinding section has no pump, but is



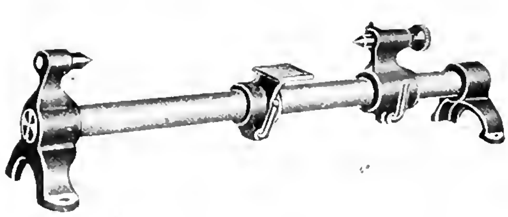
Sterling Combination Wet and Dry Grinder.

equipped with a revolving disk which throws a supply of water on the wheel when running. The tool grinding wheel is 24 inches in diameter by 3 inches wide; the dry wheel is of the same diameter, but 4 inches wide.

The weight of the machine, with the counter-shaft, is 1,800 pounds.

WELLS BENCH CENTERS.

The engraving we show herewith illustrates a new bench center built by the F. E. Wells & Son Co., of Greenfield, Mass. These bench centers are strong and inexpensive, and in many cases they take the place of the lathe in testing work to see if it runs true on the center. The tail-center is pressed outward by a coiled spring, so that it holds the work securely,

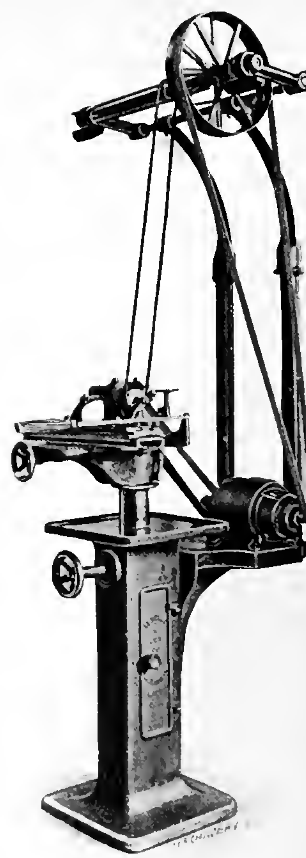


Inexpensive Bench Centers, taking the Place of the Lathe for Balancing Shafting, etc.

while still allowing it to revolve freely. This arrangement also permits the work to be inserted and removed quickly. This center may be adjusted along the bar to suit different lengths of work. A test indicator may be furnished in connection with this center-rest, if it is desired to show how much the work is running out at any point.

MOTOR DRIVE ARRANGEMENT FOR WELLS GRINDER.

F. E. Wells & Son Co., of Greenfield, Mass., has provided a motor drive on its cutter and reamer grinder, arranged as shown in the accompanying half-tone. As may be seen, the motor is mounted on a bracket, clamped to the rear of the column, and is directly belted to the emery wheel spindle. The work spindle, which is given a longitudinal movement in the operation of the machine, is driven from a drum on the overhead counter-shaft, which is supported from the motor bracket, and belted to the outer end of the armature shaft, as may be clearly seen from the engraving. An idler, which does not show in the cut, is provided, by means of which the work driving belt tension is kept the same, regardless of the adjustment of the cross slide on which the work belt is mounted.



Motor Drive with Self-contained Counter-shaft for Wells Grinder.

The motor is so placed that the table can be swung to present the work at any angle to the wheel, without interference with the belts or upright standards. The motor is encased in dust-proof covers, which keep the dust away from the armature and bearings. As may be seen, all the parts of the arrangement are self-contained, and neither the motor nor the counter-shaft has to be fastened to the wall. The plain cutter and reamer grinders are furnished in the same way, but since a revolving work spindle is not used for these, the counter-shaft is done away with, the spindle being driven directly from the armature shaft.

SPRINGFIELD MOTOR-DRIVEN BRASS FINISHERS' LATHE.

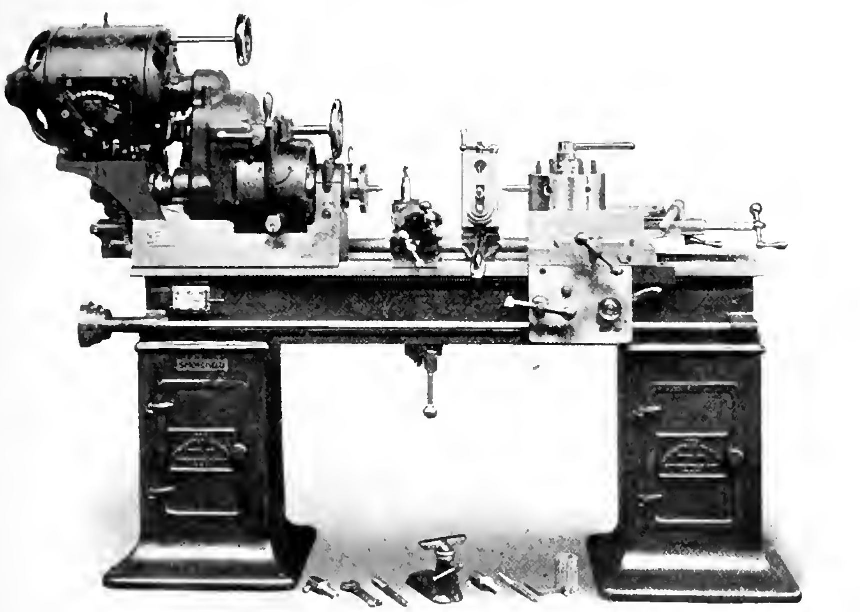
The half-tone engraving shown herewith illustrates quite clearly the motor drive mechanism provided by the Springfield Machine Tool Company, 633 Southern Avenue, Springfield, Ohio, for its brass finishing lathe.

The head-stock shown provides for four mechanical speed changes, and this, in combination with the Lincoln 6 to 1 variable speed motor with which the lathe is driven, gives the entire range of speed necessary for the work for which the machine is intended. The Lincoln motor (see description in the New Tools Department of the March, 1906, issue of MACHINERY) is provided with mechanism for shifting the armature and field longitudinally in relation to each other, so as to obtain a stronger or weaker field at the desire of the operator, thus diminishing or increasing the speed of the machine. This movement is effected by the hand-wheel shown projecting from the upper part of the motor casing. It is within convenient reach of the operator, who can thus make the changes with great ease. The starting box is placed at a convenient point, and releases automatically when the power is turned off. The motor is reversed in this case by a double throw switch on the bed at the head of the machine.

The head-stock, with its gearing, clutches, etc., is of neat and compact design, all the working parts being enclosed to protect them from injury and dust. Of the four mechanical changes of speed, two are obtained by the short lever seen just in back of the friction lever. This operates a sliding gear arrangement. Two more changes are obtained by the usual friction back gear mechanism, operated by the vertical lever. The clutches used for this friction back gear drive have been built by this firm for many years, and have given entire satisfaction. The lower hand-wheel shown just over the main spindle bearing is used for rotating the spindle for such minute adjustments as are required, for instance, in finishing a square thread, ending in a drilled hole. The journals throughout the head-stock mechanism are self-oiling, with large oil receptacles which seldom require refilling.

The turret is large and heavy, with bushed holes. It is provided with an ingenious indexing and locking mechanism operated by the handle shown at the top of the turret. The backward movement of the handle withdraws the locking pin, a forward movement rotates the turret into a new position, when the locking pin drops back into place locating the turret, and then the returning of the handle to its first position clamps the turret firmly to the carriage. Both screw and lever feed are provided for by the slide, the screw feed being used where fine adjustments are required. As is usual in brass finishing lathes, the turret is mounted on a cross slide. The cross slide is centered on the carriage by means of a taper pin, which insures absolute alignment. A taper attachment is also provided, of which the taper bar is contained in the center of the bed. It may be adjusted to any required taper up to 4 inches per foot. The slide on the bar is gibbed to take up all wear. All the ways of the turret, cross slides and carriage are fitted with taper gibs throughout.

The apron is provided with a power feed, driven by a three-



Springfield Brass Finishing Lathe, as arranged to be driven by Lincoln Variable Speed Motor.

step cone. The feed is reversed by the lever at the side of the apron, and is engaged by a friction clutch. When the power feed is not in use, the carriage may be clamped to the bed by means of the rigid clamping device shown at the right of the apron.

The chasing bar is of very heavy construction, supported by large, stiff brackets. The different pitches are obtained by using different threaded leaders and followers in the usual fashion. Provision is made in this machine for cutting either right- or left-hand threads without changing any gears. A handle at the end of the bed operates tumbler gearing, which reverses the direction of the rotation of the leader; this provision makes left-handed leaders and followers unnecessary. Taper threads may be chased with this tool by tilting the slide on which the forward part of the chasing bar rests, when it is in working position. A heavy spring keeps the follower in contact with the leader, thus assuring uniformity of lead to the thread being cut.

* * *

Few people realize what a tremendous industry the moving picture industry has become in a few years. One of the French companies, manufacturing the films for moving picture machines has a capital of $900,000, and in 1906, according to an item in *Industritidningen Norden*, the net profit from this investment amounted to fully one million dollars. In 1907 the sales were nearly twice the sales in 1906. It is stated that the company sells about 19 miles of films a day, and that they keep continually in stock 30 tons of films, representing a value of $1,400,000. It is also stated that all the moving picture enterprises in Paris represent a capital of over $20,000,000, and that there are fully as many English and American firms in this industry as there are French.

AN AMERICAN MECHANIC IN EUROPE—1.

THE FIRST OF A SERIES OF LETTERS FROM OSKAR KYLIN* ON THE EDITORIAL STAFF OF MACHINERY.

Berlin, March 14, 1908.

The industrial depression which last fall started in New York and with that as a center spread over Europe, seems to have affected the machine tool market here to quite a large extent. Machinery dealers report business very dull throughout the country, the machines that they ordered from American manufacturers six months or more ago are now coming in, and as the demand is small at the present time, they are obliged to store them. The depression is most evident in the line of large machine tools. Smaller machine tools for every day uses are in fair demand, and in small tools, business is still better. Schuchardt & Schutte report a falling off of about 50 per cent of last year's business in all kinds of machine tools and small tools.

The machine tool manufacturers here do not seem as yet to feel the depression in any marked degree. They are generally running their shops with nearly full force, and do not complain about any hard times. Ludwig Loewe & Co. reported a fair amount of business on hand, working with very nearly full force. A small manufacturer here that six months ago employed 125 workmen has now reduced his force to about 90 men, but he stated that business was unusually good then, is satisfied with present conditions, and is optimistic about the future. This marked difference between the reports of dealers and manufacturers probably results from the fact that manufacturers are still working on orders received six months or more ago.

Copying American Tools.

I have carefully investigated the copying of American machine tools abroad, and the German manufacturers no longer seem to make any secret of this practice. They openly confess that they do copy American machines, or rather that they imitate them and adapt them to the different requirements that exist in the German shops. Outright copying does not seem to be so common as imitation or rather adaptation.

There seems to be some difference between the structure of the German cast iron and the American, and the small tools designed to suit American conditions and material cannot be used with equal advantage here, as they are too light and do not wear well. The German manufacturers have studied their material and tools, and the consequence is that today a different line of tools is used here from those in America. It is a common complaint that most American manufacturers who are selling machines here do not pay enough attention to this point, and that the American machines are not made to take the German tools. The feeling is that if American manufacturers want to sell machines here they should study the German needs and adapt the machines to meet them; and since this is not being done, the German manufacturers will naturally adapt the latest and best American tools to their own requirements, retaining the new features when they conform to German needs and changing them when they do not. American manufacturers, by neglecting to study the needs here are to a certain extent responsible for present conditions; and it must not be forgotten that this does not apply to the trade in Germany alone, but to all the territory where German tools are sold, which includes all Europe and Asia. Whether justly or not the dealers here continue under the impression that during the past boom American manufacturers did not treat their foreign customers fairly, neglecting them in favor of domestic orders.

* Oskar Kylin is a young American draftsman who is making a trip through Europe for MACHINERY, and recording his impressions of foreign methods and works from the standpoint of a practical mechanic. In addition to having a thorough knowledge of American shop practice, Mr. Kylin speaks several languages fluently.

and for this reason have lost ground on the foreign market, a condition which German manufacturers have been quick to profit by.

An Interesting Interview.

An interview with Mr. C. H. Johnson, who has represented the Gisholt Machine Co. on the Continent for a number of years, is given below, as it is fairly typical of opinions here, and taken from an intelligent standpoint, as Mr. Johnson is an American. "Write the American machine tool manufacturers that more of them should begin to study the needs and conditions here, which are not the same as they are over in America. They build machines there to suit American conditions and American material, and don't think or care about the conditions or material here. Then they send their machines over and want us poor devils to sell them. There are some American concerns that know how to handle European trade, but they are very few. America mustn't think that Europe is in its mechanical baby clothes any longer, or conditions are any longer such that when the American business managers come over, buyers here salute them with 'How d' you do? Glad to see you! I am just ready to buy your machines.' Things have changed. The Germans build pretty good machines themselves now, and the material is not the same here as in America. The cast iron, for instance, that we have here is very much harder or tougher, for the tools don't wear so well here and get dull much faster, so that we can't use the American tools. The tool question has been studied out in both countries, and now they do it one way in America and another way here. We cannot force the Germans to use our tools, and we must make our machines to suit their tools if we want their trade. There are some good American concerns that do so, but the large majority don't. The American business manager goes over to Europe to make a thorough study of the European trade conditions—makes a hurried call in Berlin, and then takes the fastest express for Paris, and that is where he studies 'trade conditions.' And now since the Americans won't make their machines to suit the German tools, the Germans must do it themselves. They simply have to; and you can take my word that they do it, too. The Germans are d— good copiers. They copy lots of American machines and adapt them to their own tools, and what can we do about it? Not a d— thing! They must use their own tools, and the American manufacturer won't make his machines to suit the German tools—so there you are. And it is not so very easy to sell a machine here as in America either. I sold a milling machine here the other day, and when it came, the customer picked up and took apart every piece—in order to clean it, he said, but really to examine it. He looked at every piece, and if he had found any defects he would have refused the machine. And suppose now that I want to sell a lathe. I have to sell it against the competition of a 25 to 50 per cent cheaper German one. If I say that my lathe is equal to two or three German lathes I must get down to figures and show the buyer why. My lathe won't do two or three times as much work as the other one, and therefore I have to figure on the floor space. Three lathes will occupy so much space and mine only so much, and this represents a saving of so much a year for you. I have to figure with power, transmission and everything. So you see that it is not so very easy to sell American machines here.

"And then there is another point. During prosperous times the American manufacturers have neglected their foreign trade. They acted as if they thought, 'We will attend to our home customers and let the devil take the foreigners; they can wait.' And if a German customer has been promised one month's delivery he has often had to wait six. Now everybody wants to sell, but it is pretty hard work to get back the trade for American machines again, and it is the American concerns that are principally responsible for it."

Shop Notes from Ludwig Loewe & Co.'s Shops.

In Ludwig Loewe & Co.'s Works there is a tendency to abandon the milling operation for finishing heavy castings, such as large bed-plates. They are going back to the old way of planing these castings, which they claim costs less, because the milling cutters wear too fast and are too expensive both as to first cost and maintenance. This may be on account of the difference in the wear on German cast iron.

An interesting experiment was tried in these works for forming a milling cutter that would cut a perfectly square thread in the ordinary thread milling machine. As generally known, the "square" thread cut in an ordinarily equipped thread milling machine, although close enough for most ordinary purposes, is not perfectly square but somewhat wedge-shaped. An ordinary Pratt & Whitney thread milling machine was used, a square thread screw, cut in a lathe, being placed in position the same as for milling a thread. In the place of the cutter an antimony disk was mounted on the cutter spindle. The screw was revolved and the antimony "cutter" pressed against it and caused to revolve with it. By this action the disk was formed to the right shape. A steel cutter was made to the shape thus produced, but as it did not work well, the experiment was carried on to find another shape that would cut more satisfactorily. The experiment was made on account of an inquiry from the German government.

[The experiments, if conducted as described, seem quite unprofitable. No one-piece rotary cutter of appreciable diameter can be formed which will not interfere with the overhang of a square thread.—Editor.]

MISCELLANEOUS FOREIGN NOTES.

Projected Russian Steel Trust.—It is stated by *Engineering* that a Russian steel trust is about to be formed and that the promoters of the scheme desire to create a concern along the same lines as the United States Steel Corporation. The present unions between steel makers and the trade agreements are understood to have proved unsatisfactory and inefficient, but definite action has not, as yet, been taken.

Profits in German Machine Tool Trade.—A number of the principal German machinery manufacturing concerns have issued their financial statements for the last accounting year, and it is plainly in evidence that up to the present time the business has financially been an exceedingly good one. Thus, some of the large companies report net profits from $200,000 up to $800,000, and the paying of dividends varying from 12 per cent to 20 per cent as against from 8 per cent to 16 per cent in the previous year. It is now stated that the prospects for the German machinery trade, while not as bright as they have been, are still fully satisfactory.

Messrs. A. A. Jones, Pollard, and Shipman, Ltd., Leicester, England, have placed a new design of high speed drilling and tapping machine on the market. This machine is of stiffer construction than usual, and is particularly intended for using high speed drills up to their full capacity. The machine will drill one inch holes in mild steel at a rate of three inches per minute. The machine is back-geared and the main drive is by a three-inch belt. Instead of the common feed lever, a hand-wheel is employed. The drill spindle is bored to take No. 3 Morse taper shank. It has a vertical travel of 10 inches. The table is 17 inches in diameter. The maximum distance between the drill spindle and the table is 33 inches.

British Shipbuilding Trade.—We have previously referred to the fact that the British shipbuilding concerns were not fully satisfied with the prospects in their trade. Present orders, it is stated, are practically confined to high-class steamers, and for these there is a very keen competition. Of course, the building of large vessels in the last few years has been carried to such an extent that naturally the number necessary for the immediate demands of the trade is filled for the present. The probable state of affairs is that the activities of the past few years have been abnormally high, and that business now recedes temporarily only to enter on thoroughly healthy and normal conditions.

Steel Industries in Europe.—It appears that while the steel industry in certain of the European countries is rather depressed, there is still considerable activity in the development of new plants. A large iron works is under construction in Italy near Naples, for which six blast furnaces and large rolling mills will be erected. From France a depression is reported, although not as accentuated as elsewhere. The exports of iron and steel in that country still show an increase over the exports for the corresponding months last year. In

Germany the steel syndicate has decided to make no change in prices, and it is reported that the export trade shows signs of improvement. To a great extent the works are now kept busy with materials for the German Government railroads.

German Competitive Restriction.—Consul General Richard Guenther mentions in a consular report the following incident, illustrating the restrictive law in Germany covering unfair competition. An Austrian merchant was recently convicted in the criminal court at Konstanz, Germany, of having violated the law against illicit competition. He was sentenced to imprisonment for three months. This foreign merchant, who intended to establish in Austria a factory for preserving vegetables, had come to Singen and approached the employe of a similar factory there, trying to induce him to reveal the business methods, technical appliances, and manner of production in vogue in the establishment; also where the supplies in raw materials were obtained and the names of the customers of the factory. He offered money gratuities to the employe, who was a sort of foreman, and promised him a better-paying position in his factory in Austria. Some of our American manufacturers, says the Consul, are very enterprising and occasionally—when in Europe—seek to obtain information by personal efforts. The case cited may be useful in cautioning personal investigators to be very circumspect, so as not to violate existing laws in foreign countries.

Sales of Machinery in Italy.—According to the *London Commercial Intelligence*, protection as to payment for machinery sold to Italian firms may, according to Italian commercial law, be secured, if the sale, within three months from date of invoice, is registered at the chancery of the civil and penal tribunal of the city where the machinery is to be installed. This registration offers protection for the final payment of machinery. In order to secure this privilege of protection, it is necessary for the seller to send in an application addressed to the "Regia Cancelleria del Tribunale Civile e Penale, Sezione Commerciale" of the city or town where the machinery is delivered, stating details regarding price, terms of payment, etc. This application is made out in duplicate on Italian stamped paper, one copy being returned by the tribunal after registration. The expense for the stamped paper is about 70 cents. The application should also be accompanied by the contract for the sale of the machinery, or by a copy of the invoice. The copies must be stamped and registered with the Italian government at a representative office (undoubtedly the Italian Consular office would in the United States be the proper place). An amount sufficient to cover postage for the return of the duplicate application should be enclosed.

* * *

ANGLES OF HOPPER SIDE INTERSECTIONS.

The perplexing problem of finding the angle of intersection between the various inclined planes in a rectangular hopper has been previously dealt with in the columns of Machinery, in the "How and Why" section of the May, 1907, issue and in the "Letters Upon Practical Subjects" section in the August, 1907, issue. In these articles general formulas were given, which, however, are more or less complicated and require considerable time in applying to each separate case. In the current Data Sheet Supplement, accompanying the engineering edition, diagrams are therefore presented which permit the required angle of intersection to be read off at a glance, when the inclinations of the side planes of the hopper are known.

In sheet metal work of this character it is common to express the magnitude of angles by giving the inclination in inches per foot; in inches rather than by expressing the angles in degrees. This practice has been adhered to in arranging the diagrams given. The curves, however, have been plotted from the formula

$$\text{Cos}\, F = -\cos x \cos y,$$

in which the various angles are expressed in degrees, and where F = the angle of intersection between the sides of the hopper (commonly called the angle of flare), x = the angle which one of the hopper sides makes with a plane parallel to the bottom of the hopper (or with a horizontal plane), and y = the angle which the other hopper side makes with the same plane. Upon examination it will be found that the formula given above is identical with the one given in the article in the August issue, already referred to. This formula in that issue, however, was given the form

$$\cos EBF = \sin \alpha \sin \beta,$$

where angle EBF = the angle of flare, and α and β, the angles made by the hopper sides with a vertical plane passed down the hopper at right angles to the plane in relation to which angles x and y are measured. The angles α and β thus are the complements of angles x and y, and consequently

$$\sin \alpha \sin \beta = \cos x \cos y,$$

from which it is clear that the two formulas referred to are identical.

* * *

PERSONAL.

Charles C. Tyler, lately of the Allis-Chalmers Co., has been appointed works manager of the Remington Arms Co., Ilion, N. Y.

George A. Seib, formerly superintendent of the Monarch Typewriter Factory, Syracuse, N. Y., has been appointed superintendent of the Remington Typewriter Co.'s factory, Ilion, N. Y.

J. L. Cone, for several years foreman of the carriage assembling department of the Remington Typewriter Co., Ilion, N. Y., has been appointed assistant superintendent of the machine assembling department.

David Hunt, Jr., general sales manager of the Warner & Swasey Co., Cleveland, Ohio, sailed February 29 for a three months' trip abroad. He will visit England and the Continent.

John Montgomery formerly foreman of the screw department has been appointed assistant superintendent of the machine tool and equipment departments of the Remington Typewriter Co., Ilion, N. Y.

T. D. W. Moore, for three years general manager of the Remington Arms Co., Ilion, N. Y., has accepted the position of general manager of the Savage Arms Co.'s plant at Utica, N. Y. Mr. W. J. Greene retires as general manager of the Savage Arms Co., but still continues as vice-president.

R. S. Stangland has been placed in charge of Muralt & Co.'s construction office at New Fort Lyon, Colorado, and will superintend the erection of the complete lighting, heating and power plant which his firm is building for the United States government at the New Fort Lyon Naval Hospital.

Jerome Orcutt, who for several weeks has been acting as general manager and superintendent of the Remington Arms Company's plant, Ilion, N. Y., in connection with the management of the Union Metallic Cartridge Co.'s plant at Bridgeport, Conn., has returned to Bridgeport, and will confine himself to the management of the Union Metallic Cartridge Co.

W. O. Renkin, formerly of Valley Park, Mo., and an occasional contributor to Machinery, is now located at Chakradharpen, India, as resident engineer for Julian Kennedy, construction engineer, Pittsburg, Pa., for the erection of blast furnaces and steel works for the Tata Iron & Steel Co. Mr. Renkin expects to be in India at least three years.

The well-known inventor of the Schmidt superheater, Mr. Wilhelm Schmidt, of Kassel-Wilhelmshöhe, Germany, has been promoted to Honorary Dr. Engineer of the Technical Institution of Karlsruhe, "in appreciation of his services for making use of superheated steam in steam engines, particularly in locomotives, and for his initiative efforts in the construction of apparatus and superheaters for highly superheated steam."

Anton M. Olsen, an apprentice of Kempsmith Mfg. Co., Milwaukee, Wis., has the distinction of being the first apprentice west of New England to receive the diploma awarded by the National Machine Tool Builders' Association. Mr. Olsen signed the National Machine Tool Builders' uniform apprentice contract May 25, 1904, at the age of sixteen. The apprentice service required is 11,520 hours divided in four general annual periods of 2,880 hours each. Mr. Olsen completed this term in the early part of March, and received his diploma.

OBITUARY.

George P. Curtis, who for the past twelve years was connected with the city sales department of Charles H. Besly & Co., Chicago, died February 26.

John Burry, inventor of a stock ticker in common use in brokers' offices, hotels, clubs, etc., for recording stock market quotations, died at his home on Staten Island, March 12, of illuminating gas poisoning. Mr. Burry was born in Switzerland in 1861, and came to the United States at the age of nineteen. He had made many inventions and improvements of printing telegraph machines. The stock ticker, brought out in 1880, was the most successful.

George J. Meyer, treasurer of the National Tool Co., Cleveland, Ohio, died at his home, 2003 Holmden Ave., February 23, of consumption. Mr. Meyer was one of the incorporators of the National Tool Co., and held the position of treasurer from its incorporation until his death. He was previously employed by the Dyer Co., Cleveland, as a draftsman and machine designer, and thus was a practical machine designer as well as a business man. Mr. Meyer was highly regarded by his associates, and his untimely death leaves a place hard to fill. He left a widow and two children.

James H. Oliver, a well-known plow manufacturer of South Bend, Ind., died March 2. He was born in Roxburgh, Scotland, August 28, 1823, and came to the United States with his family when a lad of thirteen, settling near Geneva, N. Y. After working on a farm for a few years, he went to Indiana and became a mill worker, and after accumulating a small sum, began to make plows. The problem of making a cast iron plow that would scour in the black Western soils was what he set out to solve, and the Oliver chilled plow was the result. The demand increased so rapidly that in 1875 the present plant at South Bend was built, covering thirty-two acres and employing 5,000 men.

NEW BOOKS AND PAMPHLETS.

Proceedings of the Seventeenth Annual Convention of the Association of Railway Superintendents of Bridges and Buildings, held in Milwaukee, Wis., October 15-17, 1907. 344 pages, 6x9 inches. S. F. Patterson, secretary Boston & Maine Railroad, Concord, N. H.

Columbia University Quarterly. December, 1907. 141 pages, 7x10 inches. Published by Columbia University, New York.

This issue of the *Columbia University Quarterly* is devoted to the Columbia Schools of Mines, Engineering and Chemistry, and will be found of general interest to those contemplating courses in these well-known institutions.

The Weathering of Coal. By S. W. Parr and N. R. Hamilton. 37 pages, 6x9 inches. Published by the University of Illinois, Urbana, Ill., for general distribution.

The bulletin relates to the weathering of coal and losses in fuel values which result from storage. That coal deteriorates in storage is generally known, but the data available have been meager. The results of tests outlined give specific information that should be valuable to manufacturers, power plants, and others using large quantities of fuel.

Effect of Brake Beam Hanging on Brake Efficiency. By R. A. Parke. 63 pages, 6 x 9 inches. Published by the Westinghouse Air Brake Co., Pittsburg, Pa.

This publication is a reprint of a paper presented by Mr. Parke before the New York Railroad Club, April 18, 1897. It is a clear and comprehensive analytical discussion of the complicated conditions involved in the design of car brake systems of maximum efficiency, and in a way has become a classic that is often referred to for analysis of the complicated forces entering into car braking and brake action. Those familiar with the paper will be pleased to note that it has now been put in shape for general circulation, and it can be recommended to those interested in the design and mathematical analysis of railway car brakes.

Locomotive Catechism. By Robert Grimshaw. 817 pages, 5x7 inches. Published by Norman W. Henley & Son, 132 Nassau Street, New York. Price, $2.50.

This work, first published in 1893, has had a large sale, the present edition being the 27th. It has been entirely revised, enlarged and reset, and contains over 3,000 questions and answers. It is, in fact, a practical treatise on locomotive construction in detail and a treatise on locomotive operation as well. The catechism style enables a great deal of information to be given in short, concise paragraphs, and is well suited to the needs of men who are not used to reading technical books. The work is one, also that can be read with profit by any one who desires to obtain general information on locomotive construction and operation. The illustrations are well made, the paper is of good quality, the binding is flexible, and the corners are rounded, which adapt the book to carrying in the pocket, although its size is somewhat too great to make it a comfortable pocketbook.

Reference Book for Statical Calculations. Vol. I. By Francis Ruff. 136 pages, 5x7½ inches. Published by Spon & Chamberlain, New York. Price 5d.

This book was first published in German and to meet the wants of English engineers has been translated into English. The work presents the application of grapho-statics to the constructions most frequently met in engineering work. It contains tables of moments of inertia and resistance to bending on cross sections most in use, and transverse forces and moments of applications for simple beams subjected to concentrated loads and distributed loads. Bridge trusses, strut frames, roof construction, cantilevers, open web girders are analyzed graphically; also curved beams with three joints, suspension bridges, frame work columns, earth pressure, sustaining walls, vaults with abutments, concrete constructions. The work will be found useful by all who have occasion to analyze the forces in engineering structures. The tables are conveniently arranged and data not usually found in engineering handbooks are included.

Engineering Reminiscences. By Chas. T. Porter. 335 pages, 6x9 inches. Illustrated with portraits of many prominent engineers. Published by John Wiley & Sons, New York. Price, $3.00.

This work first appeared as a series in *Power* and the *American Machinist*. Mr. Porter was the originator of the high-speed engine, and has had a most interesting career. His writings have a charm and interest rarely exceeded by any. The book is a contribution to engineering literature of much historical value, and it is a matter for general congratulation that the memoirs of a man who has done so much for engineering should be put into a book for general circulation. Electrical engineering owes much to the Porter-Allen engine, as incandescent lighting would have been impracticable with the old slow-moving, irregular-acting steam engines in use prior to Mr. Porter's development. So in a sense it may be said that Mr. Porter is very largely responsible for the enormous development of electrical engineering that has taken place since the first high-speed engine was constructed.

The Gas Engine. By Frederick R. Hutton. 562 pages, 6 x 9 inches. 243 illustrations. Published by John Wiley & Sons. Price $5.00.

The first edition of Prof. Hutton's work on the gas engine was published in 1903. The present edition is the third, revised and brought up to date. The development of the internal combustion motor and the importance that it has acquired since the introduction of the automobile makes the study of the gas engine and gas fuels of the greatest commercial importance. The new edition has been revised with this fact in view and special attention is called to the reference table on gaseous fuels now included. Some attention is given to alcohol motors, but the treatment of the design of engine parts included in previous editions has been intentionally omitted, it being thought best not to include this, as it would make the work too large and costly. For design and construction details the author calls attention to the work "Gas Engine Design," by Prof. Charles E. Lucke, who is a colleague and co-worker in Columbia University. Prof. Hutton's work is generally considered to be the most comprehensive theoretical treatment of the gas engine published in America.

Gages and Gaging Systems. By Joseph V. Woodworth. 249 pages, 6 x 9 inches. 258 figure numbers. Published by the Hill Publishing Co., New York. Price, $2.00.

This book on gages and gaging systems is a compilation of articles published in the *American Machinist* and Machinery, contributed by the author and others. It treats of the fundamental practice, development and efficiency of gages and gage making with numerous illustrations of various forms of limit gages, indicators, thread testing gages, snap gages, star gages, caliper gages, etc. A chapter is devoted to tri-squares, knife edge squares, combination squares, straight-edges, sizing blocks and methods of making same. Special attention is given to calipering large work and the methods developed and employed by the Westinghouse Co. are partially described. Simple methods of testing the alignment of machine tools with the ordinary micrometer are illustrated. The Gronkvist or Swedish combination gage system is illustrated, this being a new system by which less than 100 gages are made to have about 80,000 combinations. The work is one that should be useful to tool-makers, gage-makers, machinists, etc.

Practical Steam and Hot Water Heating and Ventilation. By Alfred G. King. 402 pages, 6 x 9 inches. 302 illustrations. Published by Norman W. Henley & Son, 132 Nassau St., New York. Price, $3.00.

The work reviews modern methods of steam and hot water heating and ventilation, and describes the apparatuses. It treats of the nature of heat, and the evolution of artificial heating apparatus from the open fire-place to stoves, furnaces, steam boilers, and hot water systems. The work is comprehensive and useful. It gives rules for estimating, and tables of value to engineers, estimators and others having charge of the installation of heating systems. The work as a whole appears commendable and we see little in it to criticise adversely, except in one chapter given up to rules tables and general information. Some of the statements contained are puzzling, as for example: "Air expands one one hundred and seventy-ninth of its bulk." This of course means nothing at all without an explanatory statement. A typographical error makes the rule for finding the diameter of a circle when the circumference is given, to read "Divide the circumference by 4.14159," instead of 3.14159. The general arrangement of the work is good and with few exceptions the illustrations are first class. The tables are gotten up in exceptionally fine style.

Handbook for the Care and Operation of Naval Machinery. By H. C. Dinger. 302 pages, 4½x6 inches. Published by D. Van Nostrand Co., 23 Murray Street, New York. Price, $2.00.

The larger part of this series first appeared as a series in the *Journal of the American Society of Naval Engineers*, and has been reprinted in book form with modifications and numerous additions. It is a practical treatise on marine boilers and engines, fittings, auxiliaries, with instructions on the care and preservation of the ship's hull, water-tight compartments, etc. Following are some of the subjects treated which will give a general idea of the contents of the work: Getting under way; running engines under way; accidents under way; general rules for over-hauling machinery; cylinders, valves and valve gears; engine adjustments; lining up engines; friction, oiling and lubrication; condensers and pumps; joints and packing; stuffing boxes; lagging; feed and filter tanks; feed-water heaters; evaporators and distillers; heating system; refrigerating plant; steam steering gear; air compressors, blowers and boiler engines; ash hoists and ejectors, etc. The work is one that can be heartily recommended to any one desiring an elementary, yet comprehensive work on marine machinery. It is gotten up in durable shape and is of convenient size to carry in the pocket.

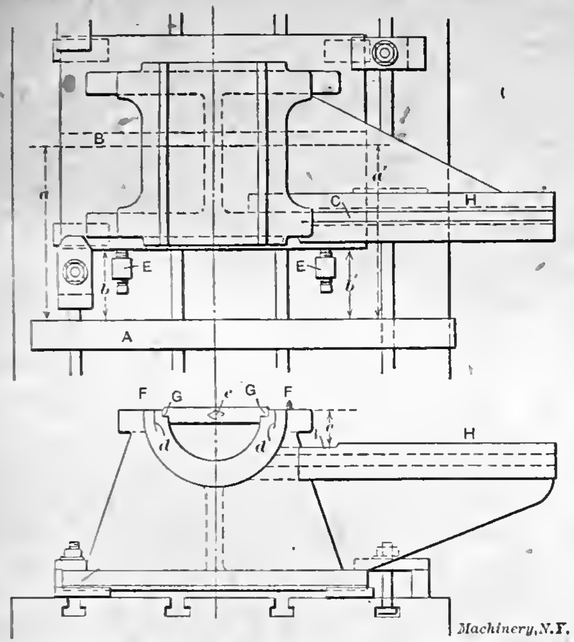
Writing for the Press. By Robert Luce. 302 pages, 5 x 7 inches. Published by the Clipping Bureau Press, Boston, Mass. Price $1.00.

This book, first published in 1886, now appears in the 5th edition. It is deservedly popular, and will be found of general value to all who write for publication or who indite business letters, or in any way express themselves in written language. The instructions to writers for the press are practical and concise and, with one exception, meet our general approval. The exception is in the directions for the preparation of copy containing illustrations. It states that the proof of any cut to be used in illustrating an article should be pasted as near as possible to the proper place in the copy. This is not objectionable when the proof is *not to be used as copy* for making the cuts but in all cases where the illustrations are copies for new cuts they should be separated from the manuscript and numbered or marked in such a way as will distinguish them. This saves the manuscript revisers the trouble of cutting out the illustrations, which will be necessary if they are a part of the manuscript. The book contains lists of common expressions with superfluous words and much other matter that characterizes bad English. A great deal of practical information regarding the business of printing and publishing is included. We would recommend the book to our readers in general, especially those who have the making up of advertising pamphlets, catalogues, brochures, etc.

Operations for the Article in this number entitled "Machine Shop Practice—Machining a Fixture Casting."

SHOP OPERATION SHEET NO. 61.

H. A. S. Howarth. MACHINERY, May, 1908.

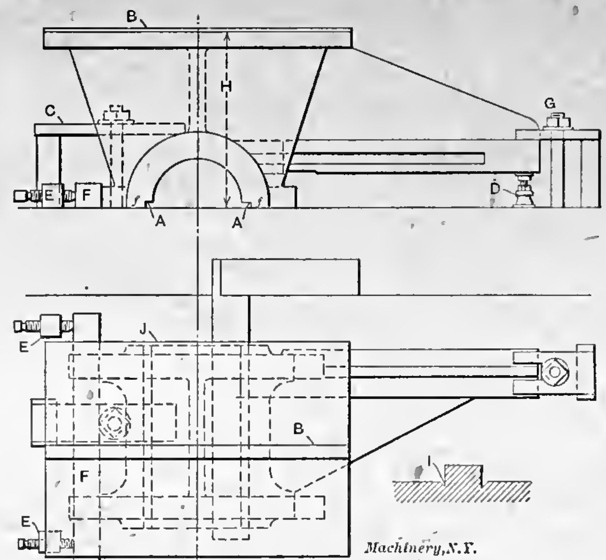


To Set Up and Plane the Bearing of a Fixture Casting.

1. Place the casting on the planer table, and insert small parallel pieces under each corner of the base.
2. Clamp a straight-edge A across the planer table, and set it square with the edge of the table.
3. Set the base of the casting with its tongue-piece B, parallel with the straight-edge by measuring at a and a', and b and b'. Place a square on the planer table and against the straight-edge, and measure from the blade of the square to the T-slot C, and ascertain whether or not it is parallel with the straight-edge. Both the T-slot and base should be as nearly parallel with the straight-edge as possible.
4. Fit a wooden centering piece in each end of the bearing, and locate the center c of the boss.
5. Place a straight edge against the side of the planer table, and measure from the straight-edge to the centers c at each end of the bearing. These measurements should be approximately equal.
6. After the casting is set clamp it firmly to the table, and place set-screw plugs E against the casting to take the thrust.
7. From one of the centers c, scribe arcs d with a radius equal to one-half the cap fitting. Remove the centers.
8. Rough and finish plane the surfaces F, and then plane the corners G to fit the previously finished cap. This fitting is kept central by working to the arcs d.
9. Cross-plane the top of the arm H at I and finish to required dimension e.

SHOP OPERATION SHEET NO. 62.

H. A. S. Howarth. MACHINERY, May, 1908.



To Set Up and Plane the Base of a Fixture Casting.

NOTE.—It is assumed that the top or bearing of the casting has been planed. This part was planed first to facilitate holding the casting when planing the base.

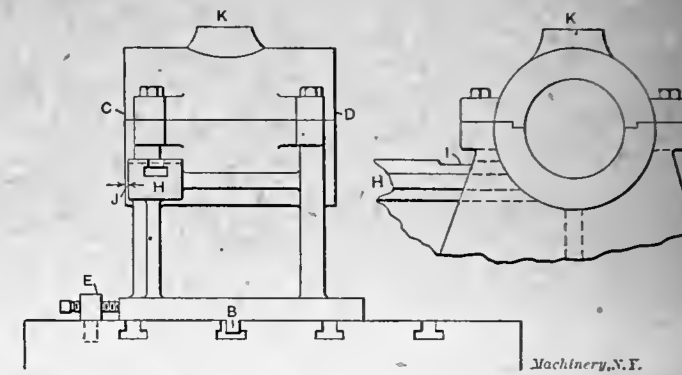
1. Place the casting on the planer with this trued surface against the table.
2. Set the finished surfaces A square with the side of the planer table, using the square as shown in the plan view. Fasten the casting to the table by the clamp C, then place the planer jack D under the projecting arm, and tighten the clamp G.
3. Place a bar F against the two lugs, as shown, and set it against them by the set-screw plugs E. Again test the casting with the square to make sure that it has not shifted. If a slight adjustment is necessary it can be made by the set-screws in the plugs E.
4. Rough and finish plane the base on both sides of the tongue B, making the distance H equal to the dimension on the drawing.
5. Finish the top of the tongue B to the required height, and on this finished surface lay out the tongue in proper relation with the ends of the bearing.
6. Finish one side of the tongue, cutting away the corner as shown at I in the sectional view. Finish the opposite side, making the tongue to the required width.

NOTE.—These corners are cut away as shown at H in order that the base of the casting may have a good bearing. If they were not removed there might be a heavy bearing at these points which would, of course, be undesirable.

7. True up the edge J of the base. This trued surface will be used in connection with a subsequent operation.

SHOP OPERATION SHEET NO. 63.

H. A. S. Howarth. MACHINERY, May, 1908.



To Set Up and Plane the Bearing Ends of a Fixture Casting.

NOTE.—All the necessary drilling and tapping is supposed to have been done, and the cap bolted in position.

1. Place the casting on the planer table with one side of the tongue B against the side of the T-slot, and hold it in this position by the set-screw plugs E, one being placed near each end of the base. Clamp the casting securely to the table.
2. Rough plane one end C of the bearing, using the vertical feed. With a square, test this planed surface before taking the finishing cut, and see if it is at right angles with the table. If the base of the casting projects beyond the bearing ends, the square may be elevated high enough to clear the base by the use of parallels.

NOTE.—Before taking these vertical cuts, be sure that the cross rail is securely clamped, and at each setting of the tool clamp the head to the cross rail by the means provided. It is also well to have the tool slide so adjusted that it works rather snugly.

3. When finishing the end C of the bearing, it will be necessary to make the horizontal distance between this end and the tongue B equal to the dimension on the drawing. The tool can be set for the finishing cut by lowering it to the table and measuring directly from the cutting edge of the tool to the tongue; or, a square may be used, the square being set with the T-slot against which the tongue rests, and the measurement being taken from the blade of the square to the cutting edge of the tool. Of course, in this latter case it will not be necessary to lower the tool. After the tool has been properly set, finish the end C.
4. Rough and finish plane the end D, removing just enough stock to make the bearing the required length.
5. Plane one side of the arm H to a distance J from the end C.
6. Finish the top of the arm H, making its surface flush with the surface I which was finished to the required distance below the top of the bearing during the first operation. Before taking the cut over the arm H, be sure that the planer will reverse at the proper point.
7. Finish the boss K on the bearing cap.

V.—SECTIONS FOR CRANE AND TELPHER RUNWAYS.

	Properties of Sections Consisting of One I- and One ⊔-beam.				
	Sectional Modulus			Moment of Inertia	Distance C

MACHINERY.

May, 1908.

A 2,000 H. P. GAS ENGINE BLOWING UNIT.*

ONE of the great changes going on in power plant equipment is the use of large gas engines and steam turbines in place of the reciprocating steam engine. The internal combustion engine and steam turbine are slowly but surely supplanting the reciprocating steam engine except for such service as reversing rolling mills and mine hoists. In other fields it apparently has an unpromising future. When the old steam engine is displaced, the fight will be on between the gas engine and the turbine. Considerations of economy incline the engineer to believe that the gas engine will be the favorite motor of the future.

Only a few years ago the internal combustion motor was, at best, considered of comparative inconsequence, its field being limited to motor boats, small power plants, etc. Even in 1893 there was exhibited at the Columbian Exposition a gas engine of about 100 H. P. which attracted much attention because of its large size. Now gas engines of 2,000, 3,000 and even 4,000 H. P. are in use, giving performance much more economical than is possible with the best steam plants using superheated steam. Of particular interest is the use of gas engines in steel plants and blast furnaces, because of the great economy afforded by the use of blast furnace gas. Instead of permitting this valuable fuel, aggregating thousands of horse-power in plants of ordinary size, to be worse than wasted, it is piped away to scrubbers and washers where the dust is so thoroughly removed that it is commonly freer from suspended impurities than the atmosphere. Delivered to the engines, it is quite capable of turning every wheel in the plant, lighting every lamp, compressing the blast and (were it not for the mechanical difficulties of reversing) the entire power of a steel plant could be derived from the gases of the blast furnaces.

The illustrations show a Westinghouse 2,000 H.P. gas-engine-driven blowing engine recently built for the Edgar Thompson plant of the Carnegie Steel Co., Pittsburg, which will serve as an example of recent gas engine and blowing engine development. The blowing cylinders are of particular interest because of the novel way in which clearance is reduced to a minimum and the inlet valves mechanically operated. This construction, known as the "Slick air tub," is one of several schemes for preventing wire drawing of the incoming air because of having to lift inlet valves. Opening the valves by power effects a considerable economy of operation, and increases the volumetric capacity.

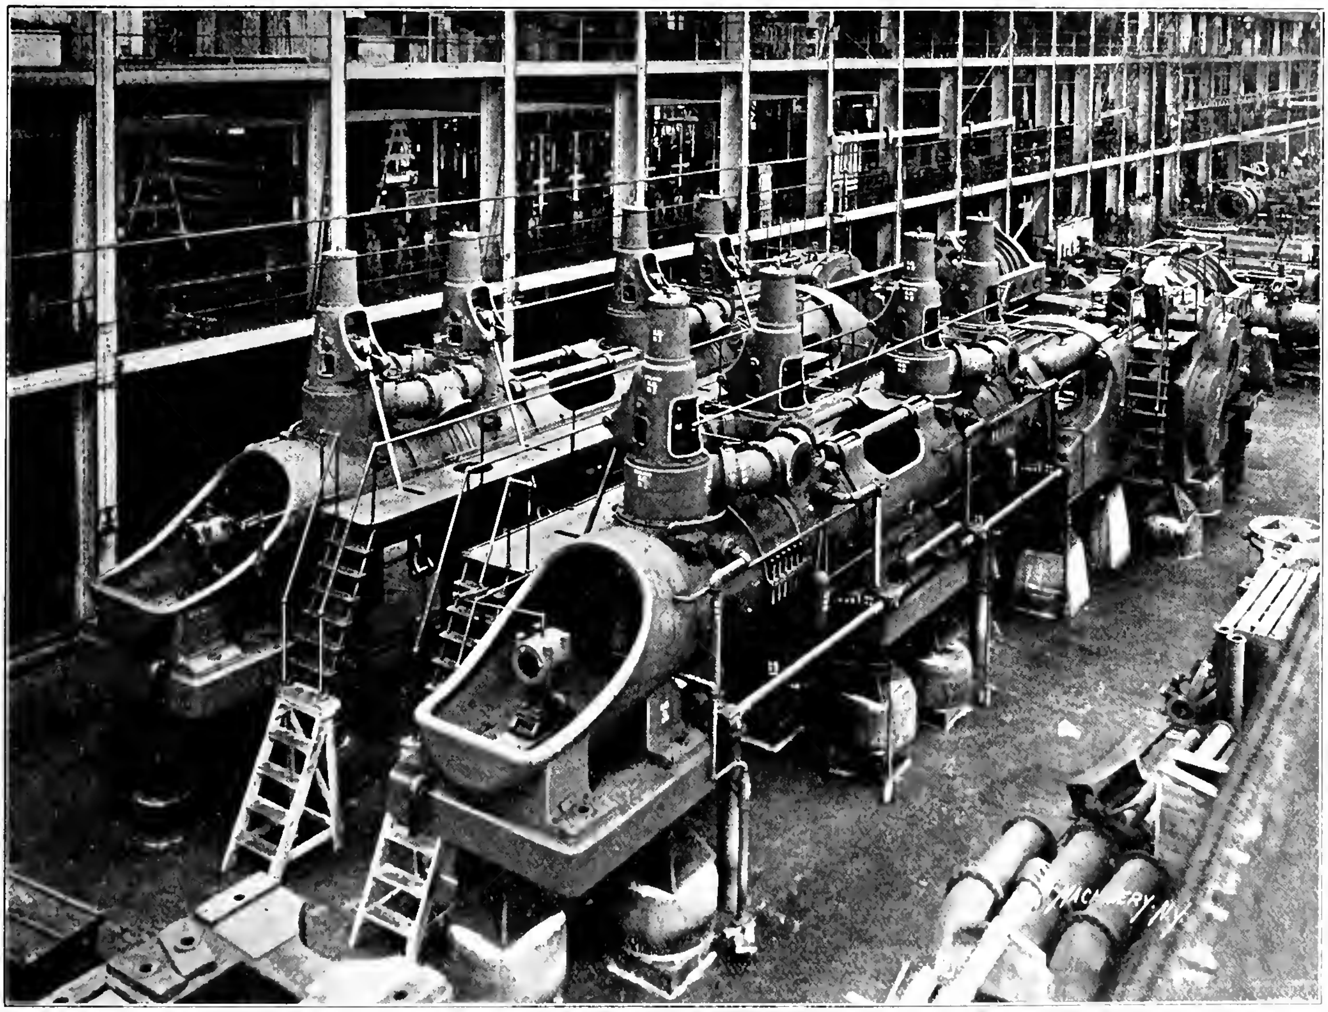

Fig. 1. The 2,000 H.P. Westinghouse Gas Engine Blowing Unit for the Edgar Thompson Steel Works, in the Course of Erection in the Shops of the Builders.

These engines are of the 4-cycle type, with two double-acting horizontal tandem cylinders acting on each of the two cranks; this gives four power strokes per revolution, the cranks being set ninety degrees apart. The cylinders are each 40 inches in diameter, and 54 inches stroke. The speed ranges from 65 to 75 revolutions per minute. The engines are intended for blowing service for the Bessemer converter plant, the blowing cylinders being of the "Slick air tub" type, which will be described later. Their capacity is 25,000 cubic feet of free air per minute, at a normal pressure of 18 pounds per square inch, running up to a maximum of 25 pounds. On blast furnace gas the brake horse-power is 2,400, which is increased to 3,100 when natural gas is used.

* For additional information on this subject, see the article on "Four 4,000 H. P. Gas Engines," published in the January, 1908, issue of MACHINERY, and other articles there referred to.

The Crank-shaft and Bearings.

The side crank construction is employed. This has the advantage of requiring but two bearings, which are easily aligned. As shown in Fig. 3, the shaft is solid, with solid cast steel cranks mounted on it. An unusual feature of the design is the fact that the pins are cast integral with the cranks, as shown in Fig. 4, thus avoiding the possibility of straining the metal between the crank-pins and the shaft in making press fits. The crank disks are cast with the crank-pins at the bottom of the core, thus insuring solid metal at this point. The dot and dash lines in Fig. 4 show the contour of the rough casting.

The main bearings, seen best in Fig. 2, are made in four parts, of which the two side pieces are adjustable by wedges. The two sides of these bearings are held together by tie-rods, passing through from side to side above the shaft. These tie-rods and the nuts for straining them may be seen projecting from the outer end of the housing in Fig. 2. By tightening the two sides together in this way, the thrust of the shaft is distributed equally between both sides of the bearing housing. This is a point of great importance in engines of large capacity. The bearing cap has a large central opening extending to the shaft, which is visible while the engine is running.

Cylinders and Housings and the Provision for Expansion.

One of the most serious difficulties met with in the design of gas engines of large size, is that of making provision for the expansion of the structure, resulting from the high heat to which the working parts are subjected. In the case of this engine, only the front housing is fastened to the foundation. The cylinders are supported by the housings at the ends, not resting on the foundation at all; and the center and rear housing are not bolted to the foundations, but are free to slide on them, as the whole structure (fastened only at the other end) expands or contracts with the heating and cooling of the parts.

This high heat also makes necessary great care in the design of the cylinders. They must be of such form that they will expand evenly under the influence of the heating, without warping or twisting in any way. As may be seen in Figs. 6 and 7, they are very nearly symmetrical. In the case of large engines, such as the ones shown herewith, the cylinders are cast in two pieces, as may be seen in Fig. 6. The two halves of the cylinders are held tightly together by the links shown, shrunk into slots in the flanges where the joint between the two halves is made. This makes the two castings practically a solid piece.

The cylinders are, of course, water jacketed. As may be seen in Fig. 6, the jacket walls of the cylinders are cast open at the center, thus avoiding cooling strains in the metal. In Fig. 7, which shows the completed cylinder, the gap between the two jacket castings is covered with the jacket band piece, which is fitted with a water-tight joint, permitting expansion or contraction without the serious strain which would result in so large a cylinder, from the difference in the expansion of the hot inner wall and the cool outer wall of the jacket, if the latter were one solid piece. The removal of this jacket band gives free access to the water spaces for cleaning. Free access is also given to the interior of the cylinder through the large valve opening shown. The valve covers and cylinder heads are also cast hollow for water-jacketing and are provided with suitable openings to facilitate cleaning them thoroughly.

Another variation from steam engine practice made necessary by the great weight of the parts and the high heat to which they are subjected, is the provision made for supporting the pistons from the cross-heads outside of the cylinder, so that no part of their weight bears on the interior surface of the cylinder. The piston of the front cylinder is carried by the main and intermediate cross-heads, while that of the rear cylinder is carried by the intermediate cross-heads and the tail bearings. The pistons are one-piece symmetrical castings, with no sharp corners to induce premature ignition. The rods are packed by water-cooled metallic packings, which receive their oil supply at the center of their length, thus properly distributing the lubrication. The hollow rods serve to feed cooling water to the interior of the piston.

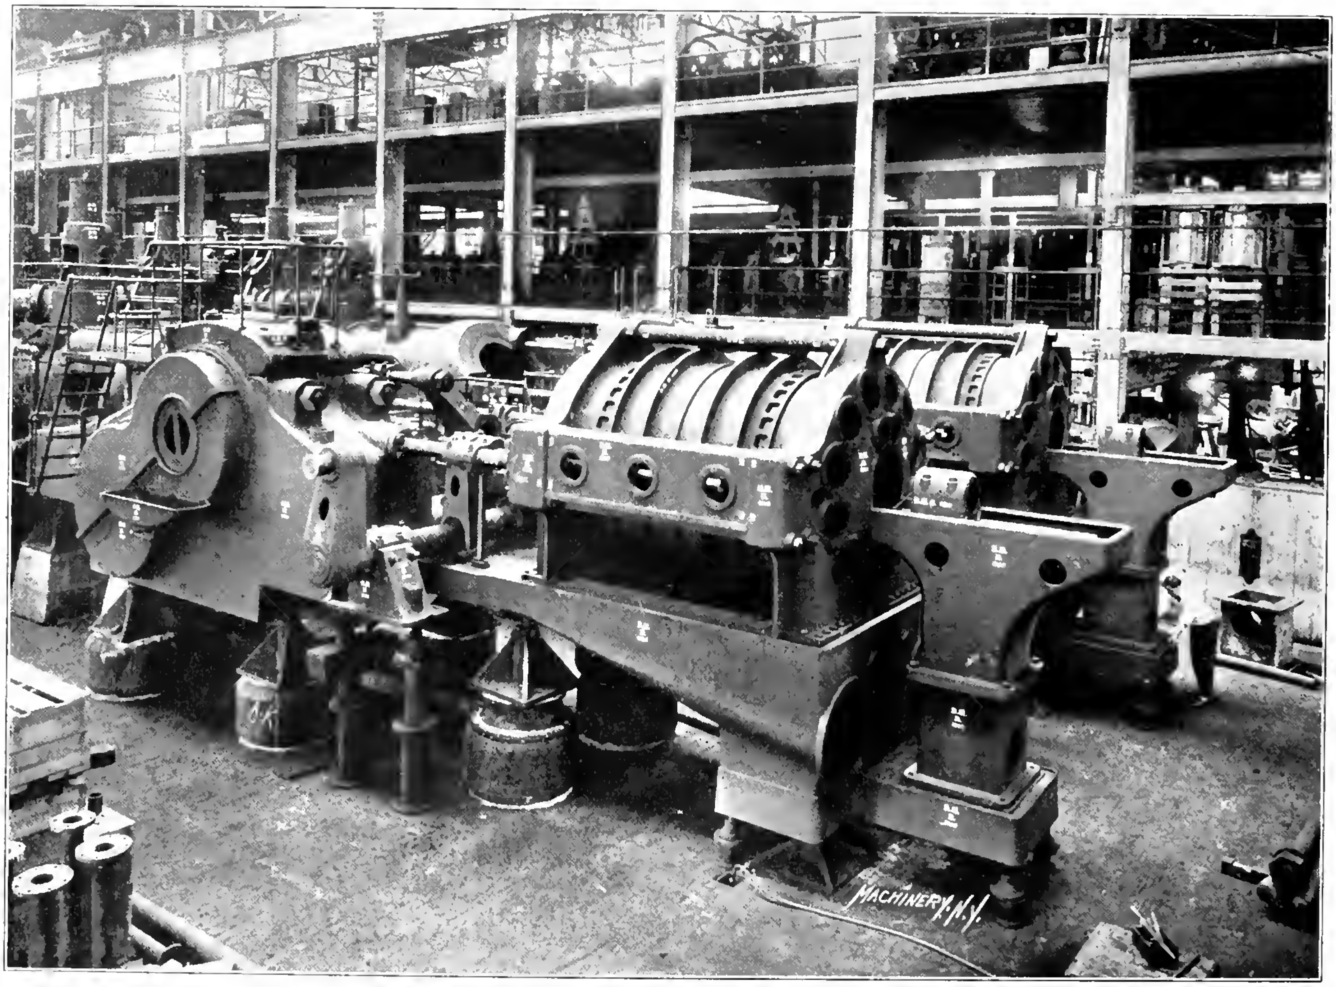

Fig. 2. Another View of the Engines, taken during Erection, showing Blowing Cylinder and Main Bearings.

Valves and Valve Mechanism.

The valves are of the poppet type, with inlet valve ports located at the top of the cylinder, and the outlet ports directly opposite, at the bottom. A mezzanine floor below the level of the engine room is provided for inspecting the lower valve gear, easy access being given to all parts of the mechanism, owing to the fact that the cylinders are separated from the housings, leaving a free, open space beneath them.

The valve gear will be best understood by reference to Fig. 8. It is operated from a lay-shaft, driven by bevel and

Fig. 3. A Completed Crank-shaft with the Cranks, Spur Gears, Blowing Engine Eccentrics, and Fly-wheel Flanges in Place.

spur gears from the spur gears on the crank-shaft, shown next to the eccentrics in Fig. 3. This use of bevel and spur gears in the place of the usual spiral gears obviates the back-lash resulting from the rapid wear of the latter type of gear, and removes the necessity for taking care of the end thrust to which it is subjected. These driving gears have "hunting teeth" to distribute the wear evenly. An eccentric is provided on the long shaft, at each end of each cylinder, the same one serving to operate both the inlet and the outlet valve.

The inlet valves (of the poppet variety, as previously explained), are held up to their seats by helical springs, as shown. The reach rod from the eccentric operates a rocker cam bearing on a lever, which forces the valve open at the proper time, and allows it to return under the influence of the spring when it is time to close it. This valve operating mechanism is an improved form of the well-known gear used on four-valve paddle-wheel engines. It is especially suited for use on gas engines, as it may be arranged to give a great

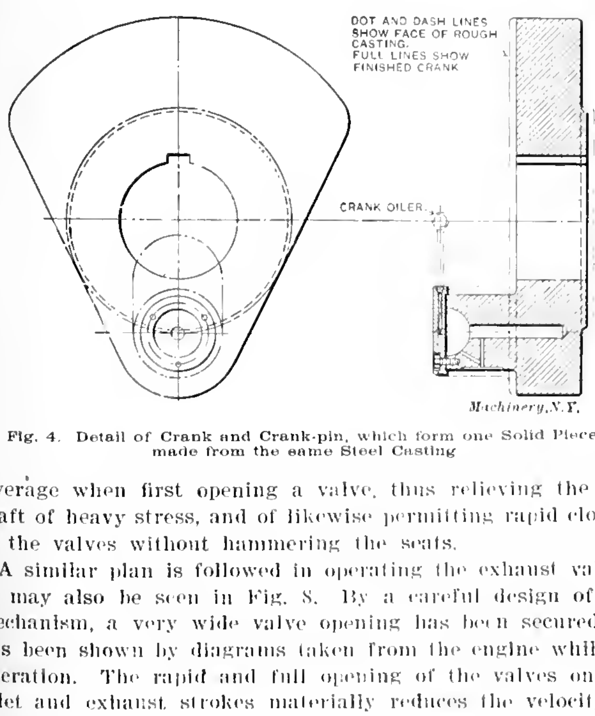

Fig. 4. Detail of Crank and Crank-pin, which form one Solid Piece made from the same Steel Casting

leverage when first opening a valve, thus relieving the lay-shaft of heavy stress, and of likewise permitting rapid closing of the valves without hammering the seats.

A similar plan is followed in operating the exhaust valves, as may also be seen in Fig. 8. By a careful design of the mechanism, a very wide valve opening has been secured, as has been shown by diagrams taken from the engine while in operation. The rapid and full opening of the valves on the inlet and exhaust strokes materially reduces the velocity of the gases, lessens the resistance to passage through the valves, and considerably increases the capacity of the cylinders.

The exhaust valves are made hollow, and are water-cooled. The cooling water is supplied to the outside portion of the valve, the outlet being by means of a pipe extending through the interior to the top, thus insuring that the valve is always full of water, and preventing the possibility of air pockets. The valve stems of both inlet and exhaust valves are oiled at about the middle of the bearing, thus insuring the lubrication of the whole surface. The valve covers are fitted with a tight joint at their inner ends, thus exposing a minimum surface to the heating action of the products of combustion, and insuring well-cooled valve seats.

Governing Mechanism.

The inlet valve combines the function of inlet, mixing, and governor valves in the single mechanism. A cast-iron sleeve, carried on the valve stem, and free to revolve on it, is provided with two sets of ports, one for gas and one for air, registering with corresponding openings in the valve bonnet in which it fits. This sleeve is revolved on the stem by reach rods from the governor, thus more or less throttling the mixture supplied to the cylinder. It is evident that the sleeve on the valve stem moves up and down, in addition to its rotation under the influence of the governor. This compound movement prevents any possibility of the governor valve sticking when the engine is running under constant load for long periods, during which the governor valve does not change its position.

Another advantage of this arrangement is the fact that the gas and air are mixed at the point where they enter the cylin-

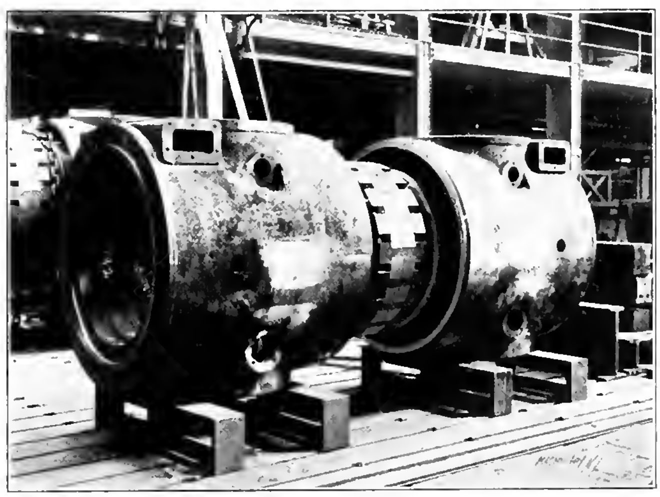

Fig. 5. Partly Finished Cylinder Casting, the Two Halves are shrunk together by the Links shown.

der, as fast as they are needed by the engine, thus avoiding large quantities of idle mixed gases with the resulting difficulty of a large volume of gases exposed to premature ignition. The governor also has the most effective possible control of the engine under these conditions, as the mixture at each end of each cylinder is independently controlled, thus giving far better regulation than can be obtained when the controlling is done at a distance from the inlet ports.

The governor acts on the mixing valves through a relay cylinder, operated by oil pressure. The sole function of the governor is to operate a small pilot valve which controls the movement of the piston in the governing cylinder, which latter is connected by reach rods with the mixing valves on the cylinders of the engine. It is evident, therefore, that the governor is not affected by the movement of the reach rods or by the force required to move them, as it has only to move this small pilot valve. A dash pot is provided on the governor to prevent hunting under variable loads. The governor is driven directly from the main shaft at a point near the front of the machine, where it is unaffected by any slight torsional deflection to which the lay-shaft may be subjected.

In addition to the governor a safety stop is provided, consisting simply of a spring-balanced pin supported in the rim of the fly-wheel, which is forced outward by centrifugal force, if the speed exceeds a predetermined limit. It then

strikes a pawl, which in turn releases a weight attached to a knife switch, which falls and thus opens the igniter circuit, this being the simplest and most positive method of instantly cutting off the power of a gas engine. A safety stop is also provided to automatically open the igniter circuit in case of the failure of the cooling water supply.

Ignition.

The method of ignition used is the result of careful and extensive experiments. The jump spark system was found impractical on all but small engines, operating on rich gas, or

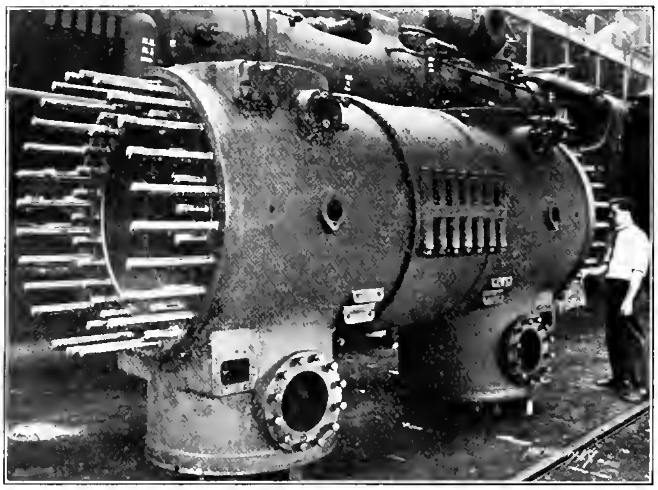

Fig. 6. Completed Cylinder Casting with the Jacket Band in Place.

low compression gasoline gas, because of the fact that the potential required to jump the gap increases directly with the pressure, so that for the high compressions necessary for producer, blast furnace and other "lean" gases, excessive potential is required. The make-and-break system of ignition has therefore been adopted. Each end of each cylinder is provided with three igniters, each with its own independently fused circuit, so that the possibility of a misfire is reduced to a minimum. This gives uniform combustion as well, the charge being lighted at more than one point. The igniter contacts are of cast iron or special bronze which has been found to have remarkable wearing qualities, especially for the low temperature required for ignition by this system. Each igniter circuit is provided with an indicator, which gives visible witness of its operation. Each side of each circuit is separately insulated so that six separate grounds are required to put one end of the cylinder out of commission.

Two forms of ignition gears are employed in the Westinghouse engine, one being mechanically, and the other electrically operated. In either case provision is made for adjusting the time of the ignition. The electrical ignition gear, used on this engine, is operated from a timer or contactor for making and breaking the igniter circuits. In place of the knock-off cams used on the mechanical gear, an electrical knock-off device is used, which is controlled by electrical magnets, operated by the timer mentioned. The advantages of this system are that the ignition is easily advanced and retarded, the same as in the mechanical gear, and that all the igniters at each end of each cylinder are necessarily operated simultaneously. The timer is shown at the right of Fig. 8.

Lubrication.

The engine oil lubrication is effected by a continuous gravity system with filters, insuring ample lubrication of all bearings, crank-pins, cross-heads, etc. All important parts are supplied with right feed oilers. The lubrication of the cylinders is effected by a timed forced lubrication system somewhat similar to, and a development from, that used in automobiles. This system, as applied to the engine, is shown in Fig. 8. Four eccentrics are used, operating valves for each of the two ends of the two cylinders. The oil is supplied at four points in the cylinder, during the suction stroke only. This is a point of great importance, as it gives two working strokes at low temperature, during which all the oil is evenly distributed over the cylinder, thus insuring good lubrication with a minimum supply of oil. The pistons do not touch the cylinders at any point, so that the piston rings form recesses which distribute the oil evenly.

Automatic Starting Mechanism.

The starting mechanism is automatic, and is operated by compressed air. An air supply pipe, controlled by an unbalanced poppet valve, is fitted to each end of each cylinder, this valve being located directly under an air knock-off cam mounted on the main lay-shaft. To start the engine it is only necessary to turn on the main air valve. This causes the poppet valves to move upward to their seats, one or more of the valves being held down, thus admitting air to the proper cylinders, causing the engines to turn over. As the air is admitted to the cylinder during the power stroke, the exhaust valves permit thė escape of the air from the cylinder during the succeeding stroke.

The "Slick Air Tub."

The blower end of this engine is not the least interesting part of the machine. It is of the design known as the "Slick air tub," which has been very successfully used for the handling of air at low and medium pressures. A great point in the mechanical handling of air at low pressures is the provision for ample port area and small clearance. This is effected in the Slick air tub in a way that will be understood from reference to Figs. 2 and 9.

The cylinder heads are stationary and are fastened to the bed, but the cylinder itself slides on the heads, being reciprocated by reach rods from a rock-shaft driven from the air tub eccentric. The eccentrics may be seen between the spur

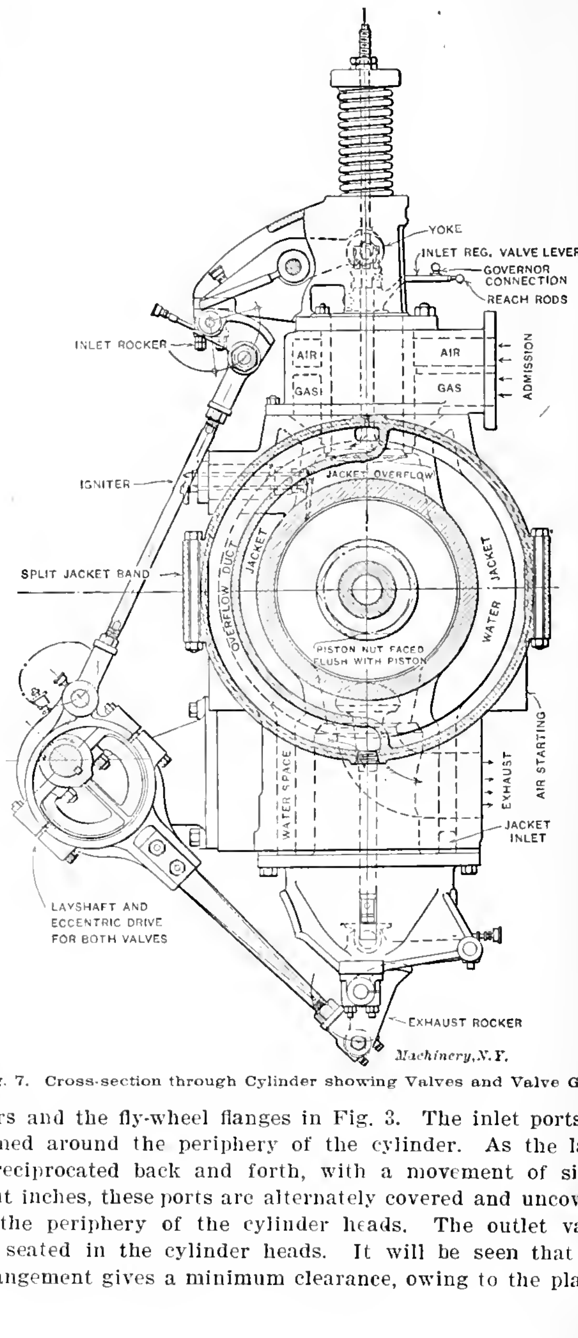

Fig. 7. Cross-section through Cylinder showing Valves and Valve Gear.

gears and the fly-wheel flanges in Fig. 3. The inlet ports are formed around the periphery of the cylinder. As the latter is reciprocated back and forth, with a movement of six or eight inches, these ports are alternately covered and uncovered by the periphery of the cylinder heads. The outlet valves are seated in the cylinder heads. It will be seen that this arrangement gives a minimum clearance, owing to the placing

of the outlet valves in the heads, and the fact that no clearance whatever is required for the inlet ports. The whole area of the heads is available for the outlet valves, while as much of the cylinder periphery as may be necessary can be devoted to the inlet ports.

The parts shown in diagrammatic form in Fig. 9, may be easily followed in the half-tone engraving in Fig. 2. It will

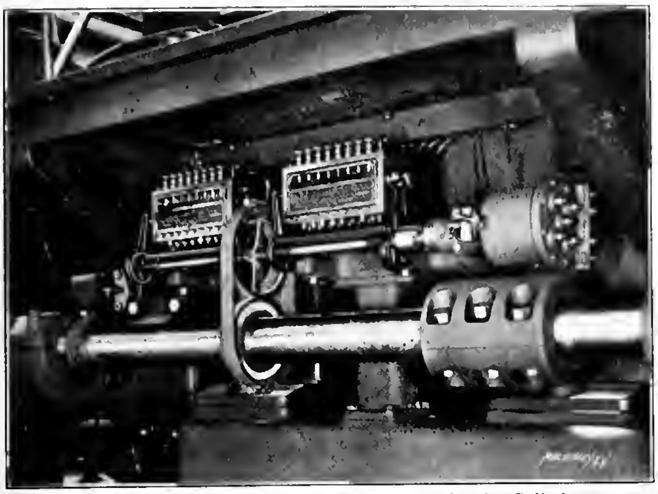

Fig. 8. The Forced Lubricating Apparatus for the Cylinders, and Ignition Timer.

be seen that the piston of the blowing engine cylinder is driven by distance rods from the main cross-head, the crank lying between the cross-head and the blowing cylinder.

The Westinghouse Line of Gas Engines.

The line of gas engines of which the one we have shown is an example, has been designed to be operated without change of design on the wide range of fuels available for the purpose. These fuels include blast furnace gas of 85 to 90 B. T. U. per cubic foot, producer gas from anthracite and bituminous coal, natural gas from the Kansas and Pennsylvania fields, and by-product coke oven gas running as high as 66 per cent hydrogen. All are being successfully employed in the same design of engine.

Various sizes are built, both vertical and horizontal, the former being employed up to 300 H. P., and the latter from there on up to the maximum 3,000 or 4,000 H. P. units. By far the largest number of them are used for driving electric generators, either directly connected or belted, the majority being for alternating current plants. The vertical design has made use of the spring coupling in this service. In horizontal engines, such as that shown in this article, these are unnecessary, except for some particularly difficult high fre-

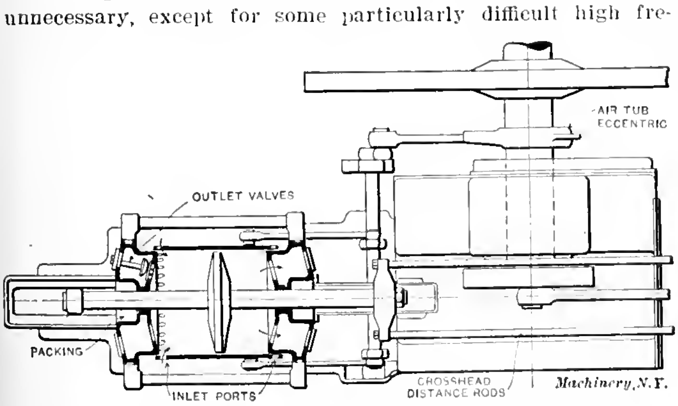

Fig. 9. Diagram showing the Mechanism of the "Slick Air Tub"

quency installations. Owing to the system of governing, applied directly to the inlet of each cylinder, a speed regulation as close as 2½ per cent may be obtained.

Owing to the inherent efficiency of the four-stroke cycle, gas engine economy is largely independent of the size, and a 200 or 300 H. P. vertical engine will give nearly the same efficiency as a large horizontal engine like the one shown. This efficiency ranges close to 10,000 B. T. U. per brake horsepower per hour. The efficiency is largely independent of the kind of gas used, owing to the fact that weaker gases will take a higher compression—almost 200 pounds per square inch, for instance, for furnace gas.

THE DESIGN OF SPRINGS FOR GAS ENGINE VALVES.

F. E. WHITTLESEY.*

Springs for gas engines should be carefully designed, and if properly proportioned for the work they must do, should be just as reliable as any other part of the mechanism. While the general data for spring design are well known to engineers, yet attention may properly be given to some considerations specially applicable to gas engine valve springs. This article will consider compression springs of round steel wire only, as the writer knows of no valid reason for the use of any other material or section for this class of springs. It is well known that square steel is less desirable than round steel for springs, both on account of the higher cost of the springs per pound, and from the standpoint of efficiency.

The first consideration is the selection of the proper values for the fiber stress S and the torsional modulus of elasticity G. Experiments have shown that a fair value for G is 12,500,000, which value is fairly constant for the various grades and tempers of steel within their elastic limits. The safe value for S is not so easily determined, because the correct value for any given class of springs is largely a matter of experience. The highest normal value of S varies from about 120,000 pounds per square inch for 1/16-inch wire, to 90,000 pounds for ⅝-inch wire, which includes the range of sizes generally used on valves. The term "normal value" is used to distinguish these figures from the higher values which can be reached by spring makers, and which are sometimes necessary, but should never be used for rapidly vibrating springs, or for springs where safety and long life are primary considerations, as in this class of springs. In fact, even the above normal values are far too high for gas engine springs. These values are used very generally on machinery springs, etc., but should be reduced very materially to obtain springs which will give the maximum of service in gas engine work. A value of S of from 25,000 to 30,000 pounds per square inch has been found to give best results for gas engine valves.

The third variable is the length of the spring, which should be as long as practicable in order to keep the pressure on the lever or cam which operates the valve from being higher than necessary at the extreme lift of the valve. To illustrate this point we will take a valve on which a pressure of 40 pounds when closed is desired, and which opens ½ inch. If the spring is under ½ inch compression when the valve is closed, and holding 40 pounds, the pressure when the valve is open will be 80 pounds. But if we use a spring under 1¼ inch compression to hold 40 pounds when the valve is closed, when the valve is opened the ½-inch travel, the pressure will be increased to only 56 pounds. The diameter and assembled length of the spring will usually be determined by the general design of the engine. The diameter should be as large as convenient, which will lessen the tendency to buckle.

We will now design a spring for an exhaust valve, the lift of the valve being ½ inch, the assembled length of the spring 6 inches, the pitch diameter of the spring 2 inches, and the value of S at extreme compression 25,000 pounds per square inch. We will make the spring 7¼ inches long, thus giving a total compression of 1¾ inch, and a final pressure of 56 pounds. The following formulas will be used:

$$P = \frac{11d^3S}{28D} \quad \ldots (1) \qquad f_1 = \frac{22D^2S}{7Gd} \quad \ldots (2)$$

P = pressure at given compression,
d = diameter of wire in inches,
D = pitch diameter of spring in inches,
f_1 = deflection of one coil in inches,
S = fiber stress in pounds per square inch,
G = torsional modulus of elasticity.

[The common form of the formulas (1) and (2) is

$$P = \frac{S\pi d^3}{16R} \quad \ldots (3) \qquad f = \frac{32PR^2l}{G\pi d^4} \quad \ldots (4)$$

In these formulas P, d, S, and G, denote the same quantities as in formulas (1) and (2), and

* Address: Care Raymond Mfg. Co., Corry, Pa.

R = pitch radius of spring in inches,
f = deflection of the whole spring under load,
l = full length of wire in spring.

The formulas (3) and (4) can easily be transformed to the form in (1) and (2) by writing $\pi = 22/7$, $R = D/2$, and $l = \pi Dn$ (n being the number of coils in the spring).—EDITOR.]

We use formula (1) to determine the size of the wire. Substituting the known values, we have

$$56 = \frac{11d^3 \times 25{,}000}{28 \times 2}, \text{ or } d = 0.225.$$

We therefore will use No. 4 Washburn & Moen gage wire, which is 0.225. To determine the deflection per coil, we will substitute the known values in formula (2), as follows:

$$f_1 = \frac{22 \times 4 \times 25{,}000}{7 \times 12{,}500{,}000 \times 0.225} = 0.112 \text{ inch.}$$

The free length of the spring is $7\frac{1}{4}$ inches, and the length with the valve open is $5\frac{1}{2}$ inches, the compression therefore is $1\frac{3}{4}$ inch. Then $1\frac{3}{4} \div 0.112$ (the compression per coil) gives $15\frac{3}{4}$ acting coils approximately, and adding one coil on each end, for a flat bearing to be ground at right angles to the axis of the spring, gives $17\frac{3}{4}$ total coils. Therefore the spring will be 2-inch pitch diameter, $7\frac{1}{4}$-inch free length, No. 4 W. & M. gage wire, $17\frac{3}{4}$ total coils, squared and ground ends, holding 40 pounds at 6 inches long, and 56 pounds at $5\frac{1}{2}$ inches long, with a fiber stress at $5\frac{1}{2}$ inches long of 25,000 pounds per square inch.

If it is desirable that the pressure, when the valve is open, rise *as little as possible* above 40 pounds, we must make the spring as long as possible and still compress to the closed length given. We will assume a spring 2 inches pitch diameter, to hold 40 pounds when 6 inches long, and as little over 40 pounds as possible at $5\frac{1}{2}$ inches long. As we do not know the pressure at $5\frac{1}{2}$ inches long, we will take the fiber stress 25,000 pounds at 6 inches long, instead of at total compression.

Using formula (1): $40 = \frac{11d^3 \times 25{,}000}{28 \times 2}$, or $d^3 = \frac{224}{27{,}500}$, and $d = 0.200$.

We will therefore use No. 5 W. & M. gage wire, which is 0.207.

Using formula (2): $f_1 = \frac{22 \times 4 \times 25{,}000}{7 \times 12{,}500{,}000 \times 0.207} = 0.1215$ inch

compression per coil when holding 40 pounds. Then $5\frac{1}{2}$ inch solid length less twice 0.207 gives the length occupied by the acting coils when solid, or 5.086 inches, and $5.086 \div 0.207 = 24.5$ acting coils. Further, $24.5 \times 0.1215 = 2.975$ inches compression, which added to 6 inches gives 8.975 inches free length of the spring, say 9 inches. The spring therefore compresses 3 inches when holding 40 pounds, with a value of S of 25,000 pounds and at $5\frac{1}{2}$ inches long, being compressed $3\frac{1}{2}$ inches, holds $46\,2/3$ pounds, with a value of S of $\frac{46\,2/3}{40} \times$ 25,000 or $29{,}166\,2/3$ pounds.

In these examples we have not corrected the values of S to allow for the variation in sizes of wire used, from the theoretical sizes obtained, as it is not necessary to do so in practice. It is interesting to note, however, the difference in this value at final compression, obtained by the above method of proportion based on 25,000 pounds at 40 pounds pressure, from that obtained by using the original formula with the final pressure of $46\,2/3$ pounds, and wire of 0.207 inch diameter. The first method gives 29,166 pounds, while the second method gives 26,782 pounds, this difference being caused by the difference of 0.007 in the size of wire.

* * *

The growing practice of casting threaded holes in machine details is referred to by the *Engineering Record*. Wrought iron nuts are inserted in the molds and properly located, being held securely by projections from the cores. For work which does not necessitate any high degree of accuracy, the nuts can be placed in the casting close enough for the purpose required. This obviates the necessity of drilling and tapping operations at the same time, as wrought iron threads have greater strength than the threads cut in the cast iron itself.

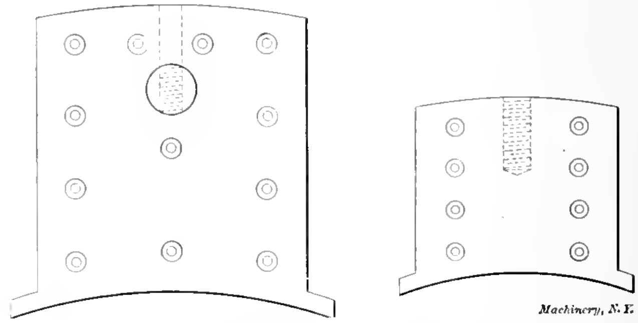
POLE PIECE DESIGN FOR DYNAMOS.*

E. A. LÖF.†

To give a definite rule for the design of pole pieces is almost impossible, due to the many different shapes of poles used by the various dynamo manufacturers. The parts of which a pole piece consists are the punchings, the end-plates, the rivets, and the bolts holding the pole piece to the frame. Each of these parts will in the following treatise be treated separately, and some data and dimensions will be given, illustrating the present practice of their design.

Punchings.

The punchings are made up of soft sheet steel, carefully annealed, and of a size of about No. 16 U. S. gage. Before assembling, each punching should be thoroughly lacquered with an approved insulating varnish, and then left to dry. For determining the number of punchings required for a pole piece of a certain width, it may be said that the lacquer occupies about 5 per cent of the total width. The punchings are pressed together in a hydraulic press. The shapes of the punchings vary greatly, dependent upon the electrical design.



Figs. 1 and 2. Examples of Types of Pole Piece Design.

Figs. 1, 2, and 3 show a few of the various forms of punchings used. Some manufacturers have one of the face-corners of each punching cut off, and the laminations are laid with the beveled corners alternately to one side and then the other, thus producing a pole piece with saturated tip.

End-plates.

To give the pole piece a more substantial construction, an end-plate of heavier thickness is provided for each end. These end-plates are made up of tank steel, and are of the same form as the punchings. The edges are either straight or rounded. If straight, they should be chamfered at 45 degrees, and if rounded, the radius should be equal to the thickness of the plate, as shown in Figs. 4 and 5. The thickness of the plate is determined by the size of the rivets holding the pole pieces together. Table I gives suitable thicknesses based upon standard rivet diameters.

TABLE I.

Rivet diameter	$\frac{3}{16}$	$\frac{1}{4}$	$\frac{5}{16}$	$\frac{3}{8}$	$\frac{7}{16}$	$\frac{1}{2}$	$\frac{9}{16}$	$\frac{5}{8}$	$\frac{3}{4}$
End-plate	$\frac{1}{4}$	$\frac{1}{4}$	$\frac{3}{8}$	$\frac{3}{8}$	$\frac{1}{2}$	$\frac{1}{2}$	$\frac{5}{8}$	$\frac{5}{8}$	$\frac{3}{4}$

Rivets.

Some methods of distributing the rivets are shown in Figs. 1, 2, and 3. This distribution, however, is entirely dependent upon the shape and size of the pole piece. If there is not sufficient space for a standard size rivet, a greater number of smaller diameter rivets should be used. Rivets should not be placed too close to the edges. The distance from the rivet to the edge should never be less than the diameter of the rivet. If less, the end-plate is liable to break.

TABLE II.

Building-up pressure in tons	10	15	20	25	35	40	60
Rivet diameter	$\frac{5}{16}$	$\frac{3}{8}$	$\frac{7}{16}$	$\frac{1}{2}$	$\frac{9}{16}$	$\frac{5}{8}$	$\frac{3}{4}$

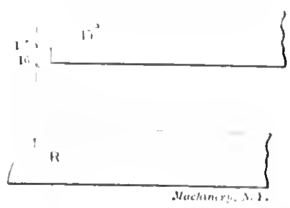
The building-up pressure required for a pole piece is usually a reasonable guide for determining the rivet diameters. Table II gives dimensions of rivet diameters such that the building-up pressure will head-up the rivets cold in pairs.

* See MACHINERY, January, 1907: Mechanical Calculations and Data for Dynamo Design.

† Address: 2121 W. Monroe St., Chicago Ill.

When the building-up pressure is 60 tons and over, 3/4-inch rivets should be used, if there is sufficient space for them. Larger size of rivets than 3/4 inch should not be used.

Fig. 3. A Third Type of Pole Piece Design.



Figs. 4 and 5 Design of Edge of End-plates

For determining the number of rivets required, it has been found from actual practice that as an average for every square inch of rivet there is about 40 square inches of punching area. Thus,

$$\text{Approximate number of rivets} = \frac{\text{Area of punching in square inches}}{40 \times \text{area of one rivet}}$$

Table III gives for each rivet diameter the area of the rivet, and a suitable pitch that will allow 40 square inches punching area for each square inch of rivet cross-section. It also gives the distances from the center of the rivets to the edge of the end-plate.

TABLE III.

Diameter of rivet....	$\frac{1}{4}$	$\frac{5}{16}$	$\frac{3}{8}$	$\frac{7}{16}$	$\frac{1}{2}$	$\frac{9}{16}$	$\frac{5}{8}$	$\frac{3}{4}$
Area................	.049	.077	.110	.150	.196	.249	.307	.442
Pitch..............	$1\frac{3}{8}$	$1\frac{3}{4}$	$2\frac{1}{8}$	$2\frac{1}{2}$	$2\frac{3}{4}$	$3\frac{1}{8}$	$3\frac{1}{2}$	$4\frac{1}{4}$
Distance to edge.....	$\frac{3}{4}$	$\frac{7}{8}$	1	$1\frac{1}{4}$	$1\frac{3}{8}$	$1\frac{1}{2}$	$1\frac{3}{4}$	$2\frac{1}{8}$

As mentioned before, the spacing of the rivets is, to a great extent, dependent upon the size and shape of the pole pieces, and good judgment must be relied upon to adjust the diameters and pitch so as to suit each particular case. The rivets may be either of the cold rolled steel tight-fit type or of the wrought iron clearance type.

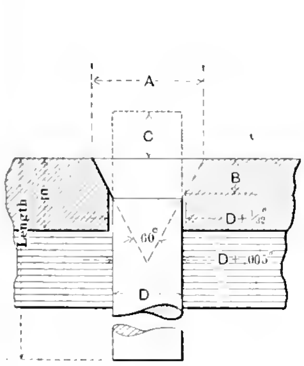


Fig. 6. Tight-fit Rivets.

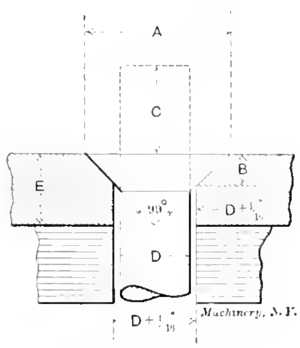

Fig. 7. Clearance Rivets.

Cold Rolled Steel Tight-fit Rivets.

For this type of rivets the holes in the punchings should be 0.005 inch larger than the rivet diameters. This will produce a tight fit when assembled. The holes in the end-plates should be 1/32 inch larger than the rivets. The riveting is done cold in the press; only the final peening of the head is done by hand. Tight-fit rivets are used in all bolted-in pole pieces. Fig. 6 and Table IV give dimensions for a standard line of tight-fit rivets.

TABLE IV. TIGHT-FIT RIVETS.

(See Fig. 6 for notations.)

Rivet Diameter D	A	B	C	E
$\frac{1}{4}$	$\frac{3}{8}$	$\frac{1}{8}$	$\frac{3}{16}$	$\frac{1}{4}$
$\frac{5}{16}$	$\frac{1}{2}$	$\frac{5}{32}$	$\frac{3}{16}$	$\frac{3}{8}$
$\frac{3}{8}$	$\frac{5}{8}$	$\frac{3}{16}$	$\frac{1}{4}$	$\frac{3}{8}$
$\frac{7}{16}$	$\frac{3}{4}$	$\frac{1}{4}$	$\frac{1}{4}$	$\frac{1}{2}$
$\frac{1}{2}$	$\frac{13}{16}$	$\frac{9}{32}$	$\frac{5}{16}$	$\frac{1}{2}$
$\frac{9}{16}$	$\frac{15}{16}$	$\frac{5}{16}$	$\frac{3}{8}$	$\frac{5}{8}$
$\frac{5}{8}$	1	$\frac{5}{16}$	$\frac{7}{16}$	$\frac{5}{8}$
$\frac{3}{4}$	$1\frac{3}{16}$	$\frac{3}{8}$	$\frac{9}{16}$	$\frac{3}{4}$

Wrought Iron Clearance Rivets.

The rivet holes in the punchings and the end plates for this type of rivets are made 1/16 inch larger than the rivets.

TABLE V CLEARANCE RIVETS

(See Fig. 7 for notations.)

Rivet Diameter D.	A	B	C	E
$\frac{1}{4}$	$\frac{1}{2}$	$\frac{1}{8}$	$\frac{5}{16}$	$\frac{1}{4}$
$\frac{5}{16}$	$\frac{5}{8}$	$\frac{1}{8}$	$\frac{3}{8}$	$\frac{3}{8}$
$\frac{3}{8}$	$\frac{3}{4}$	$\frac{1}{8}$	$\frac{1}{2}$	$\frac{3}{8}$
$\frac{7}{16}$	$\frac{7}{8}$	$\frac{3}{16}$	$\frac{9}{16}$	$\frac{1}{2}$
$\frac{1}{2}$	1	$\frac{3}{16}$	$\frac{5}{8}$	$\frac{1}{2}$
$\frac{9}{16}$	$1\frac{1}{8}$	$\frac{1}{4}$	$\frac{5}{8}$	$\frac{5}{8}$
$\frac{5}{8}$	$1\frac{1}{4}$	$\frac{1}{4}$	$\frac{11}{16}$	$\frac{5}{8}$
$\frac{3}{4}$	$1\frac{1}{2}$	$\frac{5}{16}$	$\frac{3}{4}$	$\frac{3}{4}$

All riveting is done hot. Clearance rivets are used in all cast-in pole pieces. Fig. 7 and Table V give dimensions for a line of clearance rivets.

Bolts.

The pole pieces are secured to machined surfaces inside the frame by one or two bolts for each pole piece. These bolts pass through the frame into the pole piece. They do not, however, pass entirely through the poles, but leave the pole faces smooth and unbroken. For smaller pole pieces the treading is done directly in the punchings, but for larger sizes it is advisable to provide a large solid iron cross bar passing lengthwise through the pole piece. This bar in then drilled and threaded for the bolts. The former practice is shown in Fig. 2 and the latter in Fig. 1. The method of fastening the pole pieces by means of bolts permits the removal of the poles and the field coils without separating the frame, and repairs can be made in the shortest possible time. If only one bolt is used for holding the pole piece in place, it is advisable to provide a dowel pin to prevent the pole piece from turning.

In Figs. 8 and 9 are shown two kinds of bolts. The one shown in Fig. 8 is mostly used for rotating field pole pieces. Fig. 9 shows a machine bolt tapped into the pole punchings.

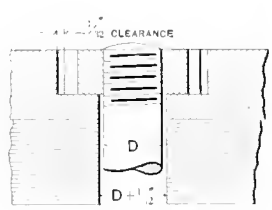

Fig 8 Steel Bolt for Rotating Field Pole Pieces.

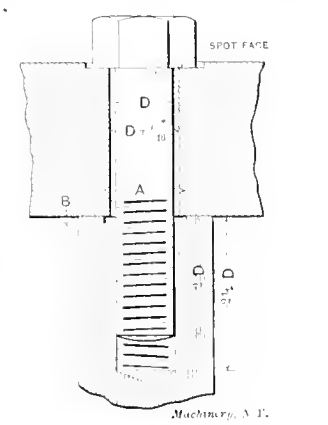

Fig 9 Machine Bolt tapped into Pole Punchings

Referring to the reference letters in Fig. 9, if D is less than $1\frac{3}{8}$ inch, then $A = D + \frac{1}{4}$ inch, and $B = \frac{1}{8}$ inch. If D is larger than $1\frac{3}{8}$ inch, then $A = D + \frac{3}{8}$ inch, and $B = 3/16$ inch. The diameter D of the bolts can be calculated from formulas as given in any mechanical handbook.

* * *

A new employers' liability bill, intended to meet the objections found by the Supreme Court of the United States, in declaring the previous bill passed unconstitutional, was passed by the House of Representatives at Washington on April 6. On April 9 the bill was also passed by the Senate. This law is specifically directed towards railroads engaged in interstate commerce, and will hold railroad companies liable for all injuries to employes while engaged in commerce between the states or territories, and also when engaged in commerce wholly within a territory. The bill passed in the House by a vote of 300 to 1, but it is feared that the present bill may not stand the test of constitutionality when subjected to the test of the Supreme Court.

COMPARATIVE VALUE OF ALCOHOL AND GASOLINE AS ENGINE FUELS.

The technologic branch of the United States Geological Survey, under the direction of Mr. J. A. Holmes, has recently completed an elaborate series of tests on the relative value of gasoline and alcohol as producers of power. The tests, over two thousand in number, probably represent the most complete and exact investigation of the kind that has been made either in this country or abroad, and includes much original research work.

Professor R. R. Fernald, engineer-in-charge of the gas producer section and professor of mechanical engineering in the Case School of Applied Science, Cleveland, Ohio, was in general charge of the tests. R. M. Strong, formerly connected with the engineering department of Columbia University, had personal supervision of the work. He was assisted by a corps of specially-trained men.

These tests were conducted at the fuel testing plant of the Geological Survey at Norfolk, Va., and show the following results in regard to the comparative fuel consumption of 73 degrees specific gravity gasoline and commercial completely denatured alcohol, per unit of power.

Correspondingly well-designed alcohol and gasoline engines when running under the most advantageous conditions for each, *will consume equal volumes* of the fuel for which they are designed. This statement is based on the results of many tests made under the most favorable practical conditions that could be obtained for the size and type of engines and fuel used. An average of the minimum fuel consumption values thus obtained, gives a like figure of eight-tenths pint per hour per brake-horse-power for gasoline and alcohol.

Considering that the heat value of a gallon of denatured alcohol is only a little over six-tenths that of a gallon of gasoline, this result of equal fuel consumption by volume for gasoline and alcohol engines probably represents the best comparative value that can be obtained for alcohol at the present time, as is also indicated by Continental practice. Though the possibility of obtaining this condition in practice here has been thoroughly demonstrated at the Government fuel-testing plant, it yet remains with the engine manufacturers to make the "equal fuel consumption by volume" a commercial basis of comparison.

The gasoline engines that were used in these tests are representative of the standard American stationary engine types, rating at 10 to 15 horse-power, at speeds of from 250 to 300 revolutions per minute, while the alcohol engines were of similar construction and identical in size with the gasoline engines.

The air was not preheated for the above tests on alcohol and gasoline, and the engines were equipped with the ordinary types of constant level suction lift and constant level pressure spray carbureters. Many special tests with air preheated to various temperatures up to 250 degrees F., and tests with special carbureters were made, but no beneficial effects traceable to better carburation were found when the engines were handled under the special test conditions, including constant speed and best load.

The commercial completely denatured alcohol referred to is 100 parts ethyl alcohol plus 10 parts methyl alcohol plus ½ part benzol, and corresponds very closely to 94 per cent by volume or 91 per cent by weight ethyl alcohol (grain alcohol). No detrimental effects on the cylinder walls and valves of the engines were found from the use of the above denatured alcohol.

The lowest consumption values were obtained with the highest compression that it was found practical to use; which compression for the denatured alcohol ranged from 150 to 180 pounds per square inch above atmosphere.

Eighty per cent alcohol (alcohol and water) for use in engines of the present type would have to sell for at least 15 per cent less per gallon than the denatured alcohol in order to compete with it. The minimum consumption values in gallons per hour per brake-horse-power for 80 per cent alcohol is approximately 17.5 per cent greater than for the denatured alcohol used, or for gasoline. A series of tests made with alcohol of various percentages by volume, ranging from 94 per cent to 50 per cent showed that the minimum consumption values in gallons per hour per brake-horse-power increased a little more rapidly than the alcohol decreased in percentage of pure alcohol. That is, the thermal efficiency decreased with the decrease in percentage of pure alcohol. This decrease in thermal efficiency or increase in consumption, referred to pure alcohol is, however, comparatively slight from 100 per cent alcohol down to about 80 per cent alcohol. Within these limits it may be neglected in making the calculations necessary to compare the minimum consumption values for tests with different percentages of alcohol.

The nearer the alcohol is to pure, the greater the maximum horse-power of the engine. The per cent reduction in maximum horse-power for 80 per cent alcohol as compared with that for denatured alcohol used was less than 1 per cent, but the starting and regulating difficulties are appreciably increased.

With suitable compression, mixtures of gasoline and alcohol vapors (double carbureters) gave thermal efficiencies ranging between that for gasoline (maximum 22.2 per cent) and that for alcohol (maximum 34.6 per cent) but in no case were they higher than that for alcohol. The above thermal efficiencies are calculated from the brake-horse-power and the low calorific value of the fuel, which for the gasoline was 19,100 British thermal units per pound and for the denatured alcohol was 10,500 British thermal units per pound.

As has been previously demonstrated, alcohol can be used with more or less satisfaction in stationary and marine gasoline engines, and these gasoline engines will use from one-and-one-half to two times as much alcohol as gasoline, when operating under the same conditions. The possibilities, however, of altering the ordinary gasoline engine as required to obtain the best economies with alcohol are very limited; for the amount that the compression can be raised without entirely redesigning the cylinder heads and valve arrangement is ordinarily not sufficient, nor are the gasoline engines usually built heavy enough to stand the maximum explosive pressures, which often reach 600 and 700 pounds per square inch. With the increase in weight for the same sized engine designed to use alcohol instead of gasoline, comes an increase in maximum horse-power of a little over thirty-five per cent, so that its weight per horse-power need not be greater than that of the gasoline engine, and probably will be less.

The work was taken up to investigate the characteristic action of fuels used in internal combustion engines with a detailed study of the action of each fuel (gasoline and alcohol) as governed by the many variable conditions of engine manipulation, design and equipment. These variables were isolated, so far as possible; their separate and combined effects were determined; worked out under practical operating conditions; and lead up to the conditions required for minimum fuel consumption. The results show the saving that can be obtained over conditions for maximum consumption, and also establish a definite basis of comparison under conditions most favorable to each fuel. This latter is a point of much commercial interest and a study of the comparative action of gasoline and alcohol may be of great service in solving some of the general internal combustion engine problems where other than liquid fuels are used.

Many of the tests of internal combustion engines have been made, but most of them, especially in this country, were by private concerns, for a specified purpose, and the results are not generally available. Furthermore, as is generally recognized by those familiar with gas and especially gasoline engine operation, the conditions influencing engine performance are so numerous and varied as to make the value of off-hand comparison very limited and oftentimes misleading, exact comparisons only being possible under identical conditions or with reference to the actual known differences in all conditions that influence the results.

This investigation was made with a view to supplying the continually increasing demand for more complete and exact information concerning the operation and design of gasoline and alcohol engines and to assist the Government and others interested in the larger and more general internal combustion engine problems.

GEAR-CUTTING MACHINERY—5.

RALPH E. FLANDERS *

This installment of this series of articles on gear-cutting machinery, continues the discussion of machines for cutting the teeth of worms, and of spiral and herring-bone gears, begun in the last issue.

Automatic Machines for Milling Helical Gears with Formed Cutters.

A number of full automatic machines have been built in an experimental way for milling spiral gears with formed cutters. They have usually been modelled after the automatic spur gear cutter. Evidently the mechanism has to be considerably more complicated. The first complication involved is due to the fact that the index wheel must be under the influence of both the helical and the indexing movements, as in the Reinecker machine in Figs. 85 and 86. The differential gearing there shown is the arrangement generally used to effect the combination of these movements in the automatic helical gear-cutter.

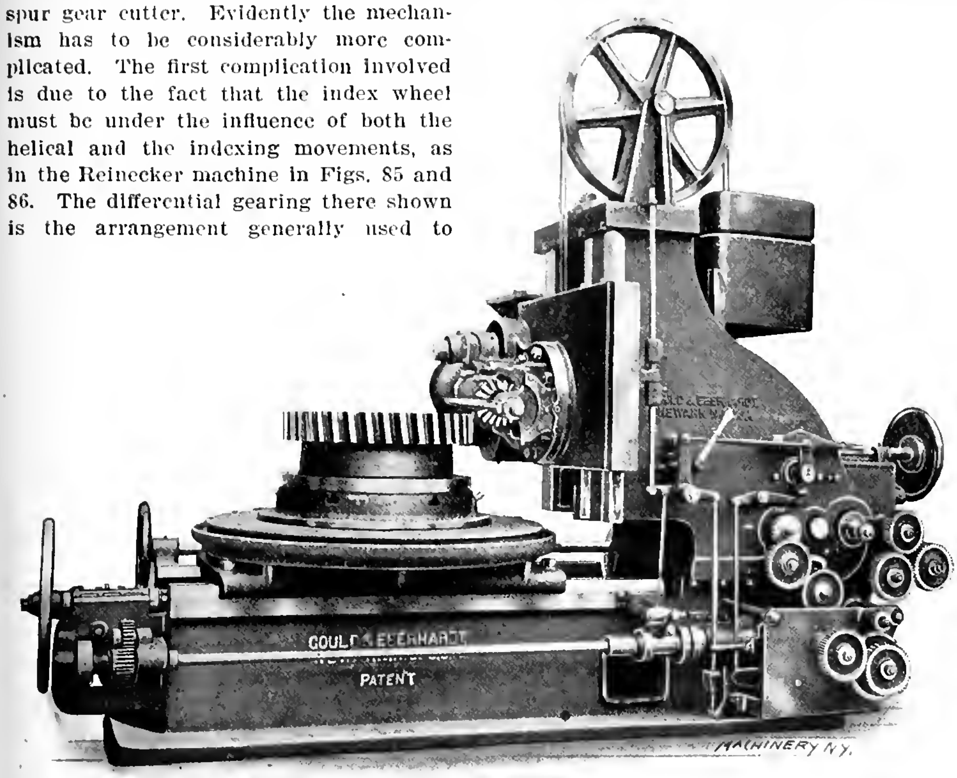

Fig. 91. Automatic Helical Gear-cutting Machine, made by Gould & Eberhardt.

Another complication is introduced by the necessity for relieving the cutter on its return stroke, after finishing the forward feed through the blank. Backlash in the rotating mechanism between the cutter slide and the work so alters the position of the cutter and the work on the return stroke, that the latter will drag on the one side of the groove it has just cut, unless it is separated slightly from it. This has been done in various ways in the various machines built; in some cases by mounting the cutter on a supplementary holder which rocks back out of the way on the return stroke, and in other cases by withdrawing the work by mechanism provided for the purpose.

These various complications seem to have militated against the commercial success of the automatic spiral gear cutting machine to such an extent that, so far as we know, but one of the various designs built has ever left the shop where it was made. The design we refer to is that shown in Fig. 91, built by Gould & Eberhardt of Newark, N. J. As will be seen, it is a machine of large capacity, built in the form of the horizontal machines for cutting spur gears, shown in Figs. 29 to 36. The cutter spindle is, of course, set in a swiveling head, and is driven by worm gearing. Three sets of change gears are used—one of them for the indexing mechanism, one for obtaining the proper lead of the helix, and one for changing the feed. The relieving mechanism operates as follows: As the cutter is being rapidly returned to allow the work to be indexed for a new cut, the work is withdrawn slightly from contact with the cutter by a cam actuated device, connected with the indexing mechanism. On the conclusion of the indexing, the work is again brought up to the cutting position, and the cutter is fed downward for a new tooth.

Molding-Generating Principle for Cutting Helical Gears—Planing Operations.

Passing by the templet, odontographic, and describing-generating principles, for the reasons mentioned in the introduction to this section (page 511), we come to the molding-generating principle. This is applied to helical gears in the same way as to spur gears, with such modifications as are necessary to allow for the helical shape of the teeth. The counterpart of Fig. 6 is shown in Fig. 92. The forming cutter and the blank to be cut are rolled together as in Fig. 6, while the forming cutter is reciprocated axially. In combination with the axial movement, however, the cutter has to be given a rocking movement about its center line, so that its teeth will follow the path of the dotted lines shown, which indicate the helix of the spiral gear which the cutter represents.

This process was contemplated by Mr. Fellows, of the Fellows Gear Shaper Co., in the original working out of his system of gear-cutting. Given suitable cutters, the necessary changes in the machine shown in Fig. 63, would simply be those involved in giving the cutter a rotary rocking motion in unison with its reciprocating movement, to compel the tooth to follow the line of the helix of the gear which the cutter represents. It is not probable that this process will ever come into commercial use, as the great number of helix angles required would involve too large a stock of cutters.

The counterpart of Fig. 7, for helical gears, is shown in Fig. 93. Here the forming rack has teeth set on the same angle as the helix angle desired in the gear being formed. The rolling of a plastic blank over this forming rack will form in the blank helical teeth of the shape desired. A top view of the rack is shown, which will make this clearer. Instead of the forming rack shown by the full lines, we may use one like that shown in the dotted lines, whose teeth coincide with those of the first, but which moves in a direction at right angles to the direction of its teeth. If this dotted rack is moved at such a rate of speed that its teeth always coincide with those of the rack shown in full lines, they will evidently both form teeth of exactly the same shape in the blank.

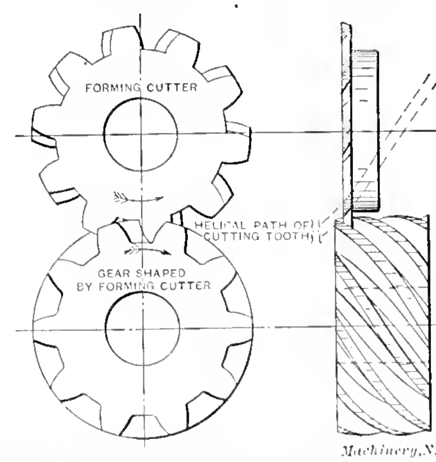

Fig. 92. The Molding-Generating Principle arranged to employ a Cutter having a Helical Shaping Action, cutting Teeth in a Solid Blank; compare with Fig. 6

In Fig. 94 we have the dotted rack of the top view of Fig. 93, shown engaged in the operation of generating the teeth of a

* Associate Editor of MACHINERY.

gear identical with that in Fig. 93. This view has been taken at an angle so as to show the normal view of the rack. If the proper relative rates of rotation of the work and movement of the rack are maintained in Figs. 93 and 94, and the normal sections of the racks in each case are the same, the gears generated will be the same. It is evident in Fig. 94 that the teeth of the rack may be replaced by shaper or planer tools T_1 and T_2, which may be used in forming teeth on the blank

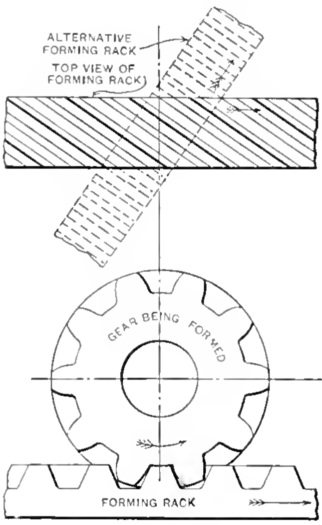

Fig. 93. A Rack with Teeth set on an Angle, Operating by Impression on the Molding-Generating Principle, to form Teeth in a Helical Gear; compare with Fig. 7.

Fig. 94. Shaper Tools representing Teeth of Imaginary Rack, Operating on the Molding-Generating Principle to generate Teeth in a Helical Gear; compare with Fig. 8.

by rotating the gear and moving the tools endwise, in the proper ratio prescribed by the conditions in Fig. 93. Fig. 94 is thus the counterpart of Fig. 8 for helical gearing. Similar counterparts may be drawn for Figs. 9 and 10, showing the milling and grinding processes, but since no practical application is made of these, they are omitted.

Fig. 94 is interesting in that it hints at the principle on which the action of the helical gearing is based. As drawn, it shows very plainly the action of the well-known Sellers drive for planers. It will be noted that for a short space the rack teeth exactly fill the outline of the gear tooth. Contact between the gear and the rack takes place on straight lines, running diagonally across the plane faces of the rack teeth. Much might be written about the contact between spiral gears and racks, and the contact of spiral gears with each other, that has not been published, so far as the writer is aware; but since this subject is not germane to the subject of this series of articles, it will not be touched on here.

Practical application has been made of the principle shown in Fig. 94. The Bilgram spiral gear planing machine, involving this principle, is shown in Fig. 95. The work is mounted on a spindle carried in a head, which swivels about a vertical axis so that it may be set to the helix angle of the gear being cut. The cutting tool, having a shape to represent a tooth of the imaginary generating rack, is carried by a ram which works in and out, cutting on the return stroke. This ram is carried by a head which is fed along the bed of the machine. This longitudinal feeding of the ram-carrying head is connected with the rotary movement of the work spindle by change gearing, in the proper ratio for the case in hand, so that the gear will roll with the movement of the head just as it would if it were acting under the influence of the imaginary rack, one of whose teeth is represented by the cutting tool. The conditions are thus exactly the same as in Fig. 94.

Under these conditions, if the machine is set properly, the cutting tool will start to work at one side of the blank, and pass through it, feeding at the end of each successive stroke, with the work rolling in such a way as to form a tooth space of the proper shape. This action is modified somewhat by the method of indexing adopted, which is the same as for the somewhat similar spur gear planing machine by the same builder, shown in Fig. 48. The arrangement used indexes the work at every stroke, so that when the tool has once passed through the work, the gear is entirely completed, every tooth having been worked on. This indexing movement and the rolling motion required for the generating are superimposed on each other by suitable mechanism so that neither interferes with the other.

It may be mentioned incidentally that this machine is the only one known to the writer in which *all* the requirements for theoretical accuracy in cutting helical gears have been taken care of. There is a minute, though actual, error involved in even the otherwise perfect hobbing process for cutting these gears.

The Hobbing Modification of the Molding-Generating Principle of Cutting Helical Gears.

Instead of using the shaper or planer tool to take the place of the teeth of the imaginary rack shown in Fig. 94, we may use a hob, in the same way that it was used in Fig. 50 for hobbing spur gears. This condition is shown in Fig. 96, which should be compared with Figs. 50 and 94. The upper or plan view best shows the respective angular settings of the work and the hob. The hob is set at an angle with the line of movement of the imaginary rack equal to its own helix angle, as for spur gears. The gear being cut is set at an angle with this same line equal to its own helix angle, so that in this case (in which both gear and hob are right-hand) they are set at an angle to each other equal to the difference between the helix angles. If the hob represented by the worm in the diagram is revolved in the direction shown, its teeth will have the same outline and the same movement as the teeth of an imaginary rack, moving in the direction shown. If the work be revolved in the proper ratio with the hob, the latter will form the teeth in the former in the same way that the imaginary rack would, provided it is fed progressively through the work in the direction of line X X.

This necessity for feeding the hob through the work introduces an added complexity to the machine in the case of

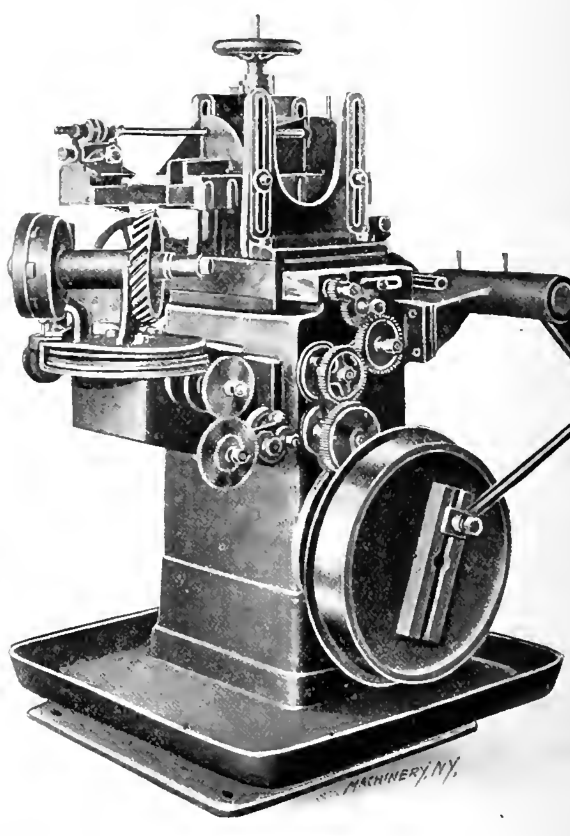

Fig 95. The Bilgram Machine for Cutting Helical Gears, operating on the Principle of Fig. 94.

spiral gears, beyond that needed for the spur gear hobbing machine. To understand this, suppose that in Fig. 96 the spindle mechanism is stopped, so that both the spindle and work ceased to revolve. To make it possible to feed the hob through the work in the direction of line X X without having the teeth of the one strike against the other, it will be necessary to revolve either the work or the hob. Suppose that the work be connected by change gearing with the feed-

screw of the cutter slide, so that it is revolved as the cutter is fed up or down, in the same way that the work in Fig. 81 is revolved as the table is fed backward and forward. Under these conditions, the cutter may be moved through the work freely, the latter revolving to allow the cutter to pass. Not only must the work revolve in a definite relation with

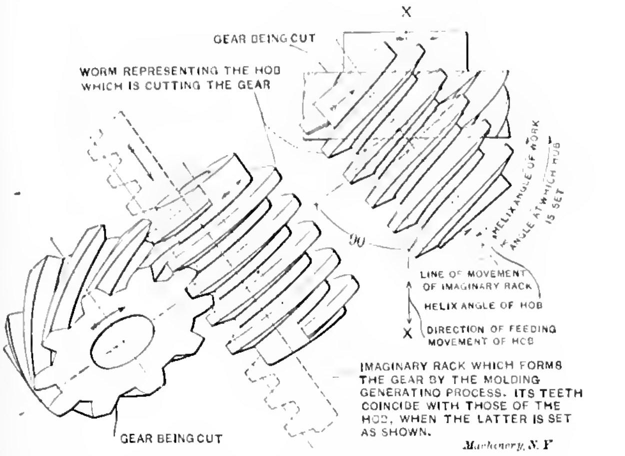

Fig. 96. Molding-Generating Method of Cutting Spiral Gears, as Exemplified in the Hobbing Process; compare with Figs. 50 and 94.

the feeding of the cutter slide, but the work must also revolve in unison with the cutter or hob, as for spur gears. It must then be so connected with the cutter and with the cutter slide feed-screw that it will be under the influence of either or both of them, without any interference of the two movements with each other. This connection is usually made by a "jack-in-the-box" or differential mechanism, exactly identical in principle with that shown in Fig. 86 for combining the indexing and helical feeding movements for revolving the work in the Reinecker universal machine. In the case of the spiral gear hobbing machine we have a helical feeding movement and a cutter spindle movement to combine for revolving the work.

A typical arrangement of the mechanism used for this purpose is shown in diagrammatic form in Fig. 97. Power is applied to the machine through driving shaft G. The bevel gears shown connect this driving shaft with vertical shaft H, by means of which the hob is driven. Change gears shown connect shaft G with shaft E. Considering for the time being that worm-wheel B and the attached bevel gear D are stationary, the rotation of E and the cross arm A keyed to it,

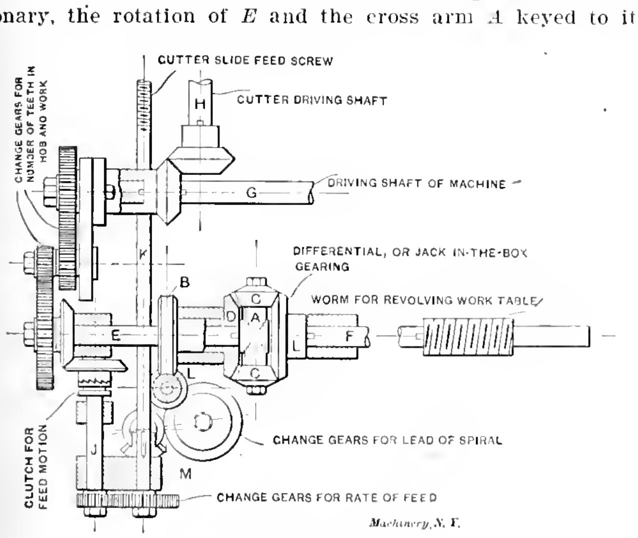

Fig. 97. Typical Arrangement of Gearing for Spiral Gear Hobbing Machine.

will cause bevel gears C to roll around on stationary gear D, thereby revolving gear L and shaft F to which it is keyed, thus rotating the work table. The change gears connecting G and E are selected to give the proper ratio of movement between the hob or cutter spindle and the work table, to agree with the number of threads in the hob and the number of teeth in the gear being cut. The cutter slide feed-screw K is connected by change gears with shaft J, which is, in turn, connected through the clutch and the bevel gears shown with shaft E. The clutch furnishes the means of stopping and starting the feed, and the change gears serve to give the rate of feed desired. Change gears are also provided connecting bevel gear M on feed-screw K, with worm L, which drives worm-wheel B, running loosely on shaft E. By this means, supposing for the moment that shaft E and its attached cross arm A are stationary, the rotation of the feed screw is communicated through the change gears to worm-wheel B and its attached bevel gear D, which, driving bevel pinions C on their stationary studs, revolve gear L, and with it shaft F and the worm driving the work table. In this way, by selecting suitable change gears, the work may be revolved to agree with the length of the lead of the spiral on which its teeth are formed, so that the cutter may be fed up and down through it without interfering with the teeth.

We thus see that the mechanism shown in Fig. 97 may be arranged to connect the hob and the work in the proper ratio, as for cutting spur gears, and also for connecting the feed-screw and the work in the proper ratio as for cutting spiral gears in the milling machine. But this mechanism not only performs these two functions separately, but it will perform them together, as well, so that either the feed or the cutter

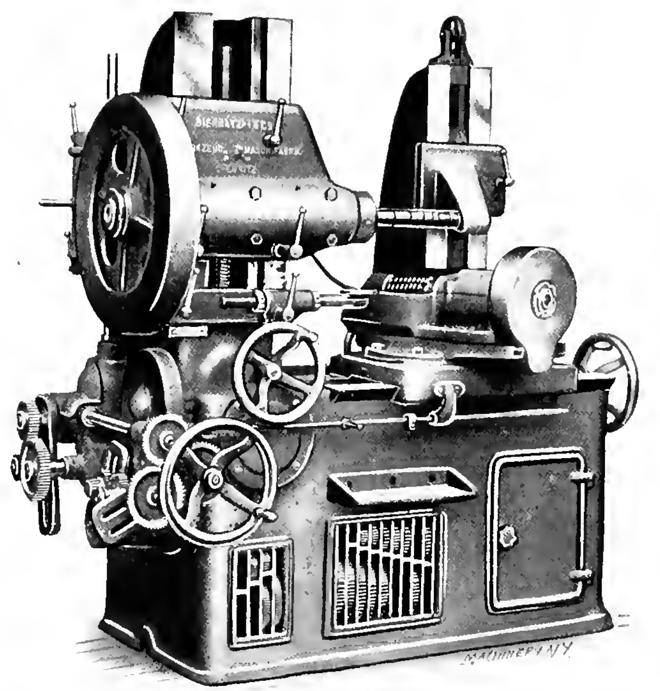

Fig. 98. Biernatzki Gear-hobbing Machine.

revolving mechanism may be started, stopped or reversed independently of the other movement, and the work will still be properly controlled under all conditions. The mechanism shown is not that invariably used, but it is typical of the arrangement employed in many hobbing machines designed for cutting helical gearing.

Hobbing Machines with Cutter Slide on Bed.

The first hobbing machine for spiral gears we show is that in Fig. 98, made by Biernatzki & Co., 60 Zschopauerstrasse, Chemnitz, Germany. This machine is built on the general lines of the orthodox automatic spur gear cutter shown in Figs. 21 to 28. The machine is stiffly constructed, the column and head being apparently made in one piece. A noticeable feature is the rigid construction of the outer work support. In a smaller size machine this is mounted on the front of the bed, but in the case shown it is supported on ways at the rear, behind the cutter slide. A rack and pinion movement, operated by hand-wheel, is provided for moving it toward or away from the column. This rapid adjustment is very convenient in changing the work. Three sets of change gears are used, as in Fig. 97. Those just behind the hand wheel at the left are set for the lead of the spiral, those at the end of the bed are set for the feed of the cutter, while the ones at the rear are altered to give the proper ratio of movement for the number of teeth in the work and the hob. The arrangement of the machine in general is the same as

for its prototype, the automatic gear-cutter. One point of difference which may be noted is made necessary by the fact that the work is constantly revolving, instead of being intermittently indexed. The work support clamped to the face of the column in the regular gear-cutter is usually a simple abutment, adjusted by screw and nut to support the work against the thrust of the cutter. In this case, as may be seen, the support carries a disk or roller against which the work bears as it revolves.

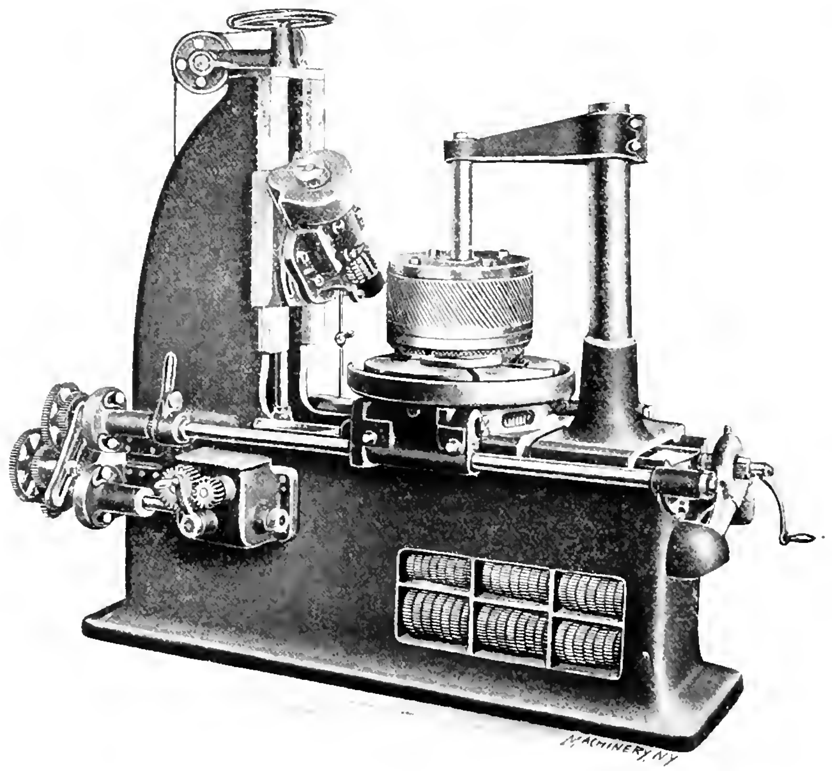

Fig. 99. Gear-hobbing Machine, made by Gould & Eberhardt, Newark, N. J.

Horizontal Form of Gear-hobbing Machines.

The Gould & Eberhardt hobbing machine, shown in Fig. 99, has previously been described in MACHINERY.* In this machine the "horizontal" form of construction has been adopted, in which the work is carried by a slide adjusted longitudinally on the top of the bed, while the cutter slide is mounted on the face of a vertical column, following thus the general plan of the machines shown in Figs. 30 to 39, and 53 to 57. This machine is rigidly constructed, the column and bed being in one piece, and special attention being given to the construction of the cutter head and work table to give the stiffness so necessary for accuracy and output in a machine of this kind. The outboard support for the work is particularly noticeable. It consists of a heavy post, carried by a slide working on the same ways as the work table, to which it may be connected to form one piece. A rapid traverse for the cutter head is provided, so that it is ordinarily unnecessary to operate the feed of the cutter slide manually. The cutter head may be swung around through an angle of 180 degrees above the horizontal. With this arrangement, the driving gear is always above the center line of the head, so that less clearance is required below the work. This means that blanks can be held down closer to the table, giving less overhang and greater rigidity. In Fig. 100 this machine is shown hobbing spiral gears.

In Fig. 101 we show a machine built by Holroyd & Co., Ltd., of Milnrow, near Rochdale, England. The engraving shows a spur gear in the machine having its teeth hobbed, but provision is made for hobbing spiral gears as well. As may be seen, the cutter spindle is driven by an internal gear of large diameter. The engraving shows quite plainly the usual method followed of supporting work in machines of this type. The work is centralized with the table by the arbor which passes through it, but most of the support is taken by brackets mounted on the table or face-plate, and provided with T-slots in their upper faces by which the work is clamped to them. This arrangement makes the work practically solid with the face-plate.

Of the three shafts extending along the front side of the bed, the lower one (E in Fig. 97) is connected with the cutter driving mechanism and drives through change and differential gearing the upper of the three shafts (F in Fig. 97) which is connected with the index worm of the work table. A place for change gearing will be seen at the base of the column carrying the cutter slide. This connects the feed movement of the cutter with the central shaft (L in Fig. 97) which in turn is connected with differential gearing in the enclosed casing seen at the right-hand end of the bed, in the foreground. In this, as well as in previous machines shown, provision is also made for hobbing worm gearing, the mechanism being introduced at the right-hand end of the bed for this purpose. Reference will be made to this later.

A still larger size of this machine is made, though for spur and worm gears only. This will operate on blanks up to 72 inches in diameter, and will cut gears up to 2 inches circular pitch by the hobbing process. The makers state that with these machines, the time for cutting a cast iron wheel of 84 teeth, 4 inches circular pitch, 21½ inches face, was 1 hour 21 minutes. Another one of the same pitch with 144 teeth, 3 inches wide, took 2 hours. Reckoning on the basis of 84 teeth, this would make about 6 inches feed per minute, and allowing for about 3 feet a minute quick return, an automatic gear-cutter would barely be able to accomplish this.

In both of these machines provision is made for intermittent indexing, so that a formed gear-cutter can be used. For this purpose the lower shaft in Fig. 101 may be driven through a friction slip if desired. The lever shown below the differential gear box at the right-hand end may be used to release or arrest a disk keyed to this shaft, so that it may be allowed to make one revolution when desired. The change gears at the end of the machine are then set for the number of teeth required. Under these conditions it will be seen that it may be used for gear-cutting by the formed cutter method, being then practically the same sort of machine as those illustrated in Figs. 33 to 36, except that it is not fully automatic.

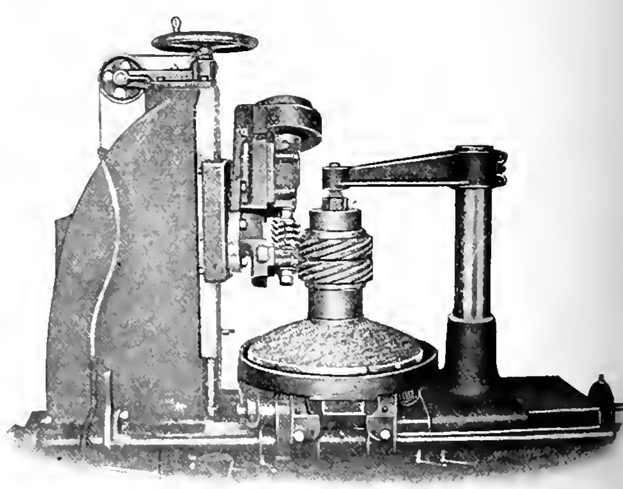

Fig. 100. Gould & Eberhardt Machine cutting Spiral Gears.

In Fig. 102 is shown a gear-hobbing machine* built by the Newton Machine Tool Works, Inc., Philadelphia, Pa. It is shown at work on a spiral gear, which is supported in a somewhat different manner from the cases previously shown.

* See "New Machinery and Tools" in the November, 1907, issue of MACHINERY.

* See "New Machinery and Tools" in the December, 1907, issue of MACHINERY.

A special support, in the form of a cast sleeve or column, is provided for raising the work high enough above the table so that the driving gear of the spindle clears the table when the cutter has been fed through the work. In cutting spur gears, of course, it is not necessary to set the work so far above the table, less clearance being required for the spindle driving gear.

The Pfauder machine, shown in Fig. 103, is sold by Schuchardt & Schütte of New York, Berlin, London, etc. The differential mechanism is shown quite plainly in this engraving, which represents the No. 4 machine. The change gearing above the index worm shaft is for the lead of the helix, that below, for the feed, while the larger gearing at the left end of the machine is for connecting the hob and the work in the proper ratio. The cutter spindle of this machine is driven by herring-bone gears to insure smoothness of action. This line of machines is made in a great range of sizes. The smallest of these has a maximum capacity for a blank 6 inches in diameter, while the largest will take a gear 101 inches in diameter. Provision is made in the larger sizes for intermittent indexing of the work table by hand, so that the teeth may be cut by formed cutters if desired. The swiveling head is adjusted by a worm on the larger sizes.

Hobbing Machines of Special Types.

The machine shown in Fig. 104, made by the Grant-Lees Machine Co., 6901 Quincy Avenue, Cleveland, Ohio, cannot be classified structurally with any of the previous examples. It is an outgrowth from a hobbing machine for worm gears, formerly built by its designer, Mr. John Grant. It has previously been described in MACHINERY* where its novel features have been explained. The work is mounted on a vertical spindle, carried by a slide which is adjusted horizontally for the diameter. The feed of the cutter through the work is effected by raising the spindle vertically. The cutter is driven by a combination of bevel gears which is best shown in Fig. 105, and it may be adjusted throughout a full circle. The bevel gear on the hob spindle meshes with a large ring bevel gear, which in turn is driven by a bevel pinion on the driving shaft. The bevel pinion on the hob shaft occupies a different portion of the ring bevel gear from that occupied by the driving pinion, so it may be adjusted around the full circle without interference. Provision has been made in the mechanism to revolve the work as it is fed upward, independently of the movement given by its connection with the hob, thus meeting the requirements for spiral or helical milling. The machine is shown in Fig. 105, completing a helical gear.

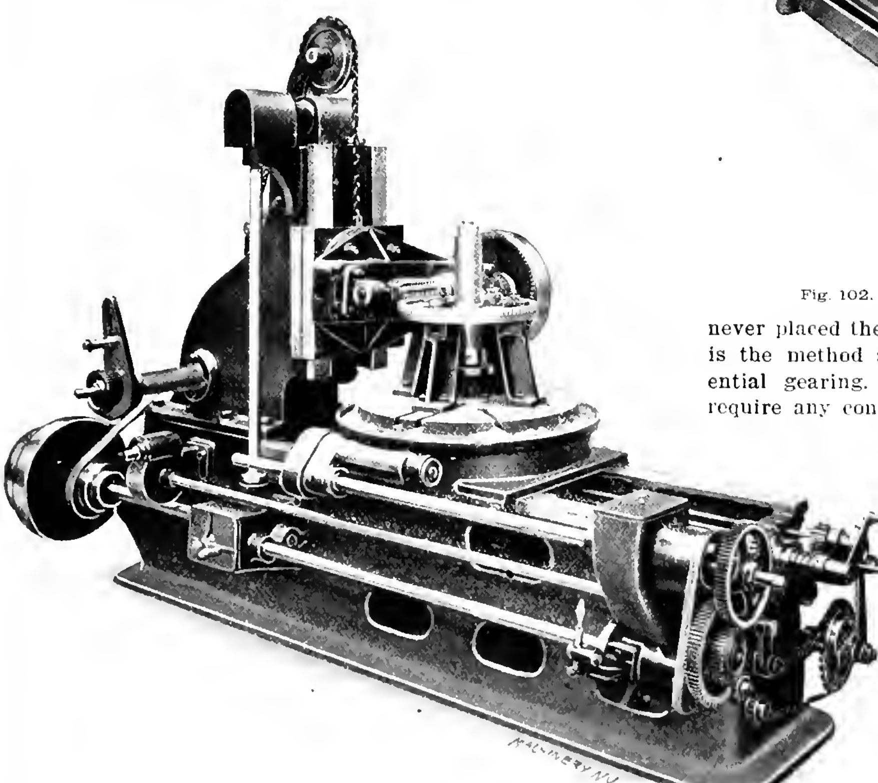

Fig 101. Holroyd Gear-hobbing Machine. Though shown cutting Spur Gears, it will cut Helical Gears as well

A gear-hobbing machine, built by Geo. Juengst & Sons, Croton Falls, N. Y., is decidedly worthy of study on account of the unique principle involved, although the builders have never placed the machine on the market. The unique feature is the method adopted for avoiding the necessity for differential gearing. The spur gear hobbing machine does not require any connection between the feed-screw and the work-revolving mechanism, because the hob can be fed back and forth through the work after it has been completed, without interference. In the Juengst machine the same effect is accomplished by setting the feeding movement at the angle of the teeth of the work. As is shown in Fig. 106, the work is mounted on the column, while the cutter, which may be swiveled to agree with its helix angle, is fed along a slide which may be, in turn, swiveled to agree with the helix angle of the work. The line of travel of the hob, as shown in Fig. 107, being thus set in the same direction as the teeth of the gear, the hob can be fed diagonally through the work without interfering with the teeth, whether the machine is in motion or not, it being taken for granted, of course, that the hob and the work are properly geared together. Differential gearing is thus done away with, being replaced by the swiveling adjustment of the cutter slide, which permits the line of travel of the hob to be adjusted to the helix angle of the work.

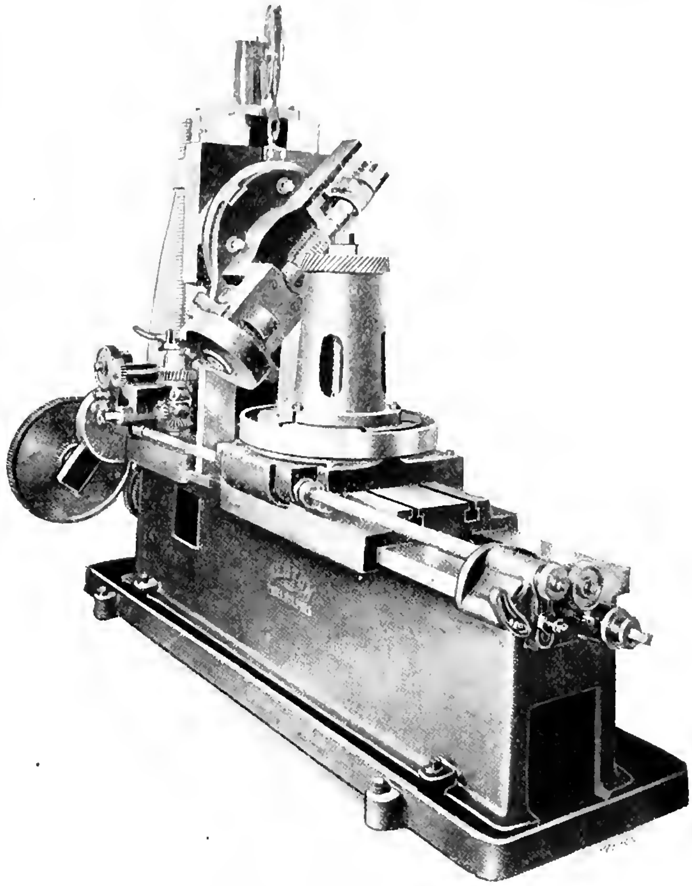

Fig. 102. Newton Machine at Work on a Helical Gear.

This same result has been accomplished in another way by a patent granted to an English inventor. With his arrangement the work is mounted on a table on the bed, while the cutter slide feeds up and down the column as in the orthodox arrangement for hobbing machines, shown in Figs. 53 to 56

* See "New Machinery and Tools" in the October, 1907, issue of MACHINERY.

and 99 to 103. The column, however, instead of being solid with or bolted to the bed, is mounted on ways so that it may be fed horizontally at right angles to the line of adjustment of the work table. The feed-screw controlling this adjustment is connected by change gearing with the vertical feed-screw of the cutter slide on the column, so that these two movements take place simultaneously in any desired ratio

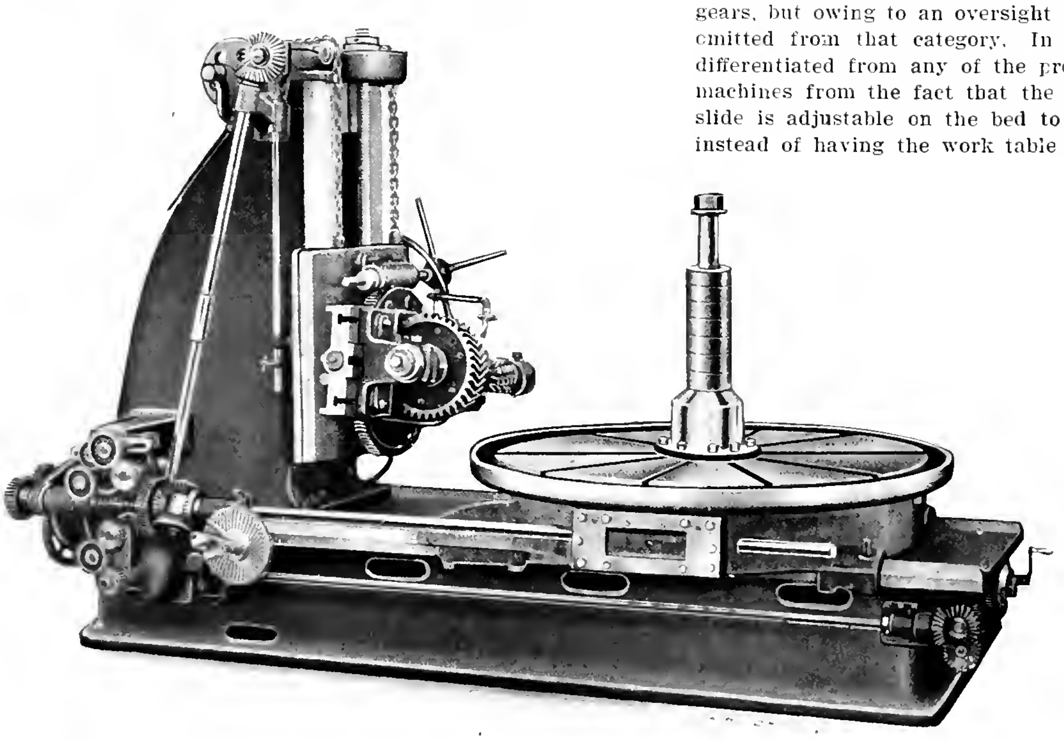

Fig. 103. Pfauder Gear-hobbing Machine, sold by Schuchardt & Schutte.

with each other. By this means the combined vertical and horizontal movements of the cutter slide give a component in an angular direction, which may be made to give any desired angle of travel, such as that shown, for instance, in the line of travel of the hob in the Juengst machine, Fig. 107.

The difficulty with this otherwise attractive plan for hobbing helical gears by moving the hob at an angle instead of using differential gearing, appears to be that a longer hob is required for going in an angular direction across the face of the gear, than would be necessary in feeding vertically downward, as is the case with the usual differential mechanism. The hob would have to be unusually long if it were desired to cut a bank of spiral gears in one operation, as is being done in Fig. 99.

There are still other methods possible for taking care of the helical movements required besides those already discussed. For instance, instead of using differential gearing to combine the motion derived from the feed-screw with that of the index worm shaft, it may be used to combine movements derived from the feed-screw with that of the cutter spindle driving shaft. Furthermore, the differential mechanism may be discarded entirely, by providing an index worm of considerable length and shifting it longitudinally at the proper rate in connection with the feeding of the cutter slide. This would impose on the work rotation in connection with the cutter slide feed without interfering in any way with the rotation due to the connection with the cutter or hob. Differential gearing would thus be avoided as in the case of the Juengst machine. This device would have its limitations for gears of small lead, as it would require too great a length of worm to give the proper amount of rotation to the work.

Another interesting spiral gear hobbing machine which has been described in MACHINERY* is that furnished by the Pratt & Whitney Co., of Hartford, Conn., for cutting the wonderful herring-bone gears, run at such tremendous speed in the De Laval steam turbine. A particular feature of this machine was the provision for correcting by a link motion the slight inaccuracies inherent in the use of change gears for obtaining exactly the lead required for the helical teeth it is desired to cut.

In Fig. 108 is shown a gear-hobbing machine made by Maschinen Fabrik Lorenz, Ettlingen, Baden, Germany. This machine should properly be shown among the spur gear hobbing machines, as no provision is made for hobbing helical gears, but owing to an oversight on the writer's part, it was omitted from that category. In its structural design, it is differentiated from any of the previous examples of hobbing machines from the fact that the column carrying the cutter slide is adjustable on the bed to the diameter of the work, instead of having the work table adjustable. In this respect it resembles the hobbing spur gear cutting machines using formed cutters, illustrated in Figs. 37, 38, and 39. The machine is made in several sizes. The example shown, which is next to the largest size, will take work up to 110 inches in diameter.

Spiral gearing is cut on this machine in a way analogous to that followed in the Reinecker universal machine shown in Figs. 85 and 86, although the provisions for indexing are entirely different. A formed cutter is used, which is fed down through the work, the latter being revolved in unison with the feeding as in the case of the universal miller. The indexing is then effected by change gears and the one revolution crank shown at the side of the base in the engraving. In indexing, the dividing worm is connected with the index gearing and disconnected from the spiral mechanism; after

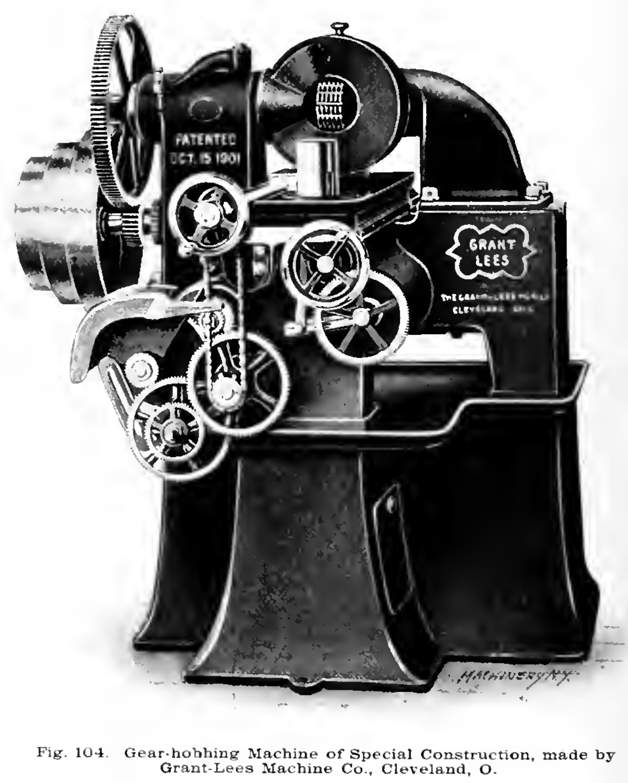

Fig. 104. Gear-hobbing Machine of Special Construction, made by Grant-Lees Machine Co., Cleveland, O.

the indexing, the connection is again made with the spiral mechanism, while the indexing motion is released. The index or work-driving worm-wheel is of bronze, driven by a worm of special construction, which the builders claim gives a much more durable contact than is ordinarily obtained.

* See "The De Laval Steam Turbine and its Manufacture" in the November, 1904, issue of MACHINERY.

It would appear from the drawings furnished the writer that the Reinecker universal gear-cutting machine (see Figs. 85 and 86) could be arranged to hob spiral gears by the simple expedient of connecting the indexing change gear train positively with the cutter driving mechanism instead of through the friction slip used for the semi-automatic indexing. This would give a combination identical in principle with that shown in Fig. 96. Probably the matter of German patent infringements accounts for not using the machine for hobbing spiral gears.

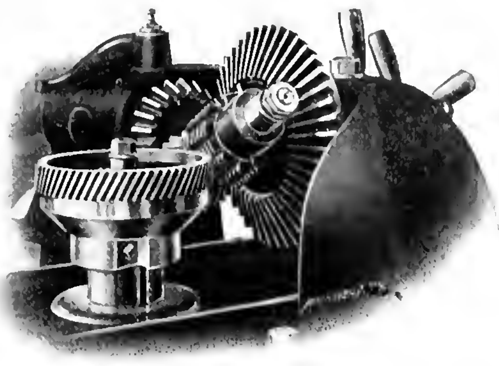

Fig. 105. Grant-Lees Machine hobbing a Helical Gear.

Besides the machines we have just described, two of the hobbing machines illustrated and described under the heading of spur gear machinery are adapted to the cutting of helical gears as well. These machines are the Rhenania machine shown in Fig. 54, and the Wallwork machine shown in Fig. 56. The only change necessary to adapt these machines to cutting spiral gears is the addition of the differential gearing, and the connection for change gearing between the feed-screw and the work table revolving arm. Provision is made for this mechanism in the design of the machines. Of course all of the hobbing machines we have described are adapted for cutting spur gears, and those shown in this installment of this series should be included in the list when studying spur gear cutting machinery.

The Field of the Hobbing Process for Cutting Helical and Herring-bone Gears.

There are some limitations to the hobbing process of cutting helical gears. It is not particularly successful in the cutting of gears of such small lead and great helix angle that they would be classed as worms, rather than spiral gears. For such cases, the rate of rotation which has to be given the blank is so great in proportion to the downward feed of the cutter by which the rotation is effected (through the change and differential gearing) that it is almost impossible to drive it, the difficulty being the same in kind, though reversed in direction, as that met with in cutting very steep pitches in the lathe. By a slight complication of the machine, however, mechanism could be introduced to overcome this difficulty, and make the hobbing machine universal for all kinds of gears within its range.

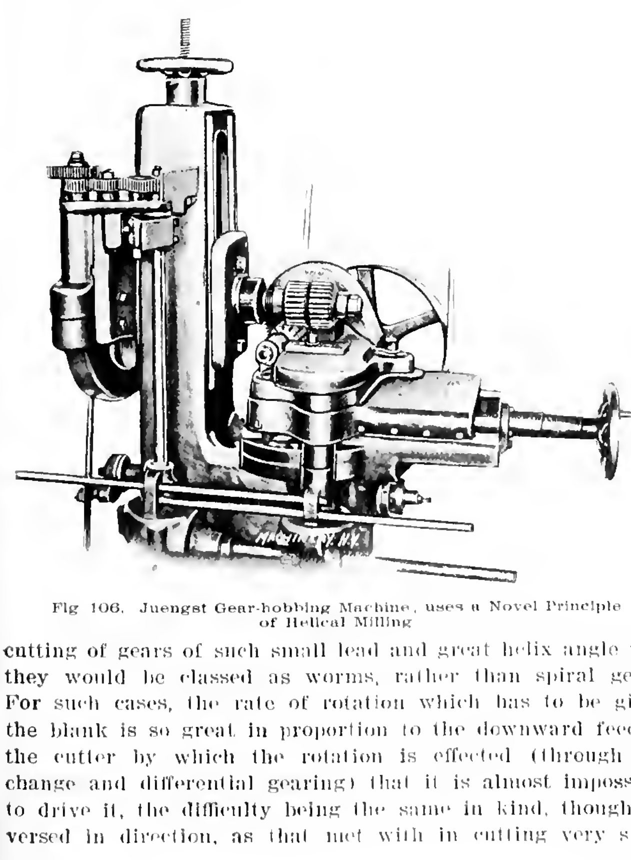

Fig. 106. Juengst Gear-hobbing Machine, uses a Novel Principle of Helical Milling

In the discussion of the hobbing processes for cutting spur gears, it was stated that its field was not yet definitely determined. It may be said, on the whole, that there is no such indefiniteness in regard to the field of the hobbing machine for cutting helical gears. With a well-constructed machine and with hobs of proper shape, spiral gears can be cut more accurately and cheaply by this method than by any other known. There are none of the mechanical difficulties of indexing and relieving to be taken care of as is the case in automatic machines working on the formed cutter process; and there are none of the uncertainties as to tooth shape due to interference met with in cutting a helical groove with a formed cutter, as shown in Fig. 80. There has been some little difficulty in getting the correct shape of teeth by the hobbing process, due to the elasticity of the mechanism connecting the hob and the work, and to errors in the construction of the hob itself. These difficulties, however, will surely disappear with further experience and investigation.

Apparently the recent rapid development of the hobbing process for cutting spiral gears is the solution of a problem which has long seemed somewhat perplexing. The flexibility of the spiral gear, and the numerous advantages of the herring-bone or the twisted tooth spur gear for transmitting great power noiselessly and smoothly even at high velocities, have long been appreciated, but their extended use has waited for the development of some accurate and inexpensive method of forming helical teeth.

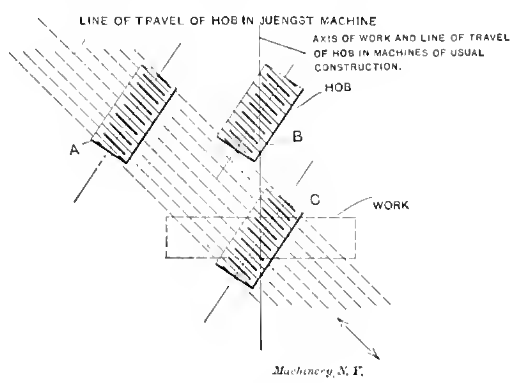

Fig. 107. Method of Feeding the Hob in the Juengst Machine

MACHINES FOR FORMING THE TEETH OF WORM-WHEELS.

To correctly classify and comprehend the various methods and machines for cutting the teeth of worm-wheels, it is first necessary to clearly define the term "worm gearing." We will consider that by worm gearing we mean gearing of the type of which a cross-section is shown at the right of Fig. 109, in which the acting face of the wheel is curved to fit the form of the worm, and in which the whole width of the wheel face is in active working contact with the worm.

The action is best understood by taking vertical sections on the center line *A-A*, and other lines such as that at *B-B*, parallel with the center line. Sections on lines *A-A* and *B-B* are shown at the right of the cut. With worm gearing of standard form, the section on line *A-A* shows the worm to have the profile of an involute rack, while the teeth of the wheel show outlines identical with those of the corresponding involute gear of the same pitch and number of teeth, suited to engage with the rack. In other words, the teeth of the gear are such as would be formed by the teeth of the worm if the latter acted as a rack in a molding-generating operation identical with that shown in Fig. 7. A section on line *B-B* shows that the teeth of the worm have a distorted outline on planes removed from the axial plane. If we consider these distorted teeth as the teeth of a rack, molding their mating tooth spaces in a gear running on the same center as the worm gear and at the same speed, it will form, by the process of Fig. 7, the distorted wheel teeth shown

for the section on line *B-B*. In a word, each section of the worm parallel to the axial section *A-A*, is a rack section, which molds in the wheel below it the proper teeth to mesh with it in accurate conjugate action. The true worm-wheel, it is thus seen, must be formed by the molding-generating process.

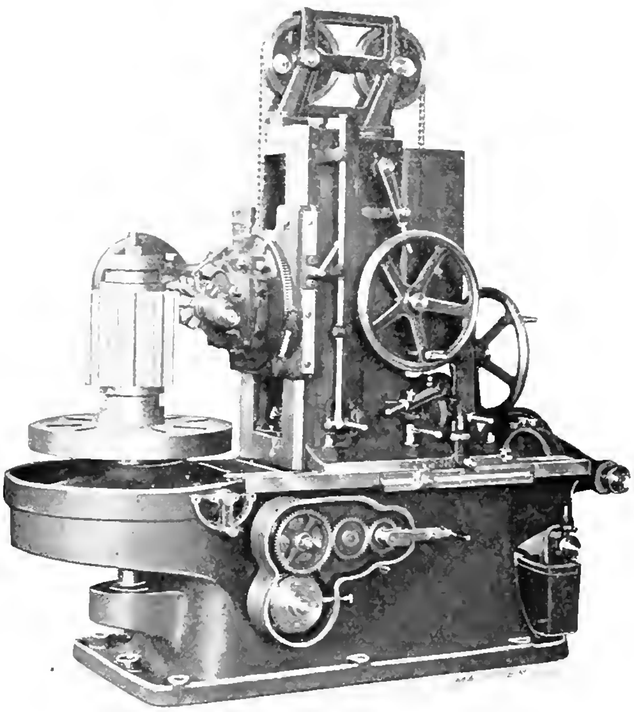

Fig. 108. Lorenz Gear-hobbing Machine.

The same worm as that shown in Fig. 109 may be made to engage with a spiral gear of the same number of teeth as the worm-wheel, provided the teeth are of the proper pitch and set at an angle to agree with the helix angle of the worm. The action of such gearing, however, does not, like that in Fig. 109, take place on all sections *A-A*, *B-B*, etc., but is confined to a point at or near the center line *A-A*. The contact, in other words, is point contact, and not line contact extending clear across the face of the wheel. Such a combination, in fact, is not a case of worm gearing, but a case of spiral gearing—and a very poor case at that.

Gashing Worm-wheels by the Formed Cutter Process.

While the method of forming a true worm-wheel is thus seen to be accurately performed only by the molding-generating process, the accurate teeth produced by that process may

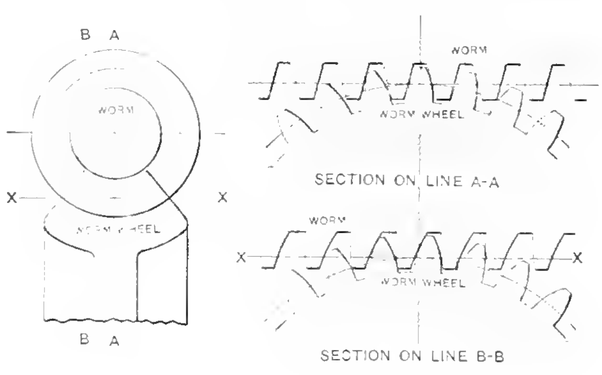

Fig. 109. Action of a True Worm-wheel.

be closely approximated in many cases by the "gashing" method, which belongs in the formed cutter classification. In this operation, illustrated in Fig. 110, a milling cutter is used, having approximately the outline of a normal section of the teeth of the worm to be used. This cutter is of the same diameter as the worm, and is set with relation to the axis of the work at the helix angle of the worm, as measured on the pitch line. It is centered over the wheel, and fed into the latter to the proper depth to form a tooth space; it is then drawn out again, the work is indexed to the next tooth space, and the cutter again sunk in to depth, the operation being repeated until the wheel is completed. In Fig. 110 a universal milling machine is being used for this operation.

With the table set at 90 degrees, the cutter is first brought centrally over the work arbor by adjusting the saddle on the knee of the milling machine, and then the work is brought centrally with the cutter arbor by adjusting the table by the feed-screw. The work table is next swung to the helix angle of the worm which is to be used with the wheel. Then the cutting is proceeded with.

This gashing process gives a tooth very closely approximating the true tooth form, when the diameter of the worm is large as compared with the pitch, and when the worm is single threaded. For multiple threaded worms of smaller diameter in proportion to their pitch, the process is impracticable. This method is used by at least one of the best known builders of gear-cutting machines in forming the teeth in the index worm-wheel. It is used under the conditions which give a very close approximation to the true form of tooth, and is employed in this particular case for the sake of the high degree of accuracy obtainable. The index wheel is divided, in cutting, by a carefully-made and carefully-preserved master wheel. The step by step gashing process allows the spacings of this superior master wheel to be accurately reproduced in the index wheel being cut—more accurately

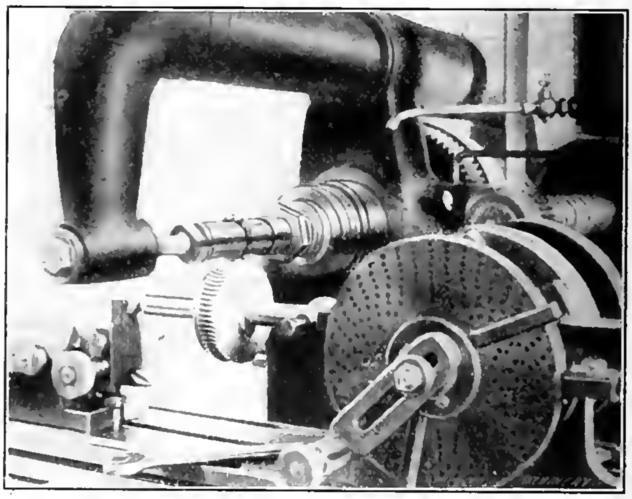

Fig. 110. Gashing a Worm-wheel in the Milling Machine.

than would be possible if it were to be reproduced by the hobbing operation.

The gashing process is also used for roughing out worm-wheels preparatory to hobbing. In a previously gashed wheel, as will be explained later, the hobbing operation is one of extreme simplicity, not requiring special machines or mechanism of any kind.

The discussion of methods and machines for hobbing worm-wheels will be continued in the next issue of MACHINERY.

* * *

The Northern Railway of France has recently conducted some tests for the purpose of comparing the superiority of locomotives of the 4-cylinder double bogie Mallet type, with two 6- and 8-wheel coupled freight engines of smaller design. According to the *Mechanical Engineer*, the tests were made on two trains weighing each 950 tons One was hauled by the two smaller engines, and the other by one Mallet locomotive. The trials extended over a period of six months, the distance run being about 12,500 miles in each case. The fuel consumed by the Mallet engine cost $458, as compared with $582 for the two smaller engines. The cost of lubricants and up-keep cost for the Mallet engine amounted to $85 as compared with $90 for the smaller engines. The wages for the men employed on the Mallet engine amounted to $219, as compared with $369 for the smaller engines. Thus, the total sum of running expenses for the Mallet engine amounted to $762, as compared with $1,041 for the 6- and 8-coupled engines, running in tandem. The first cost of the Mallet engine was $23,300, and the two 6- and 8-coupled engines used cost, together, $30,100, so that the capital saved by using engines of the newer type is nearly $7,000 per locomotive.

NOTES FROM THE NEW SHOPS OF THE HEALD MACHINE CO.

The Heald Machine Co. was incorporated in September, 1903, and succeeded to the business of L. S. Heald & Son, of Barre, Mass. The business in Barre was established by Stephen Heald in 1830, and for forty or fifty years this shop was the principal machine shop within a radius of 20 or 25 miles. While the business consisted largely of building agricultural and wood-working machinery and doing work of a local nature, large numbers of wire-drawing machines were constructed, which were sold to the most up-to-date wire manufacturers of that time. A foundry was also established in connection with the machine shop and at that time was the only foundry within a radius of 25 miles, all iron and coal being teamed that distance from the nearest railroad.

About 1860, two sons of Stephen Heald were taken into partnership under the firm name of S. Heald & Sons. In 1890, after the death of Stephen Heald, one of his sons, Leander S. Heald and his son, Jas. N. Heald, carried on the business under the firm name of L. S. Heald & Son until the year 1903, when the need of better shipping facilities (the nearest railroad then being located three miles from the factory), better labor market, and growth of the business, led to its removal to the city of Worcester, the senior partner, L. S. Heald, selling his interest to his son, Jas. N. Heald, who organized the company known as the Heald Machine Company, of which he is treasurer and manager.

For the last twenty years special attention has been given to the manufacture of grinding machinery, the line first beginning with the American twist drill grinder, which has had a wide sale, not only in this country but also in many foreign countries. Later, this line was increased by a line of grinding attachments and center grinders for use in connection with lathes, and later yet a line of ring and surface grinders was brought out for grinding piston rings, disks, dies, and similar work, this being known as the Heald ring and surface grinder. The attention of the company was then called to the importance of furnishing the automobile manufacturers with a machine which would grind the interior of the cylinders for their engines so that a better surface could be produced than by boring and reaming.

While previous practice in steam engines having thick cylinder walls had been to smooth bore for a finish, and, in some of the smaller sizes, ream for the same purpose, this was not a satisfactory method in finishing automobile engine cylinders having thin walls which spring under the pressure of the boring tool and reamer. Therefore, a method of finishing these cylinders which would produce a more perfect surface and uniform diameters was greatly needed. The company took up the study of the problem and developed a machine for accomplishing this work, known as the Heald cylinder grinder. This machine has been adopted by almost all the leading automobile manufacturers of this country, and many of the machines have been shipped to England, France, Germany, and Italy for the same service. The latest tool brought out by the company is a new internal grinder which has just been put on the market.

Fig. 1. View of Central Bay in the Heald Machine Co.'s Shop, showing Section devoted to Assembling of Machines

Fig. 5 shows the well-known cylinder grinder built by the company, under inspection test. It will be noted that the machine is built according to the unit system,—that is to say, the different portions are grouped into units as shown in Fig. 6, which is a part of the latest machine brought out. These units are afterward assembled to the frame or bed by suitable fastenings. This accords with the most modern practice and is undoubtedly a time-saver. Carborundum wheels are recommended for internal grinding on cast iron parts. The writer noted, however, that the carborundum wheels in

stock were not made by the producers of carborundum, but by another firm.

The works of the company are located in Greendale, a suburb of Worcester, directly across the street from the works of the Norton Co., and the Norton Grinding Co., making a sort of grinding settlement at this point. The shops were enlarged during the past summer, an addition of 150 feet by 90 feet being made to the main building, and wash room and toilet rooms covering a space of 30 feet by 45 feet being built in addition. This, with the new power house 26 feet by 43 feet, gives a total floor area, at the present time, of over 28,000 square feet. The number of employes before the present falling off in business was from 90 to 100.

In regard to shipping facilities, the works are located directly on the spur of the Boston & Maine Railroad system, so that cars are loaded directly at the door for shipment to any section of the country. The cuts, Figs. 1 and 2, show two views of the general arrangement of the shop. All the rooms are well lighted and ventilated, and this, together with the modern wash-room, Fig. 3, makes a very pleasant place in which to work. In all the arrangements for handling the work a complete business system is maintained, and the exact standing of manufacture in any or all of the departments is known at all times.

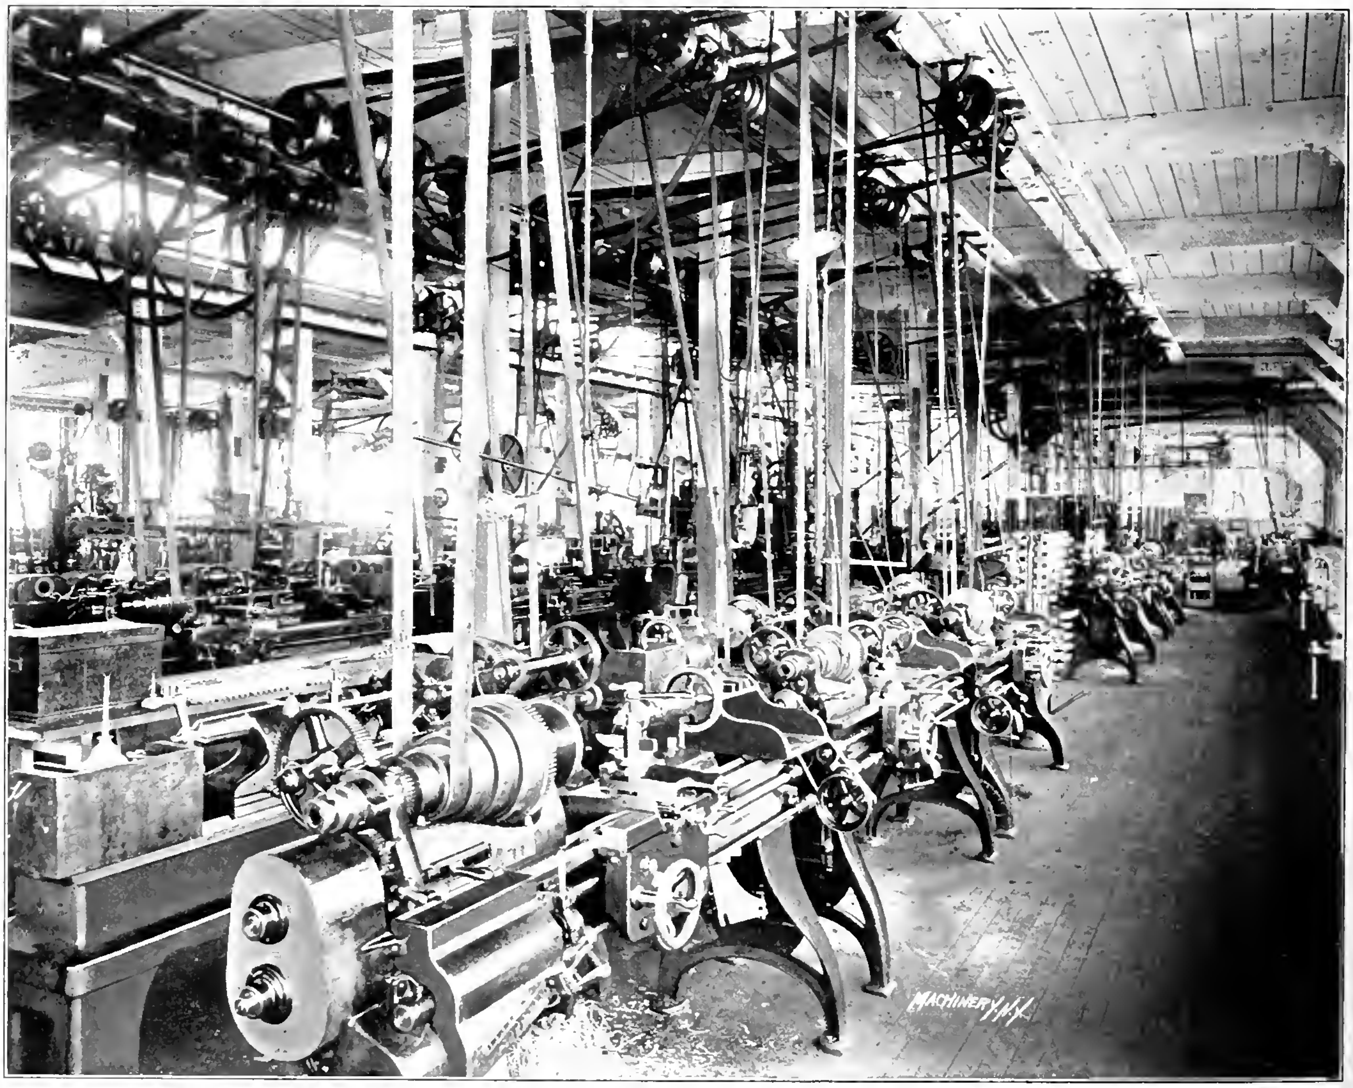

Fig 2 Lathe Department, showing the Light and Neat Appearance of the Factory.

Outline of the Heald Machine Co.'s Shop System.

In originating the stores system in use in the factory, the Heald Co. goes on the principle that a satisfactory cost system and a well-kept and well-organized stores-room go hand in hand. Fig. 4 shows a rack for holding bar stock. As this stock is of varying grades, each bar has its own color denoting its particular grade. For example, soft machine steel might be denoted by yellow, wrought iron by red, hard machine steel, blue, etc. One end of each bar is painted the denoting color when the stock is received, and the cutting off is from the unpainted end. All bar stock is cut in the stores-room.

While the stores-room can do fairly well without the cost system, the latter is a failure without the former. By that is meant that one of the factors in cost work is the material used, and unless all material is handled correctly, and properly issued to the department and to the work on which it is used, the figures obtained by the cost department would be proportionately inaccurate. The Heald Co. has, therefore, so arranged the stores-room that all material is received by that department, and complete records are kept of all material in stock (which amounts to a perpetual inventory of stock on hand), and of the proper distribution of stock, same being issued against the shop orders on which that material is to be used. There is no question but that a well-handled stores-room pays for itself many times over because of the fact that the stores department is constantly on the lookout for the future needs of the factory, and sees that the material is on hand, and that it is so kept that it can be found when wanted, which cannot be the case if material is handled in such a way that any one of the workmen can help himself to it, or when some one endeavors to anticipate the needs of the factory without some good system connected with the use of the material. So simple and yet so complete is the system installed that but three people are required to receive, keep careful record of, and issue all the stock to the factory, do the time-keeping, and figure all the cost connected with the product, for a force of from seventy-five to one hundred workmen. The same stores-room force could well take care of from 25 to 50 per cent more men.

The system originates or starts from the "production department," which issues what is called an "assembly factory order." This order covers all the work done and material

used in the manufacture and assembling of a definite number of machines of a certain kind. After the assembly order is issued, the drawing-room furnishes the factory with several sets of complete drawings showing every part used in the construction of the machines. It also furnishes, at the same time, to the production department and stores department, what is known as a schedule of parts used in the construction of the machines. This schedule shows every part used on the

Fig. 3. Wash Room. Note Individual Wash Bowls and Lockers, and Spacious Accommodations.

machine, gives the name of the part, the part number, shows how many parts of each kind are used on the machine, the material of which each part is made, and gives the rough dimensions from which the stores department makes up requisitions for the stock that will be needed to build the different parts. The schedule also gives the number of the blue-print on which each machine part is shown.

When the production department receives the schedule from the drawing-room, individual shop orders are made up for the number of each piece required for the lot of machines. These orders are made in triplicate, one copy going to the time-keeper, one copy to the stores department, and one copy to the foreman of the department in which the first operation on that particular part takes place. Immediately upon receipt of the shop orders, the stores department makes out what is called "traveler tags." These tags are held by the stores department until the material is ready for the factory, at which time they are delivered to the superintendent, who sees

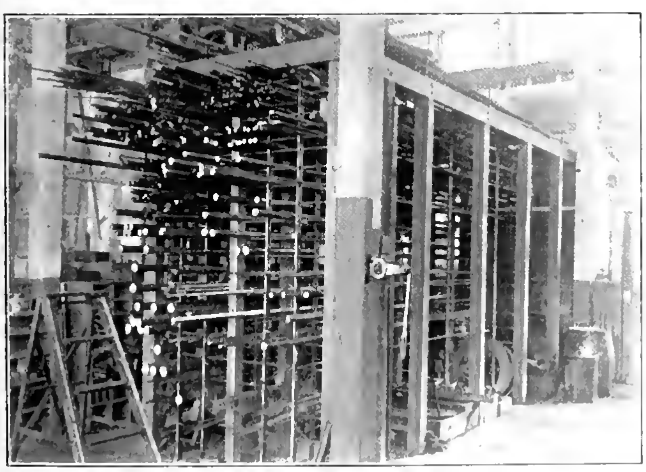

Fig. 4. Rack for Holding Bar Stock.

to it that the foreman of the department in which the first operation on the piece takes place receives the tags, each being withheld, however, until the superintendent is ready for that particular job to go through. On the back of the traveler tag is indicated the list of operations in the order in which they are to be performed. The names of the various operations are printed, and in a column in front of the name of the operation a number is placed in ink or pencil, indicating the order of the operations for the particular piece in question.

When the foreman of any department is ready to commence work on any part, he hands the workman the traveler tag for that part, which this man then presents to the stores department delivery window. He receives the stock for making up the required number of parts, after which he presents the tag to the time-keeper's window and receives his time-card, together with the proper blue-print, for which he leaves a brass check with the time-keeper, going from there directly to the time-clock, where he rings "in" on the time-card. The time-clock in use is known as the "Rochester."

After ringing in, the workman is ready to proceed with the work. He rings "out" on the time-card when leaving off work at any time, and rings "in" on the same card when commencing work again. When each operation, however, on those parts is finished, he must change his time-card for a time-card covering the following operation. This is done in order that the cost of each operation may be known, and thereby the company be in position to make comparisons of labor cost, and ascertain whether one man is a more skilled and a better producer than another. This information is valuable in order that proper adjustments of wages may be made, and is a very valuable feature for the workman, especially a good one, for when an increase in his pay is under consideration, records are ready at hand from which to determine whether or not he is worthy of an increase.

The inspection system calls for the inspection of all work after each operation. It also calls for the immediate inspection of the first part finished on each operation. The piece when finally inspected as a completed machine part is turned

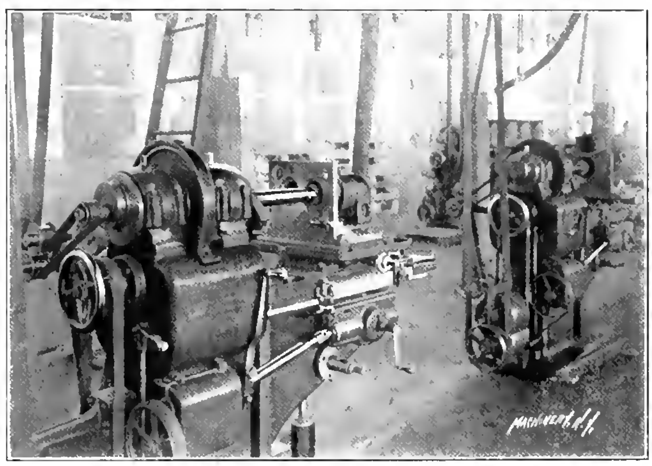

Fig. 5. Heald's Internal Cylinder Grinder under Inspection Test.

in to the stores-room by the inspector, who alone has authority to turn in material to the stores department from the factory.

Upon receipt of these finished parts by the stores department, they are placed on the shelves to await the assembling of the machines, at which time they are drawn out of stock and charged against the assembly order, the same as other material. The copy of the order originally sent to the stores department is turned in to the time clerk, who immediately proceeds to figure the cost of all operations on the part, material used, factory overhead charges, etc., making a record of these costs on a cost record card.

When the stores department issues material to the factory, the workman taking out the material fills out a blank headed "Storekeeper: Please furnish:". These blanks are each day turned over to the stock clerk, who enters on his stock sheets the material shown as given out. It sometimes happens that material is given out to the factory and afterwards returned, at which time a credit is rendered to the shop order on which it was originally issued. Such a credit is made out on a pink slip headed "Storekeeper: Please credit:". These issues and credit slips are turned over weekly to the cost clerk, and represent the actual material used for the shop order on which those parts are made up. On these issue slips the value of the material appears. This is written in by the cost clerk, who takes the prices from his stock sheets.

In order that the cost clerk may have correct prices for this purpose, the following purchasing system is in use: When purchased stock is needed, the stores-keeper notifies the pur-

chasing agent. When the purchase order is made out by the purchasing department, a copy of this order is sent to the stores department, who receives the material when it is delivered, and fills out a "voucher for material received." This voucher is handed to the purchasing department, who audits the invoice, and writes in the cost of the material, after which the voucher is returned to the stores department, where the price is transferred to the stock sheets.

There is one feature of the system that differs quite radically from many we have seen, which is that none of the foremen are called upon to do clerical work of any kind. The system is carried through the works entirely independent of the foremen, giving them all of their time to attend to their work as foremen, and leaves the clerical work to others who are better fitted for the work, and who, as a general thing, can be hired for less money. We are aware of the fact that a large number of manufacturers question the wisdom of going to the expense incurred by a satisfactory stores department and cost system, but the Heald Machine Co. claims that a very simple and inexpensive system, like that in force, will save any firm many times the actual cost of the system. Probably the greatest difficulty with those who question the wisdom of a cost system has been that the systems they have seen in force, or been in contact with, have been so loaded down with "forms" and "red tape" that the system became a burden rather than a help.

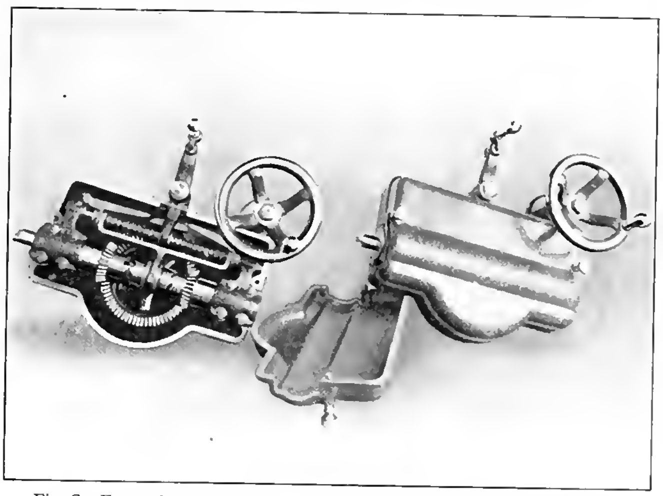

Fig. 6. Example showing Principle of Unit Construction followed in the Design of the Heald Co.'s Machines.

In preparing this article we are indebted to Mr. Heald and to his superintendent, Mr. Cowan, for much of the material.

MACHINE SHOP PROVERBS.

Hell hath no fury like a loose pulley scorned.

A fair exterior may be but a whited sepulchre for prick-punch fits.

A rusty nut will hang as plumb as a mercury bob.

The right thing in the right place—lard oil for the tap, black strap for the spindle.

"Were there "putting-on tools," then would be one man as good as another.

Better the mote in another's eye than the emery in one's own.

Lathe tail-centers were made before center reamers,—but be civilized.

That a man is a tool-maker does not make him a Joshua Rose.

* * *

In the February issue of MACHINERY reference was made to the new railway ferry connection proposed between Sweden and Germany, which will be the most remarkable railway ferry connection for both passenger and freight service in the world. The bill for the establishment of the ferry service has now passed the Swedish parliament. Four ferry boats are to be built, and direct communication will thus be provided between the government railroads of Sweden and Germany. The cost for the establishment of this ferry connection is about $2,500,000.

DROP AND STAMPED FORGINGS.*

JOSEPH HORNER.†

Joseph Horner.‡

The employment of drop forgings and stampings increases constantly and rapidly. Several firms are now equipped wholly for this class of work, and supply enormous numbers of forgings to the metal working trades. Drop forgings or stampings bear the same relation to the work of the blacksmith shop that machine-molded castings bear to that of the foundry. In each case the skilled labor of the craftsman is dispensed with, yet good wages are earned by men working by the piece. In each case the cheaper product has the advantage of much greater accuracy, and uniformity in shapes and dimensions. The numbers turned out from the dies or stamps, as from the molding machines, are often twenty or thirty times as great as those which can be produced by hand by skilled men. In each case, too, the question of machining is often inseparable from that of the methods of production adopted, because accuracy of shape, and uniformity of dimensions in forgings and casting alike are favorable to the most economical machining, since allowances which are either insufficient or excessive for the machines are equally undesirable and troublesome. The smith working at the anvil, even with the aids afforded by templets and gap gages, is unable to produce two pieces, to say nothing of twenty intricate and elaborate pieces, absolutely alike, unless at an enormous expenditure of time. It is cheaper therefore, and is the practice to "leave plenty on" to insure that the work shall "finish" all over when machined, otherwise the final corrections would occupy much more time than the actual formative work of the forging. But forgings which are stamped, all come out exactly alike from the dies, without any extra care or time spent on the part of the workman. Moreover, since the allowance left is small in amount and regular, pickling can be more usefully practiced than when allowances are excessive.

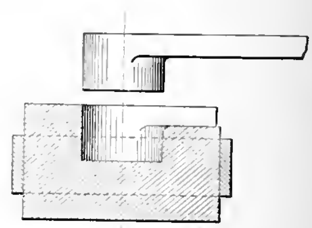

Fig. 1. Die used for Correcting or Finishing End of Lever.

The accuracy of stampings, however, is further advantageous in the fact that a considerable amount of machining is often avoided altogether. The smooth, glossy, polished and accurate surfaces left from the dies are often good enough for handles, lever webs, and bossed parts. Or, if they are required to be bright for good appearance, then a polished surface imparted by an emery wheel and buff are sufficient, without any machining in the lathe, shaper, or milling machine. Punched holes may be simply lapped, instead of being drilled

* The following articles on this and kindred subjects have previously appeared in MACHINERY: The Manufacture of Dies and Drop Forgings, March, 1900; Making Drop Forging Dies, January, 1905.

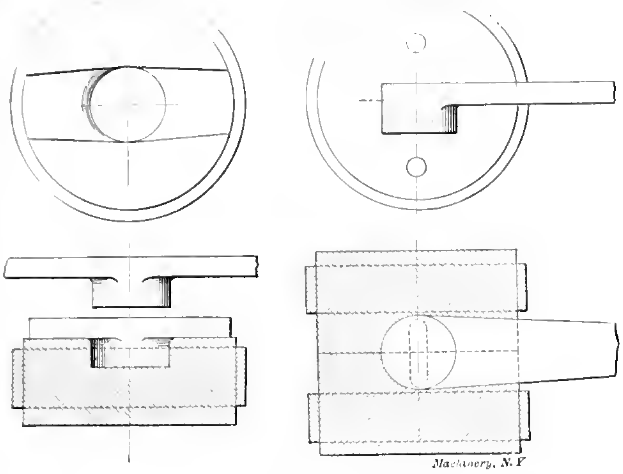
† Address: 45 Sydney Buildings, Bath, England.

‡ JOSEPH G. HORNER was born in Bristol, England, in 1847. His early technical training was acquired in serving an apprenticeship of seven years with Stothert & Pitt, Ltd., Bath, England, and by attending technical evening classes. After having finished his apprenticeship, he remained in the employ of Stothert & Pitt, where he worked, in all, considerably more than thirty years, of these, fifteen years as foreman. His training, gathered here, was most thorough, because the works, although now specializing chiefly in hoisting machinery, has, at different periods, handled many classes of manufacture. His duties as foreman kept him in close touch with all branches of mechanical work. For the last thirteen years he has been wholly occupied with technical literary work, and besides having contributed to a number of technical publications, including *Engineering*, the *Mechanical World*, the *American Machinist*, *Foundry*, *Cassier's Magazine*, etc., he was written a number of books, of which may be mentioned "Pattern Making," "Practical Iron Founding," "Toothed Gearing," "Helical Gears," "Plating and Boiler Making," "Dictionary of Engineering Terms," "Hoisting Machinery," "Tools for Engineers and Wood Workers," "Practical Metal Turning," "Milling Machines," "The Principles of Fittings," etc. He is also editor of the "Encyclopedia of Engineering."

and reamed, the locations of the holes being fixed with accuracy by the dies.

Development of Stamping Processes.

The history of die stamping goes back fifty years or more in the Black Country, and Birmingham district, England. In the blacksmith shops a limited amount of work had been done previously in dies for as long a period, but only or chiefly as a device for imparting a final finish to work which had been already prepared and nearly completed at the anvil. This practice arose out of the fact that only in this way was uniformity in a number of similar forgings economically possible. Such uniformity could only be produced on the



Figs. 2 and 3. Other Examples of Dies used for Finishing, but not for Rough Forging, Bossed Levers.
